Note.—Since reading the paper it has occurred to the author that the probability of this conclusion—that aimed at in paragraph commencing "The last case closely resembles"—is strengthened by considering that dry and moist air have very different capacities for heat. Tyndall found that, the absorption of heat by dry air being taken as unity, the air of his laboratory, not especially damp, had a relative absorption of 72, and that of air designedly moistened to be not less than 90. Thermal and electrical vibrations differ only in frequency, so that some common absorptive action in respect to air may be looked for. The heat absorbed by the moisture in the air is, after the withdrawal of the source of heat, radiated or discharged, not instantly but gradually, just as the electrical charge after cutting out a battery is parted with slowly and by degrees, as indicated by the residual charge. It may be expected, therefore, that the apparent capacity of a conductor will be least when surrounded by artificially dried air.

EFFECTS OF ELECTRICITY AND OZONE ON MILK.

It is well known, says the London *Times*, that during thunderstorms milk tends to grow acid. An Italian, Prof. G. Tolomei, has lately tried to throw some light on the nature of this action. He experimented with electricity on fresh milk in three different ways—first, by passing the discharge of a Holtz machine between two balls of platinum inserted nearly two inches apart in a bottle containing milk; second, by sending a battery current between two strips of platinum at the bottom of a U tube holding milk; and, third, by subjecting milk in a test tube to the action of a strong battery current through a silk-covered copper wire wound spirally round the tube. In each case the acidulation was delayed, not hastened. Three equal portions of milk from the same milking, thus treated, began to grow acid on the seventh, the ninth, and the sixth day, respectively; while milk not treated with electricity was manifestly acid on the third day. The electrified milk (unlike milk that has been heated to a high temperature, then cooled) coagulates naturally, or by action of rennet, just like ordinary milk. Having thus seen that electricity could not be the direct cause of acidification of milk, the Professor next tried the effect of ozone, and found it distinctly acidifying. In one case the surface of a quantity of milk was brought close under the two balls of a Holtz machine, and the milk soon became acid in consequence, the sooner if the discharge was silent (not explosive), in which case more ozone formed. In another case ozonized oxygen was made to bubble up through a quantity of milk, which in a few hours was completely acid and soon coagulated spontaneously. Prof. Tolomei is of opinion that oxygen probably also promotes lactic fermentation (a point which has been disputed). If milk keeps longer in wide shallow vessels, that is probably due, he thinks, to the cooling produced by evaporation, which is favored by a wide open surface.

[2] There is no lettering on the drawings furnished.—EDS.

SOCIETY AND CLUB NOTES.

THE NATIONAL TELEPHONE EXCHANGE ASSOCIATION.

The above Association will, as previously announced, be in annual convention this week at the Russell House, Detroit. The sessions begin on Tuesday, and will last, it is expected, until Thursday. A banquet will be given on Wednesday evening. Messrs. W. A. Jackson and F. A. Forbes are the local committee.

THE NEW YORK STREET RAILWAY ASSOCIATION.

This Association will hold its Eighth annual meeting at the Powers Hotel, Rochester, N. Y., on September 16. A report on electricity in street railway service will be presented by J. W. McNamara, president of the Albany Railway, and the representatives of electric railway systems have been specially invited to be present.

THE NEW YORK ELECTRIC CLUB.

The fall and winter meetings of the club will begin with a subscription dinner at the Club House on October 2, at 7 p. m. The dinner will be given provided 80 seats are engaged by Sept. 25. The charge, including wines, will be $5 per cover. Each member is at liberty to bring one friend as his guest. The dinner will be followed by speeches, recitations, music, etc., and President Madden has every right to expect a large gathering on this festive occasion.

THE ASSOCIATION OF EDISON ILLUMINATING COMPANIES.

Mr. W. J. Jenks, the secretary of the Association, has issued his notice of the convention to be held at Minneapolis on Tuesday, September 16, and following days, at the West Hotel. Among the topics to be discussed are: Lightning Protection; Insurance of Edison Central Stations; A National Code of Insurance Rules; Edison Patent Litigation; Central Station Steam Piping; Reorganization of Edison Interests; Grounding the Neutral Wire in Three Wire Systems. The presence of Mr. Edison is promised. An additional attraction is the great Industrial and Electrical Exposition, with its fine "Tower of Light" and other novel features. It is proposed to run a special sleeper from New York on Sunday, Sept. 14, at 9:50 a.m.

THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

The Institute will hold its first meeting for the season of 1890-91 at its new headquarters, on Sept. 16, when Prof. F. B. Crocker will deliver an address on "The New Electrical Units," and will take up for discussion the general subject of electrical nomenclature. A report will also be presented from the Wiring Table Committee.

THE SIOUX CITY CORN PALACE.

The electrical exhibit at the Corn Palace is going to be one of the leading features this year. Many attractions have already been secured. Electricity will be furnished exhibitors from batteries or 100 or 500 volt constant potential lines, 50 volt alternating, or 10 ampere constant current.

The finest space on the ground floor has been assigned for the electrical display. Full information can be obtained from the Sioux City Electric Supply Co., Sioux City, Ia.

HAIR FELT IN DYNAMO ROOMS.

Hair felt placed in the foundations of the steam engines operating dynamo stations will, it is said, effectively remedy the noise and vibration now so often complained of where a station is operated in a private neighborhood. An electric company recently had one of its ninety h. p. engines removed from its foundations, which were then taken up to the depth of four feet. A layer of felt five inches thick was then placed on the foundations and run up two feet on all sides, and on the top of this the brick work was built up. The cost of the alterations was about $300.—*Safety Valve.*

CORRESPONDENCE.

CHICAGO.

The North Side Electric Road.—The Electric Fountain.—Signs for the Times.—Telephone Subscribers Kicking.—The Thwing Electric Co.—Electric Railway Work at Aurora, Ill.—Electric Light Consolidation at Joliet, Ill.—Electric Base Ball.

THE North Side Electric Road, which was incorporated very recently, is stated to be making steady progress. The promoters of the scheme are still confident that the construction work on the line will be begun this fall. C. H. Remy states that the entire $1,000,000 of stock has been subscribed, and that the road will undoubtedly be built as projected. The names of the subscribers have not been disclosed, but it is understood that they are Eastern capitalists.

The electric fountain at Lincoln Park was viewed last Saturday evening by large crowds and was pronounced a complete success, the highest commendation on the beautiful effects produced by means of electricity being bestowed from all sides. Numerous and beautiful changes were gone through and the display lasted for an hour.

The electric light poles at the street corners have now been furnished with signs having the names of the streets on them. One can now read his location beneath the cheery light of the arc lamp and journey peacefully along without finding he has taken the wrong street.

A number of aldermen have waited on the law department relative to the rights of the telephone company to charge additional toll for connections made with telephones by subscribers in the annexed districts. City subscribers pay $125 per annum for the use of telephones. The stock yards, Englewood and old city subscribers think that this additional toll is an injustice. President Stone, of the telephone company, called on Corporation Counsel Hutchinson in regard to the matter and informed the gentleman that Englewood and Lake were outside exchanges just as much as Joliet and Milwaukee were. Mr. Hutchinson will consider the matter.

The Thwing Electric Company is the name of a new concern recently incorporated, with a capital stock of $1,000,000, by Wilber J. Andrews, Charles B. Thwing and Charles E. Piper, to manufacture and deal in electric lamps and supplies. The new company will place on the market an incandescent lamp, the efficiency of which, it is claimed, has been demonstrated within the last three months to be remarkably high. The lamp was purchased last April by J. A. Munson & Co., of Evanston, and a number were placed in the hands of the National Engineering Bureau, of Chicago, to be tested for life durability and efficiency, with highly satisfactory results. The Thwing Electric Company is backed by a number of prominent Chicago and Kansas City capitalists, and a factory has been purchased. The company will shortly begin the manufacture of their new products.

Ground has been broken at Aurora for the new electric railway, and the company expects to have twelve miles of road in operation by December 1, and twenty miles within two years. The Edison system will be employed. The west side of the city, made up largely of retired farmers, is opposing the road, whilst the east and largest side are actively supporting it and circulating petitions for the road on their respective streets. The first trouble occurred in a dispute between M. R. Bruce and Alderman Caas, resulting in the arrest of the alderman for assault.

Articles of incorporation have been filed by the Economy Light and Power Company, of Joliet, Ill., a consolidation of the Thomson-Houston and Westinghouse companies. John L. Norton, of Lockport, is president; L. E. Ingalls, of Joliet, secretary, treasurer and manager, and J. C. McMullin, of Chicago, vice-president. The two companies have been fighting each other for the last year, and the Thomson-Houston Company took the city lighting from the Westinghouse.

An exciting contest took place at Jackson Park on Saturday last, at 2:30 p. m., between the Okonites and the Kerites. The Okonites are composed of the employés of the Central Electric Company, and the Kerites are those of the Western Electric Company. The score was 21 to 6 in favor of the Kerites, and throughout the game their megohm capacity was never lowered in the slightest. The victors claim that their success was entirely due to the high insulation resistance they maintained. They short-circuited the bases in remarkable style and no faults appeared, even under the high pressure current of the Okonites. The Okonites made a gallant struggle but were unsuccessful in their endeavors to ground their opponents. The specific inductive capacity of both sides for hits of high voltage was enormous, and some fine ball was witnessed by the numerous spectators, who said they had never seen a game so free from unnecessary retardation or prolongation.

CHICAGO, Sept. 5, 1890.

DR. G. STERN, of the staff of Ganz & Co., Buda-Pesth, is spending some days in New York, *en route* from Australia, where he has been engaged for some months on important work for his house.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, *150 Broadway, New York city.*

FRANCISCO'S FALLACIES.

[137]—Were I asked the question "How can the National Electric Light Association best serve the interests of the central station companies?" I should unhesitatingly answer, "By withdrawing from circulation the pamphlets on municipal lighting which it proposes to send broadcast throughout the country," as it will open up the subject of the actual cost of producing an electrical horse power hour of energy to a fresh discussion in the daily papers, and will prove the opening wedge leading to the final bankruptcy of many of the small local lighting stations.

The thoughtful managers of local stations do not want this subject of municipal lighting agitated, for they are not making any too much money at the present time, and any discussion of lower prices for city lighting just previous to the renewal of their contracts cannot but result in financial loss to the companies.

Again, if every member of the town council is favored with a copy of the Francisco pamphlet the local manager probably cannot see how it will benefit the company, as he knows full well that the gentlemen (the "politicians," a la Francisco) who rule the little world in which he gravitates probably never heard of the N. E. L. A., or know aught of its power for good or for evil, and will be perfectly indifferent to any views the Association may give expression to unless in accord with their own ideas.

If the local "politicians" have set their heart on securing a municipal lighting plant as a stepping stone to a re-election, are they going to be swerved from their line of action because an association of interested agents says that municipal lighting is neither economical nor in the line of liberal public policy?

And if the local manager attempts to combat their arguments by reading extracts from the Francisco pamphlet, can the council not easily secure the services of an expert representative of a parent company having no interest in the local plant to work out every detail in the preparation of plans and specifications so skillfully drawn that they will show conclusively to the poor deluded taxpayer that his interests are best served by installing a municipal lighting plant that will afford a greater amount of illumination at a less rate than the local company ask?

If you doubt that any parent company would sanction such action on the part of their representative, read the following extract from Judge Armstrong's report to the National Electric Light Association:

"Capital has been induced in spite of its proverbial timidity to invest in what has been an unexplored field. Often this investment has been brought about by the parent companies themselves. Then when it has seemed as if the stormy days of doubtful experiments were about over, and there was some little possibility that this investment might begin to make returns, along comes the agent of some parent company and by specious representation induces other citizens of the same place to start a new plant, always forgetting to tell of the weary journey of the pioneer company, and pointing always to present position. The only province of this new plant is to damage and destroy what did give some promise of life and fruit, and incidentally to make a market for a little new apparatus, effectually closing, however, a profitable avenue of steady continuing business in sales to the original companies.

"It is rumored very strongly, and, indeed, stated as a fact, as strange as it may seem, that parent companies, not satisfied with permitting, have gone so far as to organize central station companies in competition with others which are abundantly able to supply all demand, strengthening, supporting and sustaining them in their unholy warfare against legitimate enterprise."

And should the local manager appear to have the best of the discussion and the expert agent is anxious to effect a sale of his apparatus, how quietly he will call the attention of the council to the absence of all figures relating to the operation of municipal plants in four other cities where the results obtained are more favorable to his side of the question. And can you blame him if he pilot the council or its committee to points like St. Louis or Cincinnati where arc lights of nominal 2,000 candle-power are furnished for less than 'the average price?'"

And in the latter event, will the Francisco pamphlet cause the "politicians," bent only on accomplishing their aims, to consider whether the large out-put of the St. Louis plant is the prime factor in the low price afforded; or that the Hickenlooper station and circuits in Cincinnati were built by Mr. Card solely with the view of securing the highest commercial results with the least expenditure for maintenance? Will the "politicians" consider these im-

portant factors, or will they conclude that if a private company can supply light at less than "the average price" probably their city can do as well?

During the discussion of the Francisco paper Mr. George S. Bowen, the honored father of the Association, said: "Prof. Barrett enjoys the confidence of every man in Chicago, whether he is a Democrat or a Republican. They all refer to him as an absolute authority. * * * I congratulate him and I congratulate the city, because he is a man of great capacity as an electrician, and is an honest and square man. That is the kind of a man we want to run our electric lights."

Now, suppose for the moment that the committee that are coming to Chicago to investigate the cost of lighting our streets should find that the statements contained in the Francisco pamphlet are not in accordance with the facts as shown by the records, and that the lighting of the streets in Chicago is being secured at a fair cost.

Would the circulation of the report be of material value in advancing the interests of the local lighting stations in the smaller towns? And, further, suppose that the press of the city of Chicago, feeling that one of their honored citizens, Mr. J. P. Barrett, had not been treated fairly in this matter, should give great prominence to the report of the committee, would the local lighting stations derive any financial benefit from such action?

I do not believe in the economy of municipal lighting. I never believed in it. And with one exception I have refrained from giving any prominence to the subject. Nevertheless, municipal lighting will always be with us in some form. It is a necessary evil that we will have to contend with just as long as personal feeling is allowed to overrule public welfare. *Then why bother with it?*

Let me call your attention to one more point and then I will close. There is another side to this pamphlet. How will certain statements contained therein affect the proposed investment of capital? The capitalist is the best friend the electric lighting industry has. Will he be so likely to invest in local lighting plants if he finds his daily paper harping on the question of the economy of municipal lighting? Or if he dreams that ill-advised legislation or bitter competition may reduce the prospective income of the projected plant?

And the agent—that living embodiment of enterprise and energy—the representative of the parent company? When he finds that he may be compelled to "make his bricks without straw," will he feel like including Mr. Francisco in his mighty petitions for the blessings of heaven when he reads the following lines in the pamphlet that was distributed at Cape May and which has been published in many papers?

"Judging the future by the past, with the mighty strides that have been made in electrical inventions, two years from now the entire apparatus at present owned by municipalities may be consigned to the scrap pile and necessitate a new outfit costing thousands of dollars. What is to done in this case? Electric light companies have already had this experience, and I can cite a case where the company paid $4,500 for their dynamos, and after a little over two years, could only realize $300 from these same machines." Will the agent wonder why an association that had been publicly cautioned not to make *any mistakes* should have been induced to indorse and stamp with its approval a statement from which the inference can easily be drawn that electrical machinery must be replaced every two years to secure the best results?

Was not the lot of the agent hard enough before without adding this burden? Has he not been telling his customers that the apparatus sent out by the electrical manufacturing companies is so perfect mechanically and electrically that plants installed eight and ten years ago are giving good satisfaction to this day? That he can show armatures that have been in constant operation for years without the expenditure of a dollar for repairs? That an investment in an electric lighting plant was a safe and legitimate investment, and that an allowance of ten per centum per annum was amply sufficient to cover all depreciation?

These statements have been the agent's stock in trade. How will they be affected now that the Association which his company has helped to build up is going to hurl broadcast the statement that "two years from now the entire apparatus owned by municipalities may be consigned to the scrap pile?" In other words, a yearly depreciation of fifty per cent. must be allowed for when figuring on an investment for electrical machinery.

And not a delegate challenged this statement. The municipality of Chicago own the apparatus sold to them by the Thomson-Houston, the Brush, the Western Electric, the Edison, and other companies. Does any one honestly believe it will be in the scrap pile two years hence?

But if these makes of apparatus are going into the scrap pile, why should capital not hold aloof for two years and then purchase the "new outfit?"

In conclusion, what remains to be done? Where is the central station to seek relief? Dare it confide in the parent company after the plain-spoken report of Judge Armstrong? I believe there is but one of two methods of procedure left open to the central station, if it would not be driven to the wall: Either to join the National Electric Light Association and have a delegate present at every meeting to fight for self-preservation, or else to form a new association to be composed only of superintendent or managing officials not in any way connected with any parent or manufacturing company, and then unite in frustrating such action as will favor present unholy warfare against legitimate enterprise.

CHICAGO. FRED. DE LAND.

ELECTRICAL NOMENCLATURE.

[138.] The letter of Dr. J. A. Fleming in your issue of August 20th shows that my proposal to give the name of Henry to the practical unit of self-induction has reached the other side of the Atlantic and is favorably received there—which is very encouraging.

I cannot say, however, that I like Dr. Fleming's abbreviation—the "hen"—and I was surprised to see that your editorial of Aug. 27th apparently approved of this clipped bird. I think that the form *hen* would be undesirable for several reasons. It destroys the identity of the name; the word already has another meaning, whereas "henry" is distinguished from the proper name by the absence of the capital letter; the idea suggested is too much "from the sublime to the ridiculous," and, moreover, a word of only five letters does not need abbreviation. The name henry is shorter than ampere or coulomb, and is as short as farad which is already cut down. I by no means favor long names, and I believe in avoiding them wherever possible, but "henry" is a short name and certainly it is not necessary for electrical terms to be written like "Sanford and Merton," in words of one syllable only.

In regard to the other units and names suggested by Dr. Fleming, I think they are well chosen, and the short forms *frank* and *gilb* are in this case more necessary on account of the length of the names Franklin and Gilbert, and they are also less objectionable when shortened.

FRANCIS B. CROCKER.

COLUMBIA COLLEGE, SEPT. 4, 1890.

REPORTS OF COMPANIES.

STOCKS AND BONDS.

BROOKLYN, N. Y.—The Edison Electric Illuminating Company's stockholders met at 362 Pearl street, Brooklyn, on Sept. 4, and increased the capital stock from $600,000 to $1,500,000 in order to extend the business of the company. The following gentlemen, representing $400,000 of the $600,000 worth of stock were present: Charles E. Crowell, Ethan Allan Doty, Edwin Packard, Jesse Johnson, and William Richardson. The latter voted against the increase.

NEW YORK CITY.—The East River Electric Light Company, New York City, has mortgaged its rights and franchises to the Holland Trust Company for $600,000. In 1885, when it was organized, it mortgaged its effects to the same company for $300,000. Under the assignment the original loan is taken up, and the company gets the $300,000 additional for its immediate use. The East River Company has not extended its wires through the subways over the extent of territory which its overhead wires occupied. With this $300,000 its officers say it will make all necessary extensions and enlarge its plant at 425 East Twenty-fourth street.

NEW YORK CITY.—The consent of a majority of the shareholders of the United Electric Light and Power Company to a mortgage not to exceed $5,000,000 has been filed in the County Clerk's office.

METAL AND SUPPLY MARKET.

HIGHER PRICES FOR RUBBER.

The Gutta Percha Rubber Manufacturing Association held its quarterly meeting last week in this city, and adopted the following resolution:

Resolved, That it is the sense of this meeting that, in view of the high prices of crude rubber, a further advance should be made in the prices of manufactured goods.

A. Spadone, the president, said that the resolution simply reaffirmed the advance of 10 per cent. on rubber goods made at the last meeting. Prices of crude rubber had advanced 5 per cent. within the past three weeks, and some kinds of rubber were very scarce. While the output of rubber in Brazil was as large this year as formerly, the demand had increased enormously in this country and in Europe, especially for the purposes of insulating electric wires. There would not be another rise in prices of manufactured rubber for at least one month, as prices of crude rubber might possibly go down.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

ALEXANDER, BARNEY & CHAPIN.

ONE of the most interesting and remarkable features of recent electrical development has been the springing up of large supply houses in various parts of the country. The rapid growth of half a dozen new industries, each rivaling if not excelling the telegraph and telephone in importance, has, in fact, necessitated the creation of these agencies for handling and distributing an enormous variety of staple goods, specialties, novelties and minor products; and the result is to-day that such concerns do a business that mounts up into the millions of dollars and bids fair to assume proportions of colossal magnitude. These supply houses are one of the best indications that could be asked for of the breadth and stability of the great electrical industries of to-day, and their prosperity must necessarily increase, *pari passu*, with the ripening to maturity and passing into common use of a score of inventions and devices that are yet crude but are destined to become things of everyday familiarity to the public, besides being also a direct stimulus to the production of hundreds of big and little appliances and details that must be forthcoming before perfection of service and economy in operation can be attained. Moreover, not a single department in the older applications of electricity has yet had all its needs met adequately, and the restless spirit of American invention every day proposes some new improvement or refinement requiring new apparatus and novel lines of supplies.

The tendency above referred to in the field of electrical supplies first showed itself, as might be expected, in the West, not only in Chicago, but in other large cities with their own territory to look after and cater to. It was only a question of time, however, when even in New York City new houses should come to the front and make a bold bid for recognition and patronage in competition with concerns that have long been known throughout the country; and now is seen the establishment here of a firm that is determined to make the strongest kind of running and to build up a great business in a very short time. We refer to the firm of Alexander, Barney & Chapin, or, as they have been playfully dubbed by a friend, "the new A. B. C. of electricity."

The members of this firm are so well known that even a brief outline of their careers will be seen to embrace most of the later industrial developments of electricity. The formation of the firm thus becomes an electrical event of the first importance. Mr. P. H. Alexander, who has been up to the present time the general manager of the Sawyer-Man Co., has been engaged in the electrical field from the early days. No small part of the central station work done by the Thomson-Houston, Sawyer-Man and Westinghouse companies in New England during the past five or six years has been worked up and carried out by him. As a reward and consequence of his efforts he was invited to take the position of general manager of the Sawyer-Man Co., and the really phenomenal success of that company's lamp business attests his able and brilliant direction, both as an executive officer and as a salesman. Probably no electrical man in a similar capacity in this country has drawn so large a salary as he. Outside of his business interests Mr. Alexander has shown himself public spirited in a most praiseworthy manner. As president of the New England Electric Exchange he has devoted much time to the harmonizing of the electrical and insurance interests in New England. The rules and regulations laid down have been of great benefit throughout the country. The standard of work and efficiency has been raised, and the good is lasting. Mr. Alexander is now a member of the National Electric Insurance Bureau, who are framing rules for the installation of plants all over the United States. It is almost superfluous to add that he is well fitted to be head of the new firm. He is a man of strong personality, whose opinions and influence are deeply felt, and a host of friends will greet his enterprise with approbation and active support.

General C. H. Barney is a telephone pioneer and known to everybody as the secretary of the National Telephone Exchange Association, which meets this week in Detroit. He began in the telephone business in 1879, resigning for that purpose his position as treasurer of the Providence Gas Burner Co., with which he had been connected for ten years. After two years' experience in Providence and Boston, during which time he constructed the first long-distance telephone line between those cities, in December, 1881, he was called to the management of the New Jersey Telephone Company, which position he held until his resignation in 1886, at the organization of the Sawyer-Man Electric Co., of which he is now the treasurer. He was one of the charter members of the New York Electric Club, and is a member of its Board of Managers. As treasurer, too, of the Sawyer-Man Co. he has had the management of large financial interests, and takes with him knowledge and experience that will be invaluable. He has been honored by the State of New Jersey with various official appointments, and has the widest possible circle of acquaintance.

The third member of the firm, Mr. Charles E. Chapin, who has been the purchasing agent of the Sawyer-Man Co., and becomes buyer of the new concern, entered the electrical field some years ago as the secretary of the Waterhouse Electric and Manufacturing Company, of Hartford, Conn. On the sale of the company to the Westinghouse Electric Company, Mr. Chapin went to Pittsburgh and was thence transferred to New York. The rapid extension of the Sawyer-Man business, both in respect to the supplies furnished to central stations and the needs without end of a large factory, has demanded great activity in the purchasing department, and Mr. Chapin has demonstrated his quality very strikingly.

The crystallization of certain industries around definite localities has already become marked in New York, and the clustering of the electrical professions and trades, in a district of which Cortlandt and Dey streets are the centre, is one of the features of the time. Perhaps the very core of this district is the handsome Telephone Building, 16, 18 & 20 Cortlandt street, which is literally an electrical hive, and it now promises more than ever to become electrical headquarters, for the reason that Alexander, Barney & Chapin will there open a large store. They have leased the street floor on the left of the main entrance, and hope, by October 1, to throw open its hospitable doors to the electrical public. It will be very elegantly fitted up, and nothing will be spared for the comfort and convenience of visitors. The firm will represent leading manufacturers in goods adapted to the electrical trade, and will keep in stock as well a line of general electrical supplies. Of some of their arrangements in this line occasion will offer presently for extended mention. In representing inventors and manufacturers the new firm from their long experience and wide acquaintance are particularly able to place goods in the channels of largest consumption. Among some of the many novelties they will at once proceed to introduce, may be named the ingenious mercury cut-out lately patented by Mr. S. D. Field, the beauty of which is that it at once recovers itself and restores the circuit to its normal condition after answering its aim as a protector for delicate instruments against "tramp" and "freak" currents. Another specialty is the attractive new insulating material, "Alexite," lately exhibited at Cape May. This material will be under the control of Alexander, Barney & Chapin. It can be made into any shape, and has the properties required for cut-outs, switches, etc., being fireproof, waterproof and acid proof. Any color of wood, paper or marble is closely imitated, so that artistic harmony with furniture, tapestries and the like, in the details of interior wiring, can be easily attained by its use.

The firm are also bringing out a new line of switches for interior electric light work, embodying valuable improvements, and these will be placed upon the market at a very early date, with a number of other things that will be touched upon in these columns from time to time as they appear. Altogether the plans of the firm have been very shrewdly and broadly laid, and the prediction may be made that their entrance upon the field will make a historic date in the electrical supply business of New York.

A NEW MANUFACTURING ENTERPRISE.

There were filed in the Ohio Secretary of State's office last week, says the Cincinnati *Commercial Gazette*, of August 17, articles of incorporation for an enterprise that bids fair to be one of the leading industries of this city and the largest of its kind in the United States. The title of the new company is The John B. Morris Foundry Company, and it is capitalized at $100,000, and officered by the following gentlemen: John B. Morris, president; Henry J. Grossius, secretary; S. L. Miner, treasurer; J. G. Niehaus and W. H. Edwards being the other two of the five directors. They are at present doing business where John B. Morris has been so successful, in the old well known Greenwood Foundry, corner Canal and Jackson streets.

The new concern, realizing that their present site is entirely too small and incommodious, have secured property at the corner of Court and Harriet streets, on which they will erect a fine commodious four-story brick building, which will be adapted to the immense business they propose to do, and it will be completed and ready for business about January 1, 1891. Their manufactures will comprise stove and furnace repairs of all kinds, machinery castings, plumbers' goods, hardware and electrical specialties, etc.

The well known business experience of the gentlemen connected with this company insures its permanent success.

NEW ENGLAND PRINTING TELEGRAPH CO.

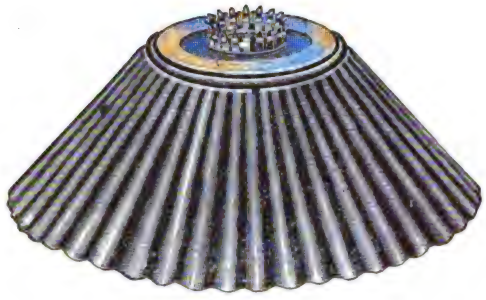
The annual meeting of the New England Printing Telegraph Company was held at the executive office of the company, 113 Devonshire street, Boston, last week. The following board of directors were elected:

Frank B. Dole, Boston; John R. Reed, Westfield; P. S. Jennings, New York; Abner McKinley, New York; James P. Cook, Boston; George W. Slade, Fall River; Maybin W. Brown, Boston. Frank B. Dole was elected president; R. H. Waters, treasurer; H. B. Humphrey, secretary; Maybin W. Brown, general manager; C. F. Hutchinson, general superintendent; executive committee, F. B. Dole, Abner McKinley, James P. Cook, George W. Slade.

A NOVEL LAMP GUARD.

A wide-awake Michigan foundryman has found a new use for lamp shades, at least when made of tin in a conical form. After trying various forms of lamp guards to protect the incandescent lamps used by the workmen in lighting the moulds, he finds the Cutter combination cone shade to give the best protection.

It is easily seen from our illustration that this shade will throw the light just where it is needed, and that when set flat on the ground it completely covers the lamp and shields it from acciden-



A Novel Lamp Guard.

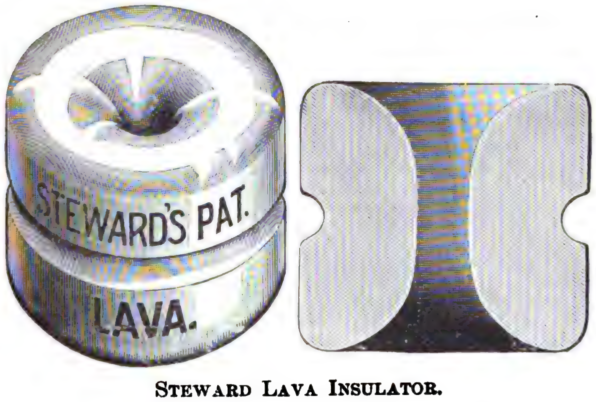
tal dropping of tools. There are many other workshops where these same qualities will be appreciated, and where the combination of a shade-holder, shade and lamp guard in one piece will make incandescent lighting still more practicable.

A FEW ENDORSEMENTS OF THE INTERIOR CONDUIT SYSTEM.

This interesting sheaf of testimonials from a large number of men, including bankers, architects, electrical engineers, insurance inspectors, underwriters, wiring contractors, electric light superintendents, and others, is a striking evidence of the extraordinary hold that the idea of wiring buildings with the help of interior conduits has taken upon the public mind. A number of the documents, such as the letters from Pierpont Morgan, T. A. Edison, and Elihu Thomson, are given in fac simile, and constitute a body of favorable evidence that the Interior Conduit and Insulation Co. does well to give the utmost publicity to. An interesting part of this pamphlet is that embracing the extracts from insurance rules which name and authorize interior conduits.

LAVA INSULATORS.

We illustrate in the accompanying engravings the lava insulator manufactured by the D. M. Steward Manufacturing Co., of Chattanooga, Tenn. The material of which these insulators is made possesses the valuable properties that it is not only a perfect insulator, but in addition is thoroughly fireproof, so that high



Steward Lava Insulator.

tension circuits can be attached to them with safety. The lava is exceedingly strong and can be molded into all conceivable shapes, whether for electric light or railway work. These insulators have come into extensive use and have in every way given the best satisfaction.

WOODHOUSE & RAWSON.

A silver medal has been awarded to Woodhouse & Rawson United Limited, of London, for their show at the Exhibition of Fire and Life Saving Apparatus now being held at Amsterdam, Holland.

THE POND STEAM SEPARATOR.

It is a well established fact that steam when being conveyed to an engine contains a large percentage of water, resulting from entrainment of water from the boiler during rapid evaporation, and condensation in the pipe connections between the boiler and engine. Water conveyed by the steam to an engine, not only represents a large percentage of loss, but also introduces an element of danger, especially to the high speed engines of the present day, in which clearances are reduced to a minimum.

The Pond separator, built by the Pond Engineering Co., of St. Louis, is so placed in the line of pipe near the engine that all the steam conveyed to the engine must pass through it. It consists of an outer cylindrical shell into which the steam enters with the entrained water, and leaves through an inner pipe extending from the top down to about one-half the length of the separator, by which arrangement an annular space is left between the two.

Pond Steam Separator.

The lower part of the separator is enlarged and forms a receiver of sufficient capacity to provide for any sudden flow of water from the boiler. An opening of proper size is provided at the bottom for removing the water, and a glass water gauge is supplied to show the level of the water at all times in the separator. A flange connection is made between the upper and lower part of the separator, so that it can be easily opened for inspection, without breaking any joints in the line of pipe. The Pond separator is guaranteed to relieve the steam of all entrained water and return this water to the boiler, either direct or by means of a trap, as the location of the separator may determine.

The Great Western Electric Supply Co.—Judging from the popularity of the Cutter E. L. Insulator, the blackening of ceilings by arc light wires should be less frequently met with than heretofore. The reason is quite plain, as there seems to be no practical way of avoiding the blackening when the ordinary porcelain insulators are used. But as this unsightly effect decreases rapidly as the distance between the wires and the ceilings becomes greater, the design of this insulator has practically solved the difficulty. One would not be surprised if the saving in the kalsominers' bills would entirely pay for the insulators where Cutter's E. L. form is used.

ELECTRIC LIGHTS IN SPANISH AMERICA.

The element of progress which has made itself manifest in the West Indies recently, a subject which not long ago was made the occasion of an oration by United States Representative Douglas, is especially notable in Havana, Cuba. As an incontestable proof of this fact, it is only necessary to cite the growth of the electric light industry in the island of Cuba.

About two years ago a number of prominent capitalists of Havana organized the Spanish-American Light and Power Company with the intention of establishing a small electric light plant for their own immediate use. A representative of this company was sent to the United States to examine the different systems of electric lighting. After investigation, a decision was made in favor of the Westinghouse alternating current system. Westinghouse apparatus, consisting of two 750 light alternate current dynamos, was at once installed at the company's central station in Havana, and the operation of the plant was hurried as quickly as possible. But even before all the wiring had been completed, the Havanese became convinced of the great boon afforded them by a general introduction of the novel system of illumination. The result was that the Westinghouse Company received a telegraphic communication asking whether it were possible to ship at once by express alternating current apparatus, exciters, switches, etc., for a capacity of three thousand incandescent lights. The Westinghouse people at once replied that, in the way of supplying electric lighting apparatus, they were always able to fill any and all orders at a moment's notice. The following day the entire plant, an express package of many thousand pounds, was shipped to Havana, and immediately upon the arrival the plant was put up, giving the company a lighting capacity of 4,500 incandescent lights. Since then the company has been doing a very profitable business, and electric lighting has constantly increased in popularity. The demand has steadily grown until it has now again become larger than the company is able to supply, and again enlargements have to be made.

The Westinghouse Electric and Manufacturing Company is now preparing for early shipment an increase of alternating current apparatus for 1,500 lights. This will give the central station in Havana a capacity of 6,000 lights.

NEW ENGLAND TRADE NOTES.

MR. HENRY A. REED, secretary and manager of the Bishop Gutta Percha Company, was in Boston for a few days this week looking up his numerous friends, who were all glad to see him, as he does not frequently get down in this section.

H. E. SWIFT MANUFACTURING Co. is the name of the new incorporated company which will succeed to the business of H. E. Swift & Co., with headquarters at 34 Oliver street, Boston. The company has been capitalized for $50,000, and the following are the officers:—H. E. Swift, president; J. A. Andrews, Jr., vice-president; W. L. Boyden, treasurer; and T. P. Swift, secretary. Their business is rapidly increasing, and they are already finding their new quarters somewhat small for the work they are doing, and are making preparations for the occupancy of another floor.

THE CONNECTICUT MOTOR COMPANY, of Plantsville, Conn., have recently made an addition to their personnel, in the appointment of Mr. F. O. Rusling, formerly with the Thomson-Houston Electric Company, as special agent. Mr. Rusling will have sole charge of the sales, and with a good motor behind him, will carry on the business of the company with his wonted energy and zeal. The Connecticut Motor Company recently increased their capital stock, and this fall will largely increase their facilities for manufacture, as their business is rapidly increasing, their sales for the month of August being the largest for any month during this year. The Connecticut motor only requires good business push to make it rank with the foremost, as it has proved very satisfactory wherever used. The U. S. Government are using quite a number, and are well pleased with their efficiency.

THE ROBINSON RADIAL CAR CO., of Boston, have perfected arrangements whereby they can manufacture trucks in large quantities, and are now receiving orders from all parts of the country. The new car which they shipped this week to the Eckington and Soldiers' Home Railway, Washington, D. C., was a thing of beauty, and the most elegant, capacious, and attractive car ever seen in that city. It is 35 feet long, with a 14 feet wheel base, fitted with the standard steel radial truck. The design is entirely new, the car having a sweeping arch roof, as seen in the latest type of steam cars, with a monitor top, not visible from the inside of the car, thereby procuring a perfect system of ventilation without any draught, and retaining the beauty of the car inside. The car is finished in rich mahogany and the ceiling is panelled with gold. The Robinson Radial Car Co. are building 14 cars for the West End Street Railway Company, to be ready this fall, and expect before this winter to have 50 electric cars running on various roads in this country.

WESTERN TRADE NOTES.

MR. JAS. LOUNSBURY, one of the managing engineers of the National Engineering Bureau, of Chicago, has returned from a trip, looking well and ready for work. The bureau makes a specialty of testing, supervising and furnishing specifications and plans of all kinds of electrical and mechanical power work.

MR. FOREE BAIN has just returned from St. Louis, where he has been for the past few days designing the electric fountain and also the electric kaleidoscope and cataract for the forthcoming exposition there. He has now gone to Iowa on a short trip to start up his new 100 horse-power generator in the coal mines there.

THE ANGLO-AMERICAN STORAGE BATTERY CO. are making a new departure in storage cells, and introducing a small battery from 3 to 5 inches in height for bell and annunciator work. It is claimed for these new cells that they give no trouble, are very certain in their operation, and that one charge lasts a very long time on the above class of work.

EDDY PLATING MACHINES.—The electroplating machine recently sold by Mr. G. A. Edward Kohler, the Western representative of the Eddy Electric Motor Company, to Rand & McNally, was one of the largest sizes built by the company, and capable of depositing 25 pounds of copper per hour. The machine is being used for electrotyping purposes.

MR. G. T. HEWES, the prominent traveling representative of the Great Western Electric Supply Company, of 190–192 Fifth Ave., Chicago, has returned to the city for a short stay from an extended and highly satisfactory business trip. He was received everywhere with enthusiasm, and his reception culminated in numerous large orders, showing the appreciation with which the large new enterprise engineered by its able manager, Mr. Geo. Cutter, is being everywhere received. Mr. Hewes leaves immediately for St. Louis, where he will be found at the Exposition, loaded with samples and happy to explain the merits of his company's many new specialties.

THE ELECTRIC MERCHANDISE COMPANY have just issued to their patrons a very attractive catalogue of their electric railway supplies, to the manufacture and sale of which they devote their exclusive attention, being the sole company so doing in the country. Their supplies are made for all systems. The catalogue contains some 70 pages of printed matter, handsomely and extensively illustrated with fine cuts, describing their numerous specialties:—Measuring instruments, testing apparatus, lightning arresters, switches, connectors, lamps and lamp material, insulated wire and tape, trolleys, street car mats, heaters, interior conduits for car wiring, poles, line material and brackets, tools, etc. All receive careful attention and their methods of use and operation are thoroughly explained. This book furnishes a very handy volume of reference for street railway men and others, showing them at a glance the remarkable strides and improvements that have been made in this line, and intimating where they can get all the latest supplies of high quality and good workmanship for their railway work.

THE GREAT WESTERN ELECTRIC SUPPLY COMPANY, 190–192 5th avenue, have brought out a very fine catalogue of their electric supplies which are in such large demand all over the country. They term the book a "Sketch Catalogue," and it is to be immediately followed by one of mammoth proportions in accordance with the size and scope of Mr. Geo. Cutter's supply house. The name certainly applies in one respect, for the catalogue is filled with excellent sketches and cuts from beginning to end, while the descriptive matter is very comprehensive and full of information. Mr. Geo. Cutter, the manager, starts off with a contradiction of any reports stated to have been circulated by competitors that his present company is owned and controlled by the company with which he was so long connected, and says, "We are in the business to sell the best of supplies to all without impartiality." All classes of electrical supplies for telegraph, telephone, electric light and power use are shown, and many new specialties of decided merit are included. A careful perusal will repay the reader, as he will find much that is new, and goods which will adequately meet all his wants. The catalogue is printed in clear type on handsome paper, bound in a tasteful cover, and is altogether very neat and striking.

NEW WESTINGHOUSE PLANTS.

The San Antonio Gas Company, of San Antonio, Texas, appears to be well satisfied with the working of the Westinghouse alternate current incandescent system. It has at present in operation Westinghouse apparatus to a capacity of fifteen hundred lights and is just placing an order for a seven hundred and fifty light increase.

The Philadelphia market house is to be illuminated by the Westinghouse alternate current arc lighting system in the near future. The Westinghouse Company has sold the city officials a forty light plant for use in the market house.

EDITORIAL ANNOUNCEMENTS

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

VOL. X. NEW YORK, SEPTEMBER 17, 1890. No. 124

Truth is of all value in itself, simply because it IS truth; irrespective of any practical application it may contain.—Alfred M. Mayer.

THE VALUE OF PIPE CLAY AND RED TAPE.

EMPEROR William, by recent warrant, has ordered that the ladies of the administration of posts, telegraphs and telephones shall be clad in a special uniform, to consist of a knitted blue jersey, with orange yellow collar, metal buttons and ornaments that presumably will correspond with rank. This regulation is, after all, but another expression of the tendency in Germany towards a military and official organization not only of the civil service but of society as a whole, and which will probably remain unsatisfied until even the beggars are covered with rags of a certain age and hue. What the energetic young emperor will do in a world where pipe clay, red tape and official uniforms are unknown, it is impossible to imagine.

By a somewhat interesting coincidence, the publication of this knitted blue jersey edict is closely followed up in a serious suggestion made at the Detroit telephone convention last week, in the paper of Mr. W. R. Patterson, to the effect that the time might be near at hand when the young ladies who constitute the staff in exchange operating rooms will be restricted as to the stuffs of which their dresses are made. But the reason that Mr. Patterson gives for a movement in this direction shows wherein the spirit of American discipline, which exists only for utilitarian ends, differentiates from that of bureaucratic Germany. It is hardly likely that the wearing of a knitted blue jersey, with an orange collar and metal trimmings, can help the German lasses to send more words per minute telegraphically, or will conduce to the greater rapidity of telephonic connections. But Mr. Patterson has a soul above buttons, and the pith of his recommendation lies in the fact that some fabrics for gowns give off more fluff and dust than others; and hence he would prefer the wearing of only such materials as would aid in keeping the switch-boards clean. We do not know but that it may be worth the while of the telephone exchanges, as a genuine feature of economy, and after the style of some leading modistes, to provide handsome super calendered finish dresses for the operators, to be worn only during office hours.

It was not alone from Mr. Patterson, however, that suggestions of a bureaucratic nature came, and we are furnished with another example of the superior spirit of American ideas, as to matters of discipline, in the admirable paper read by Mr. E. J. Hall, Jr. In the graphic and faithful sketch of this country presented by Prof. James Bryce in his "American Commonwealth," stress is laid upon the individualism and, contradictory as the qualities may seem, the "aptness for organization" of the people. Mr. Hall's paper and the principles it evolves strike us as a masterly grasping of this truth, and as a skilful plan to avail of all the value and benefit that can come from the sense of individual responsibility and the strength of co-operative aggregation. We Americans have been a little too fearful of organization, and have thought too often that system was a thing for slaves. But it is only by thorough, well designed organization that the best results can be obtained to-day from the huge masses of men and money that are a distinctive feature of our civilization. In truth, while our Government not seldom shows the evils of a disorganization resulting from the prominence in politics and office of raw, untrained persons with pet names, our industrial achievements are largely due to the working out by men who hold themselves and others well in hand, of schemes of discipline and methods of subdivision of labor that are simply perfection itself.

Many improvements seen in the telephonic field have been, and always will be, brought about by individual effort. There is no need to fear any lack of individualism, and Mr. Hall, whose own quiet personal influence is a steady factor for good, has done a public service in thus insisting on the importance of organization. It is but a few weeks ago that we had an opportunity of inspecting the plan of departmental reorganization drawn up for one of the largest electrical companies in the world, and it embodied evidence of a farsighted regard for the principles that Mr. Hall has now, in another sphere of work, so ably, so carefully, and so thoroughly enunciated. The subject and its treatment may be earnestly commended to the thought of all who are heavily burdened with the responsibilities of office or as employers of large bodies of men.

TELEPHONE "TROUBLES."

As in past years, one of the most prolific sources of discussion at the late telephone convention was the "troubles" experienced on switchboards and the apparatus connected therewith. The paper by Mr. George J. Davison which gave rise to it this year brought out again in prominent relief the numerous points at which switchboard apparatus is found to give out. When we stop to consider the extent to which an apparatus of this kind is used day and night, it is not surprising that defects are developed. The materials at our command in the construction of such boards are limited in number, and the question is one

largely of the best means of adapting it to the purposes intended. With the concentration of parts, which necessarily entails reduction in size, required on switchboards intended to accomodate thousands of subscribers, it might be expected that the difficulties would rather increase than decrease. Improved construction, however, has led to the opposite results, but enough failures still occur to make it apparent that we have not yet reached the end in this respect. It is evident that to a large extent brass as a contact metal in telephone exchanges has seen its best days, and that other metals must be employed to obtain the desired results. German silver has already found considerable employment and platinum has to some extent been used. The expense involved in the use of the platinum, however, must to a large extent bar this metal from use, but attention has lately been given to the application of aluminum for this purpose, and the results to be expected from it are certainly encouraging. Its application in the new Law board employed in Philadelphia will be looked forward to with considerable interest. Opinions among the members of the convention seemed to favor the employment of the double cord over the single cord, on account, no doubt, of the ease with which troubles due to them can be remedied. The urgent necessity of securing the greatest cleanliness and freedom from dust in exchanges is prominently brought out by the frequent annoyances arising from "dirty contacts." Indeed, all the troubles now experienced go to show that in telephony not less than in electric lighting good engineering is an essential quality of success to be attained in operation. Nowhere probably has this been realized to a greater extent than in this city, and the results already obtained are evidence of the correctness of the principles followed.

STRUCTURAL LIGHTING EFFECTS.

The flexibility of the electric light as a method of illumination long ago was illustrated by novel effects in chandeliers and candelabra. Then it invited to spectacular display in projections and in iridescent fountains. Latterly it has scored new triumphs in towers of light, and we are able this week to lay before our readers full illustrations and details of the tower that is delighting the good folk of Minneapolis. This tower, which owes its success to the refined taste and engineering skill of Mr. Luther Stieringer, marks a most decided advance in structural lighting effects, and must lead to the general introduction and use of the miniature incandescent lamp for schemes of interior decoration and illumination that have not been entertained as practical up to date.

Evidently there is a wide application for lights that have no "wrong side up," but will burn in any position and at any angle. Lines of light may now be as graceful and fluent as those of drapery. The architect and artist may design and execute free from conditions that have long been arbitrary and binding. They may mold their light or accentuate with it just as they would with masonry or color; they could not ask for decorative material more plastic, responsive or submissive. And while this is true of the ordinary incandescent lamp, it is specially the merit of the miniature lamp, which is still much more of a novelty than it ought to be. A moment's thought on the opportunities for emergency lighting, the chances in summer gardens and winter ballrooms, the desire for something out of the common at festivities and public gatherings, the delight of everybody in spectacles, and the particular favor shown towards chromatic and pyrotechnic displays—a moment's thought, we say, will show that here is work which would be at once pleasant and profitable. Why should not central stations give a little time to it? Let them see what can be done the coming season.

ELECTRIC CAR GEAR.

Those who have studied the application of the electric motor to railway purposes cannot have failed to be impressed with the attention which has of late been given to the connection of the motor with the car axle. The first devices employed were naturally those which had been used in mechanics for a long time, and they have accomplished their purpose in an eminently successful degree; but, as time passes and experience is gained with their use, it is evident that improvements can be made, and it is upon these that not a few of our most prominent inventors are at work at the present time.

Our current issue brings this out in a description given elsewhere of two forms of car gearing, both of which embody original methods. Mr. Edison has worked out a method in which, by the employment of two motors, he is able to so connect them, that in so far as their driving power is concerned, they may be used either in conjunction or differentially, so as to propel the car at different speeds, one acting then as a dynamo, and the other as a motor. The arrangement also permits of the motors being operated continuously, whether the car is moving or not, and thus overcomes the objection which is raised against the heavy draught of current required to start electric cars.

Mr. E. H. Johnson, to whom the electric railway in America owes so much, has also attacked the question in an original way, with the problem set before him of permitting the motor to obtain practically its normal counter-electromotive force before taking up the load, so that the initial current taken by the motor on the closing of the circuit, even when starting from a standstill, is practically no greater than the normal working current. He has also introduced an ingenious device by which any variation in load, whether an increase or decrease, is taken up by the motor without shock, and with the same economical use of the current. He accomplishes this by the introduction of a spring arrangement in connection with the armature, which determines the power-transmitting value of the motor, and which forms the intermediary between the armature shaft and the driven axle.

Although cable manufacturing and cable laying for ocean work has not yet become one of the standard industries of America, the aggregate amount of electric cable manufactured in this country for various purposes is very large. Occasion frequently arises to lay submarine cables in our rivers and channels, and the process is of considerable importance. This has been recognized in the recent construction by the Western Union Company of a new boat intended for cable laying purpose, as described in another column, in connection with the laying of a telephone cable across the Hudson River.

LAYING A TELEPHONE CABLE IN THE HUDSON RIVER.

PROBABLY few New Yorkers are aware that submarine cable operations are constantly being conducted in the river which separates Manhattan Island from New Jersey, and that a specially equipped cable boat carrying a trained staff is maintained by the Western Union Telegraph Company, to lay down and keep in repair the numerous cables crossing the North River. This boat, called the "Western Union," has been in commission since January last, and was built to replace the old "Orton," a vessel which had a long career of usefulness. The "Western Union" bears a general resemblance to a river tug, her dimensions being about 50 feet length by 14 feet beam. She is provided with twin propellers, which greatly facilitate manœuvring when at work cable laying or repairing. On the main deck, forward of the pilot house and bridge, is the cable drum. The drum is set vertically, the lower side bearing on a number of small rollers fixed to the deck. Round the edge of the lower side of the drum is a broad strap brake which can be nicely regulated so as to ease the drum or hold it back as the strain on the cable varies. The drum itself is revolved by a small engine supplied with steam from the main boilers. The wheel for operating the brake, and a sliding rod by which the valve of the drum-engine is opened or closed, are placed on the bridge just forward of the pilot-house, so that the foreman of the cable-gang has perfect control over the drum, and at the same time has a clear view of all that is going on. The rest of this combined paying-out and picking-up gear is very simple, consisting merely of a small iron pulley attached to the end of a long boom, which can be swung out over the side of the boat, abeam of the drum, the pulley hanging clear of the vessel's side by about 8 or 10 feet. Forward of the drum is a small steam winch, which does good service when the end of the cable has to be hauled ashore.

The equipment of the "Western Union" does not convey a very favorable impression to one who has been accustomed to the complete machinery carried by sea-going cable ships, but the gear, such as it is, seems to answer its purpose well, and presumably it is nobody's business to ascertain what damage is caused to a cable either in laying or picking up, by the defective arrangement of machinery employed.

The accompanying illustrations, from drawings made on the spot, show very clearly the general appearance of the boat when laying cable and also the details of the drum and pulley. The arrangement of the drum and pulley is open to many objections and would be looked upon with horror by most cable engineers. Fortunately the depth of water in which the boat generally works is quite inconsiderable, only some seven or eight fathoms, so that the strain on the cable is very slight and a heavy stiff cable bears on the little pulley at one point only, making a curve corresponding to a two or three foot pulley. In picking-up, however, matters must be somewhat different, and the horizontal winding-in on the drum coupled with the size and position of the pulley, rendering it difficult to give the cable a fair lead, must produce rather a queer state of affairs; and the cable is probably subjected to a very awkward and unfair strain. The objection is all the greater because all the cables in the North River contain a number of conductors, seldom fewer than seven and in some cases as many as eighteen, and such cables naturally require very careful handling to avoid any strain being thrown on the conductors unevenly.

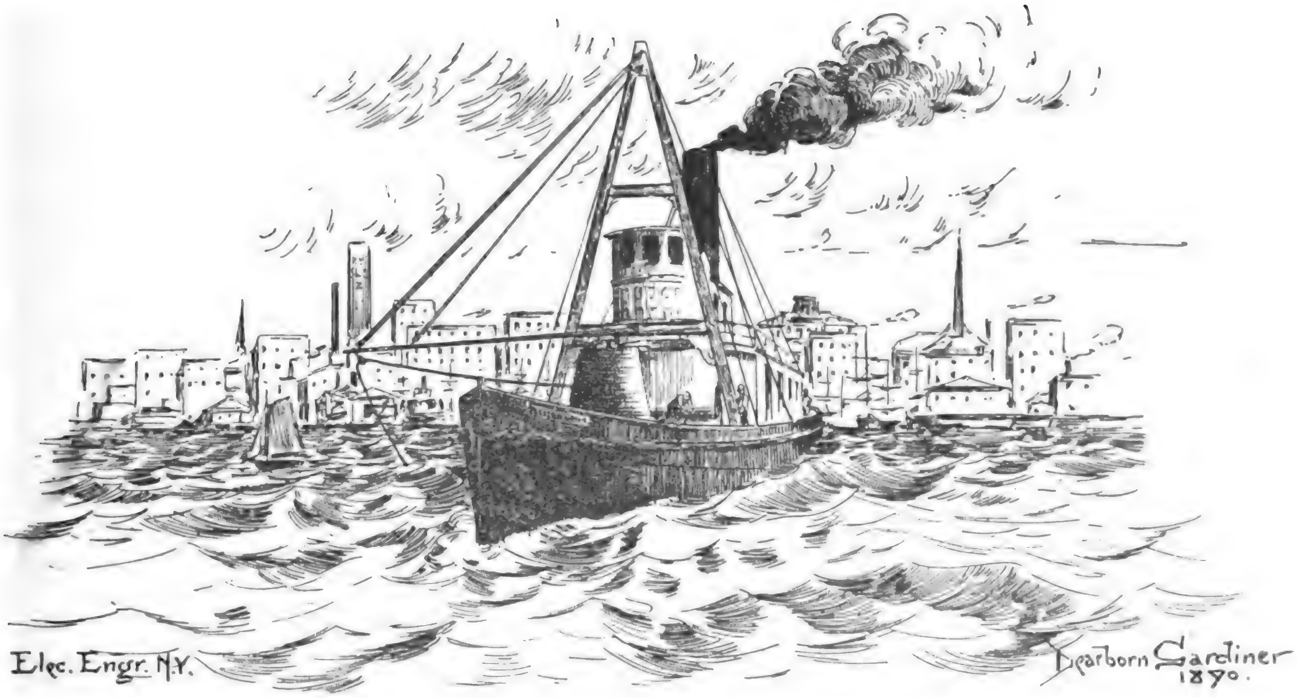

FIG. 1.—LAYING A TELEPHONE CABLE IN THE NORTH RIVER.

A few days ago the "Western Union," with her staff of cable hands under Foreman Kline, was chartered by Mr. George B. Prescott, Jr., the agent of A. G. Day, to lay a Kerite cable of special make containing eighteen conductors, for which a contract had been made with the Metropolitan Telephone Company. This cable is of a very heavy type, the length required for the North River crossing, about one mile, weighing not far short of twenty tons. The cable was transferred to the "Western Union" at Motthaven, where the factory reel was set up on jacks, and the cable wound on to the steam drum, both Mr. Prescott and Mr. Brixey, the superintendent of the Kerite factory at Seymour, being present to see that the cable was carefully handled, they also supervising all the subsequent operations. The steamer then set out for Pier 18, the landing-place on the New York side for the Metropolitan Company's cables. Here the expedition was joined by the representative of the telephone company, and by our artist,

Mr. H. Dearborn Gardiner, who made the drawings which accompany this article. The cable house is situated at the end of the Pennsylvania Railroad Company's ferry pier. Most of the cables already laid have been brought in through the piles of the neighboring dock, that of the Starin line of steamers, and in order to avoid crossing them with the new cable it was decided to take in the shore end from the end of the ferry slip, between the floating fender and the Starin dock. For this purpose a pulley was made fast underneath the cable house and a rope run out from the boat (stationed at the end of the slip) round the pulley and back to the steam winch on the boat. One end of the rope was made fast to the cable, the winch heaved in on the other and the cable was gradually hauled along to the cable house, the drum, of course, being revolved by its engine to ease the strain on the cable. This operation was effected much on the same lines as the landing of a shore-end from a regular cable ship, the only difficulty being that the irregular shape of the ferry-slip necessitated the hauling being done around a curve, the rope and cable bearing at places against the framework of the fender.

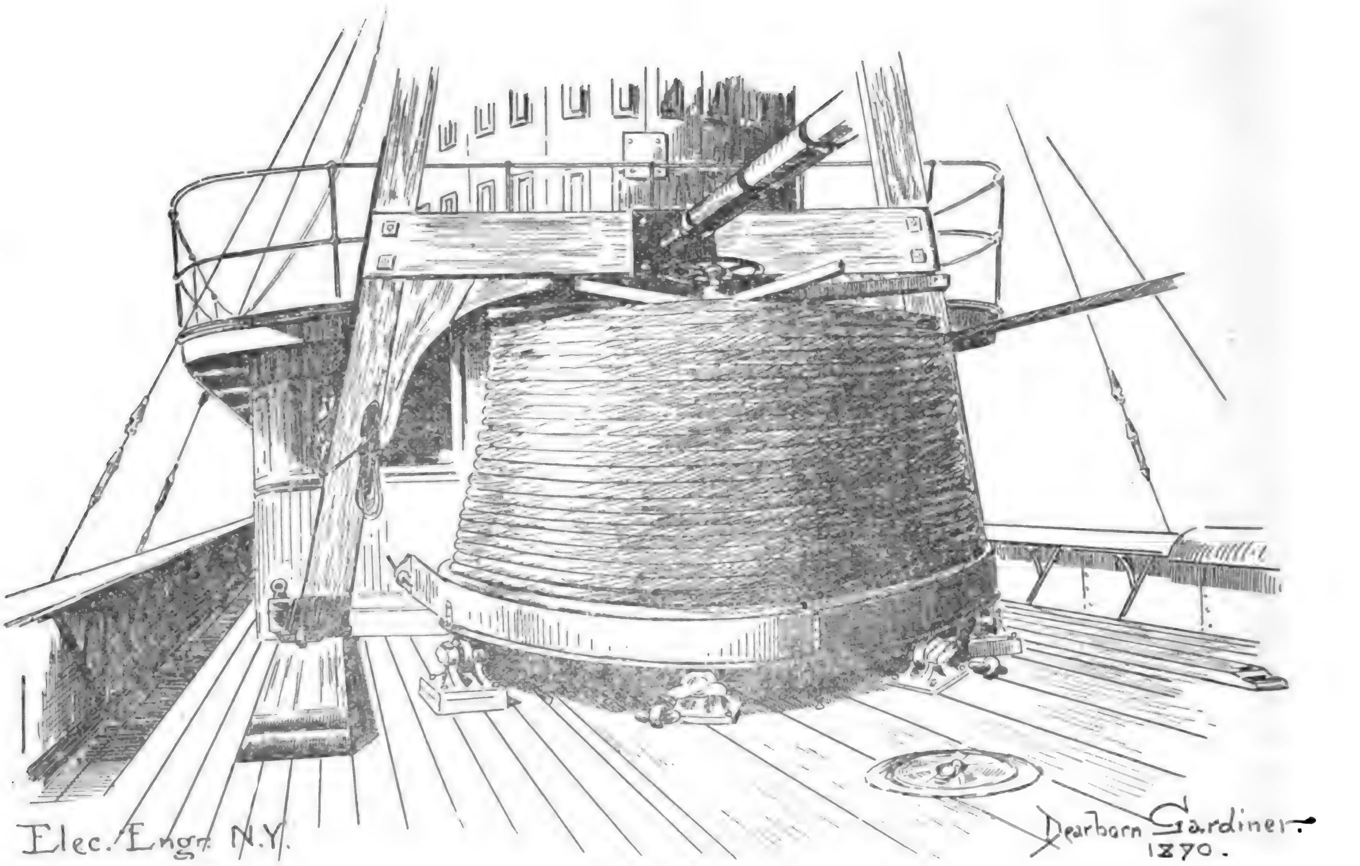

FIG. 2.—DRUM OF THE "WESTERN UNION" CABLE LAYING BOAT.

The end being successfully landed, the boat was quickly turned round by her twin screws and paying-out towards Jersey City was begun. This part of the work occupied but a very short time—some ten or twelve minutes—but getting the end into the Jersey City cable-house was the most troublesome job of all. Readers of THE ELECTRICAL ENGINEER will recollect that some time ago a number of Western Union cables were lashed and thrashed into shreds by the propeller of an Inman liner, and that quite recently the judge, in handing down his decision on the law suit which arose from this mishap, intimated that cables must keep out of the way of steamers, not steamers out of the way of cables, according to the custom that has obtained hitherto all the world over. Consequently the cables landing at this point are now taken under the Inman Company's pier, either on the bottom or among the cross-pieces of the piles.

The steamer made fast at the pier and the remaining cable had to be taken off the drum and coiled down on the dock-head. A rope was threaded through the piles and made fast to the cable-end, and the steamer, having taken up a fresh position at the foot of the dock, heaved in on the rope by means of the cable drum, thus hauling the cable through the piles. In order to get the end into the cable-house this operation had to be repeated once more, a rope being taken through the channel in which the cables run under the road, up through the cellar of the cable house and back again to the boat, and in this manner the cable was finally got into the cable-house.

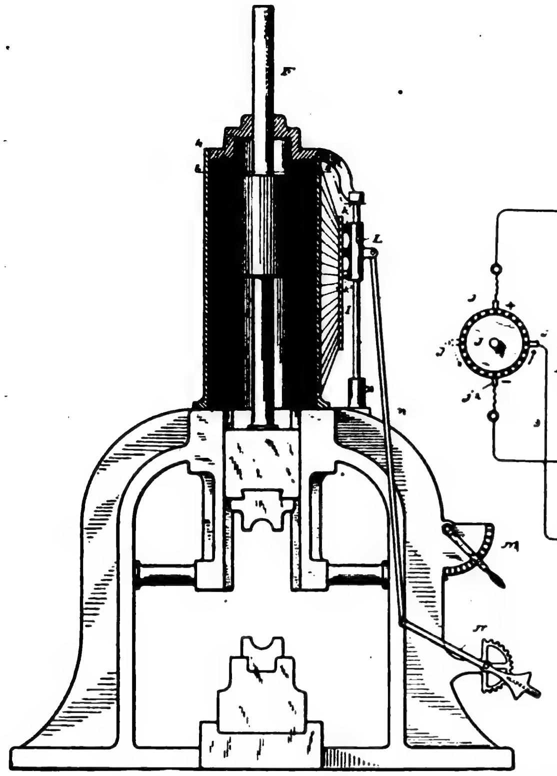
From the foreging description it will be seen that the laying of a heavy cable across the North River, under the existing conditions, is no light job. The actual laying is the simplest and quickest part of the work, but getting the ends in is quite a different matter, and the cables certainly have to endure a good deal of rough treatment. That they stand up under it and yield such good results is a convincing proof of the excellence of their manufacture.

VAN DEPOELE'S ELECTRIC POWER HAMMER.

IN the operation of power hammers for forging heavy work it is necessary that the hammer shall be able to strike directly upon the anvil or at any distance from it within the range of its stroke. To carry out this object in connection with an electric hammer, Mr. C. J. Van Depoele employs the well-known construction shown in the engraving, Fig. 1, which consists in the operation of an iron piston acted upon by a series of coils, which raise and lower the hammer according to the position of the switch governing the current passing to the coils. The special object of the construction adopted, however, is to obtain the range of motion. The piston reciprocates continually during the operation of the

machine in a constant but changing field of force, within which it may be said to float, rising and falling in accordance with the rise and fall of current above and below it, and, by moving the shifting field of force to any desired part of the motor-coils, the position in which the piston and connected parts will reciprocate can be changed at will and a blow delivered wherever desired—that is to say, the hammer can be made to strike directly upon the anvil or any distance therefrom within the limit of the coils.

The manner in which this is effected will be readily understood by reference to the diagram, Fig. 2. Here J is a



VAN DEPOELE'S ELECTRIC POWER HAMMER.

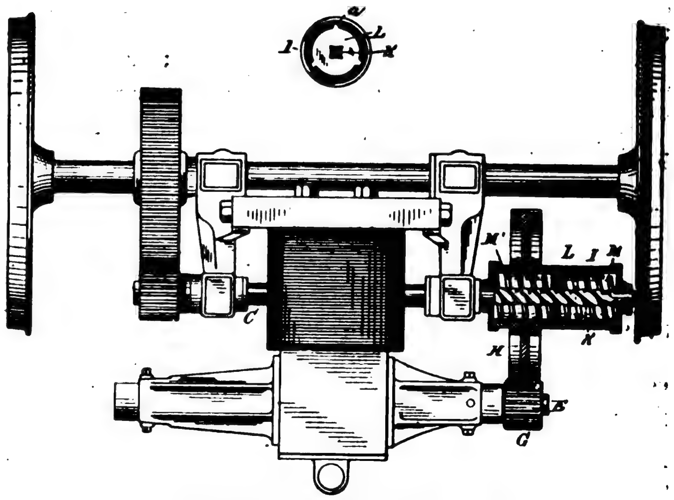
sectional commutator representing a source of continuous current. j^1 j^2 are the main positive and negative commutator-brushes, which are fixed upon the line of commutation. j is a moving commutator brush, the office of which is to cause the supply-current to rise and fall in the motor-coils by being moved around the commutator toward and away from the points of maximum and zero electromotive force. The brush, j^1, is connected with a contact-brush, k^1. The commutator-brush, j^2, is similarly connected with a brush, k^2, and the moving brush, j, is connected with a brush, k. The brushes, k k^1 k^2, are secured in a fixed relation to each other in an insulated carrier, L, Fig. 1, and maintained in contact with the commutator, I. With the positions shown in Fig. 2 current would flow through brush j^1, brush k^1, into coil 4, through coil 5, out through brush k^2, and back through brush j^2 to the commutator, J. The moving brush, j, being in central position, and, therefore, conveying no current in its travel about the commutator toward and away from the fixed brushes, will cause the current to fall in one of the motor-coils and rise in the other, and so on, so long as the brush, j, is kept in motion, it being apparent that the current which is continually rising and falling in the motor-coils is constant in direction and maintains a field of force which is gradually shifted back and forth between the coils in circuit with the brushes, k k^1 k^2; from which it follows that the piston, G, will move within the active coils, no matter in what part of the machine they may be. The current, never being interrupted or broken, the piston will therefore float within the coils without being able to escape in either direction. The speed at which the brush j is moved will determine the rate of reciprocation of the plunger, G, and in order to most conveniently regulate the power of the apparatus an adjustable resistance, M, is connected in the circuit as shown.

As a convenient means of conveying current through the circuits, the brushes k k^1 k^2 are, as stated, mounted in fixed relation to each other in a movable carrier, L, which is sustained in front of the commutator, I. In order to vary the stroke of the piston the brush-carrier, L, is adjusted up or down by means of a latch-lever, N, and a connecting rod. The lever, N, is located in a position convenient to the workman operating the machine, and the adjustable resistance, M, is also located in convenient proximity.

JOHNSON'S ELECTRIC CAR GEAR.

THE success which has attended the introduction of electric railways is sufficient proof of the immense superiority of this system over all others heretofore in use. But the experience gained in the past few years has brought out certain serious difficulties which are now well recognized, and which are claiming the attention of inventors to successfully overcome. Probably the defect most prominently brought out in the past, in the operation of electric cars, is that, while the power required to start the car is greater than that required when in motion, the electrical equipment is then least effective, and must, therefore, for the purpose of starting, be largely in excess of what is subsequently required, and even this provision is not always sufficient to avoid occasional injury to the motor by the excessive current which passes through the motor armature while the latter is at rest, and is developing no counter electromotive force.

To avoid this difficulty, Mr. E. H. Johnson, of this city, has recently designed and patented an electric car gear in which the power-transmitting value or capacity of the connection between the motor armature and the car axle will be constantly proportioned to the power required, and which enables the power to be applied gradually in starting. Attempts have heretofore been made to accomplish this highly important object by the employment of springs



JOHNSON'S ELECTRIC CAR GEAR.

interposed between the armature shaft and axle, and again, by means of frictional or rubbing devices. Mr. Johnson, however, has combined both of these in an ingenious manner by employing—associated with a frictional connecting device—a compression spring, which does not form the direct medium for transmitting the power, but which determines the frictional engagement of the connecting device, so as to adjust the power-transmitting capacity in accordance with the load. This novel result is accomplished by gradually interlocking a moving and a motionless shaft with an engagement whose value is positively progressive

until it equals the work to be done, and is afterwards invariably proportional thereto.

The manner in which this idea has been carried out in practice is shown in the accompanying illustrations. As will be seen, the motor is mounted as usual with a countershaft. The pinion, G, attached to the motor shaft, engages with the gear wheel, H, which is fixed on the hollow cylinder, I, forming a sleeve to the countershaft, C. The portion of the countershaft within the cylinder has a screw thread, K, cut upon it, the pitch of which is such as to allow the electric stop to reverse the apparatus readily and force the nut back on the thread.

The nut, L, shown in Fig. 2, which forms the intermediate connecting device, is threaded on the shaft, C, and is provided with lugs, *a*, which enter internal slots in the cylinder, I.

The operation of the gear will now be readily understood. When the car is in a state of rest, if current is applied to the motor, the pinion, G, turns the wheel, H, and cylinder, I. The nut, L, being in positive engagement with the cylinder, turns with it, and is, therefore, screwed up in one direction, or the other, according to the way the armature is running, along the shaft and against the spring, M or M′. The nut continues to turn until it reaches a point where the compression of the spring is such as to hold it back against the screw-thread with such friction that its turning movement is communicated to the counter-shaft; the latter then turns and starts the car, at first slowly and with increasing speed as the compression of the spring increases, until it reaches such a point that the nut will move no farther; this point being dependent on the load or the amount of resistance to starting which has to be overcome.

It will thus be seen that the load is brought gradually on the armature by the gradual compression of the spring, and the armature has time to make one or more revolutions and to begin to develop its counter-electromotive force before the load is placed on it. While the car is running the engagement of the shafts alters with variations in the load, so that the value of such engagement and the power transmitted change with the power required; that is to say, the point at which the nut engages with the screw-thread sufficiently to turn the shaft will depend on the load at the time of starting; and if the load afterward increases, the nut will run farther up on the screw-thread; or if the load decreases, it will be relieved and will run back toward the centre.

By the arrangement just described the shaft may also be automatically disconnected when the power is withdrawn, so that the car may run freely on down grades.

ELECTRIC LIGHTING ON THE S. S. "SEGURANZA."

THERE has just proceeded on her maiden voyage the S. S. "Seguranza," of the Brazilian Steamship Co., plying between this port and Rio Janeiro. The ship, which was constructed at Chester, Penn., is built of steel and iron upon the most approved plan, and contains all the modern improvements, together with some which have here been introduced by Capt. Lachland for the first time and which cannot fail to increase the comfort of the passengers.

Foremost among the good features is the electric light, there being no less than 400 incandescent lamps distributed throughout the ship. The electrical work, the equipment of which has been carried out by the Complete Electric Construction Co., of this city, was in charge of Mr. John A. Seely, and is noteworthy for the thoroughness with which every detail has been attended to. The entire wiring between decks is run in the Seely flexible rubber moldings, so that a double insulating protection is afforded. Every lamp on board the ship is provided with its individual cut-out. These are placed in blocks, so that should a burn-out take place, the removal of a single screw allows the block to be removed and a fresh fuse inserted.

Past experience has shown that in marine installations, switches are apt to be internally short-circuited through the medium of their metal cases. To avoid this, all switch cases between decks are made of the "S. & T." compound, which is not only insulating but largely fireproof. The switch bases are also made of the same compound.

All switches on deck exposed to the direct action of the weather and liable to be brought in contact with water are made water tight with the conductors passing through specially designed insulating bushings. The spindle to which the switch handle is attached is similarly provided with an insulating bushing, thus making the entrance of water impossible.

The ship has been specially designed to allow of rapid loading and unloading, there being no less than ten points at which this can be effected. To aid in handling the freight at night, special cluster lights have been provided. These consist of groups of six incandescent lamps placed under a reflector, and the whole is suspended on an arm, so as to throw the light downward, illuminating the deck and the side of the ship.

Still another important part of the equipment is a Huntington search light, similar to those employed on the Sound steamers. This is placed at the very bow of the ship, and has a full sweep of the horizon. The current of 10 amperes is taken directly from the incandescent circuit, which is run close to the side of the projector. With the aid of this light the entrance to harbors at night will be greatly facilitated.

The generating plant on board consists of a 400 ampere Continental dynamo connected directly to an automatic compound Ball engine of the new marine type, both mounted on the same base plate. The switchboard in the engine room has a slate base, which is probably the first of this kind placed on board a vessel, and indicates the care exercised to insure thorough insulation.

The entire plant, indeed, presents a marked advance in mercantile marine electric lighting, and the installation is a credit both to its designers and the owners of the vessel.

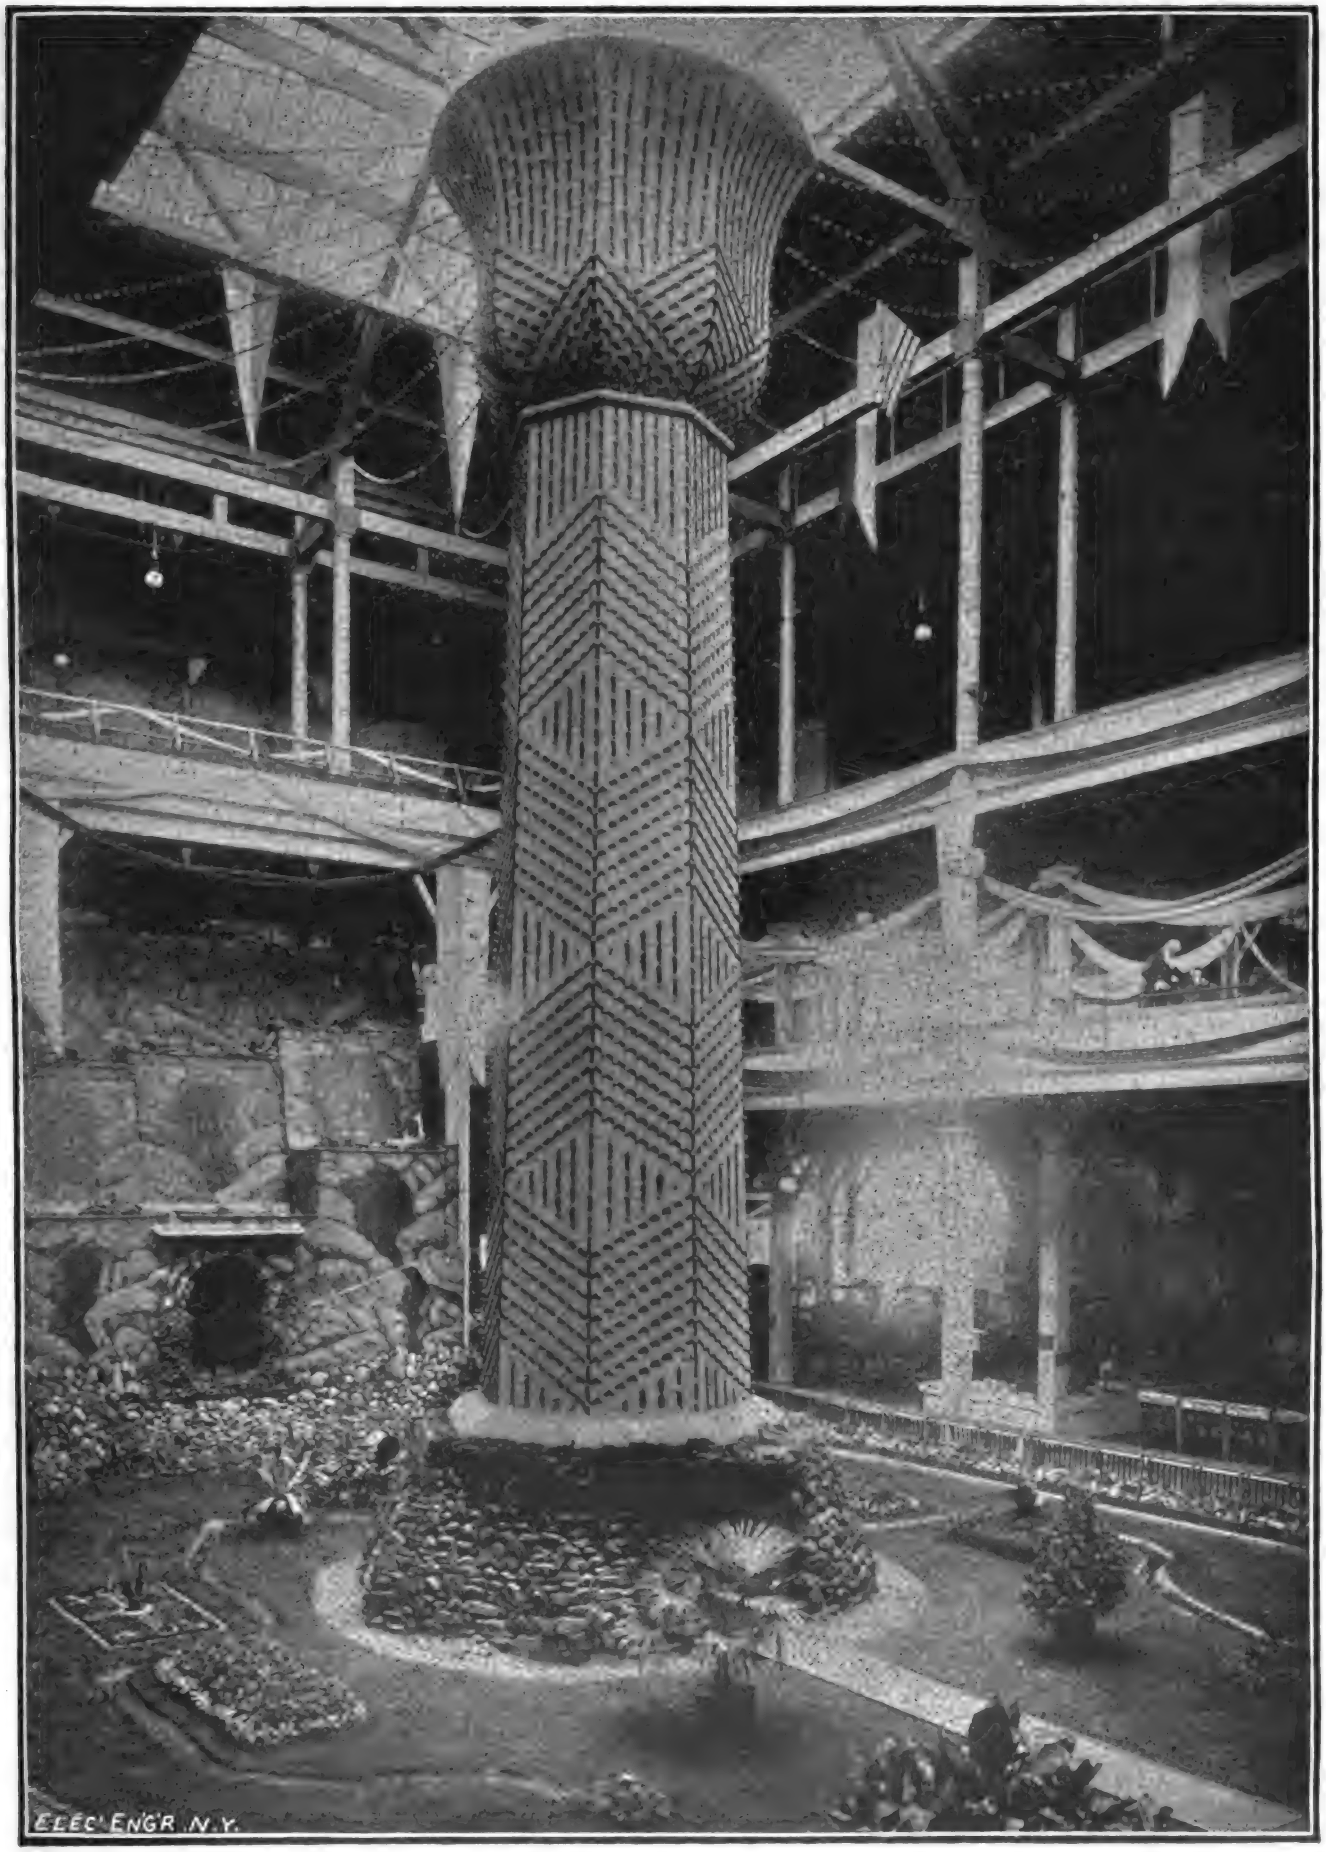
A MODIFICATION OF MR. EDISON'S EXPANSION GENERATOR.

BY W. M. MINER.

WHILE reading the article on Mr. Edison's method of generating an electric current, by the expansion and contraction of solid matter, in THE ELECTRICAL ENGINEER of Sept. 3, the idea occurred to me that as good, or better, results could be obtained from an alternating current, instead of a furnace as used by Mr. Edison.

The alternating current could by this means be converted into a continuous current for running motors, charging storage batteries, or for any other purpose, where a direct current would be most desirable.

My method of working would be something on this plan: I would make the metal expansion bars as light as possible, consistent with the necessary strength, and pass through them an alternating current of low potential, to heat them, instead of by hot air from a furnace, as proposed by Mr. Edison. This arrangement, I believe, would allow of more rapid expansion and contraction; the metal bars being light, would heat and cool quickly, allowing of more rapid making and breaking of the magnetic circuit. Consequently a more continuous current could be obtained, more elements could also be used, as the heat of each element would have less effect on the adjoining element, than it would from a furnace, as in Mr. Edison's arrangement. The shaft carrying the commutator in Mr. Edison's arrangement, could carry an additional commutator for distributing current to the metal bars.



THE EGYPTIAN TOWER OF LIGHT AT THE MINNEAPOLIS EXPOSITION.

THE EGYPTIAN TOWER OF LIGHT AT THE MINNEAPOLIS EXPOSITION.

When Mr. Henry Villard was in Minneapolis during the early Spring of this year, he made the citizens an offer to secure for them, and place at their disposal, as a special attraction for the Fall Exposition, the great Edison Exhibit shown at Paris in 1889 by Mr. Thos. A. Edison. This including the latest phonographs. A special feature, and one that rounds out the exhibit in a very remarkable manner, is the lighting spectacle furnished with the aid of the Edison Lamp Works, and represented in our engraving, Fig. 1.

The tower, which is tremendously popular, and is a brilliant success in more senses than one, was designed specially for this Exposition by Mr. Luther Stieringer, the

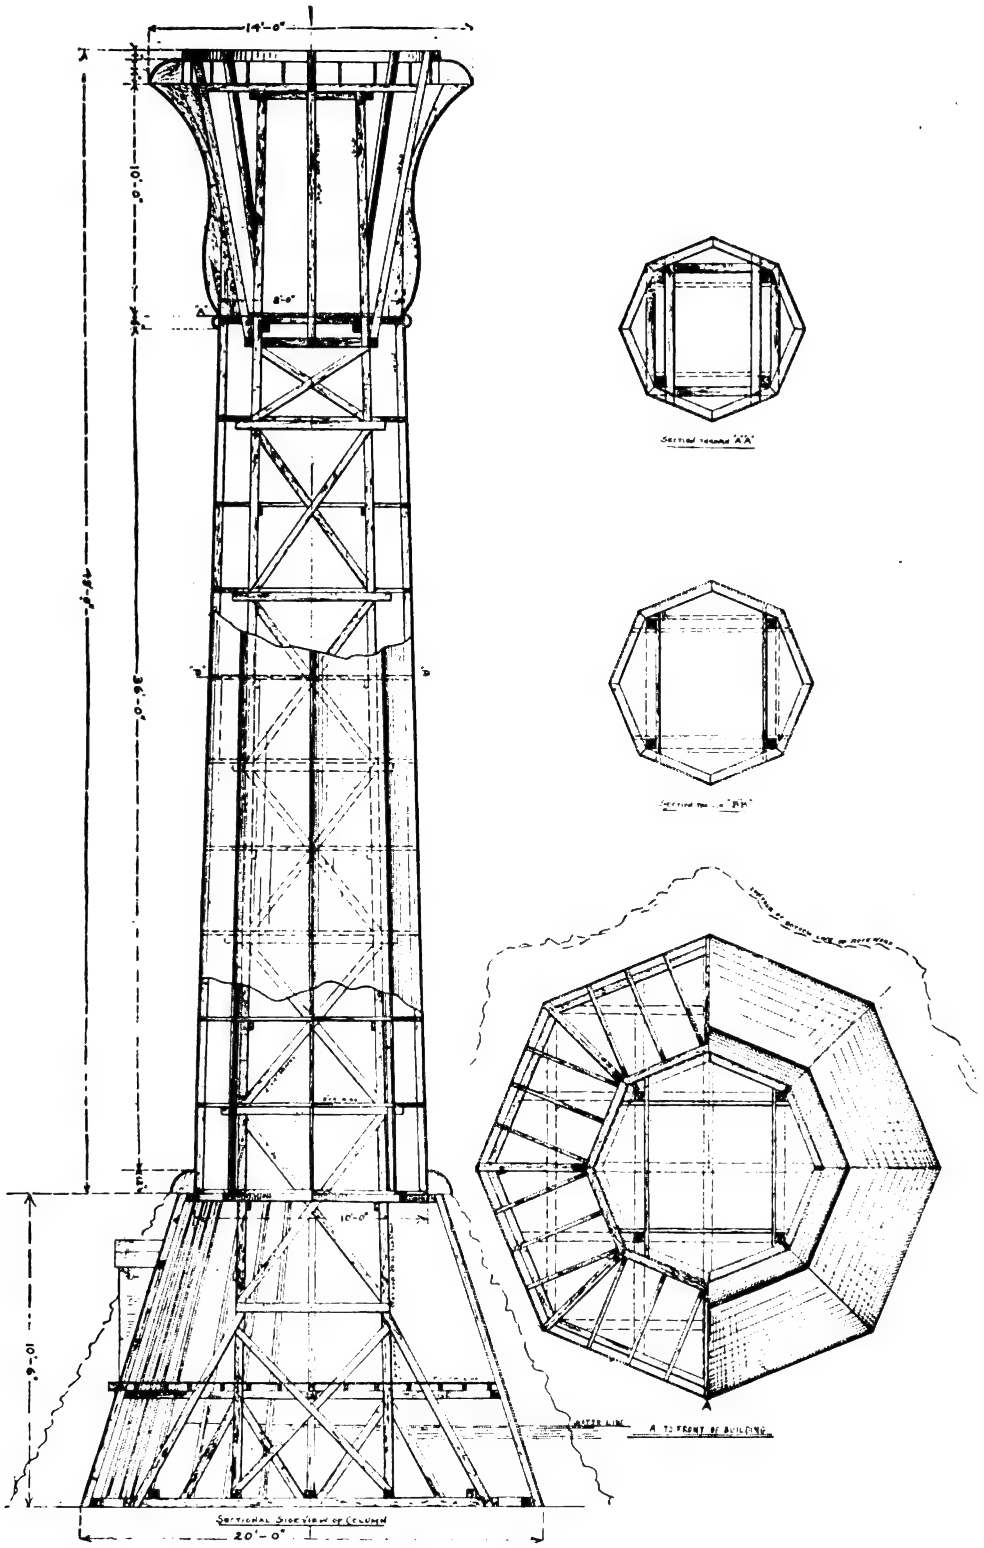


Fig. 2.—Details of Construction, Egyptian Tower of Light, Minneapolis Exposition.

generous offer was at once accepted, as well it might be, by the Exposition management. This exhibit as now being displayed at Minneapolis is wholly uncommercial in character, dealing only with the inventions as such, and well-known expert, and was the result of a special trip to the West, and weeks of patient planning. The tower may be said to present the most beautiful and bewildering arrangement of miniature incandescent lamps so far

attempted. When the immense audience assembled upon the opening night at the Minneapolis Exposition, they were amazed at the scene of splendor that lay before them. In the centre of the main building, which is three full stories in height, where there is a light well, 60 by 125 feet, stands the dazzling column, fully 60 feet high, in a blaze of grandeur, resembling a mighty lotus flower, with every separate part delineated. It stands on a rocky mound in the centre of a beautiful garden, through which a brook babbles, turning a rustic mill wheel as it speeds along across a grassy meadow where ferns and flowers grow in abundance. On one side a cascade comes rushing down, dashing against the rocks, tossing the silver spray, which is caught by the myriad colored lights, and sparkles like glittering gems.

The lotus flower is a marvel of elegance and beauty. In time with the music of the orchestra, the manipulator at the switches flashes the lights and produces the beautiful blending that charms and captivates the great audiences nightly.

The Egyptian column is fully 60 feet high, and is octagonal in form. The base, as it rests upon the garden, is 20 feet in diameter, while the diameter of the shaft proper at the base is 10 feet. The Egyptian cap is 14 feet in diameter, so that the extent of light surface is fully 4,000 square feet, or equal to the surface of the largest drop curtain on any stage. The details of its construction are shown in the engraving, Fig. 2.

The surface presents a marble-like appearance, which is produced by a covering of diamond dust. The lights are arranged in lines forming geometrical designs. They are in receptacles on mahogany-colored strips, closely studded

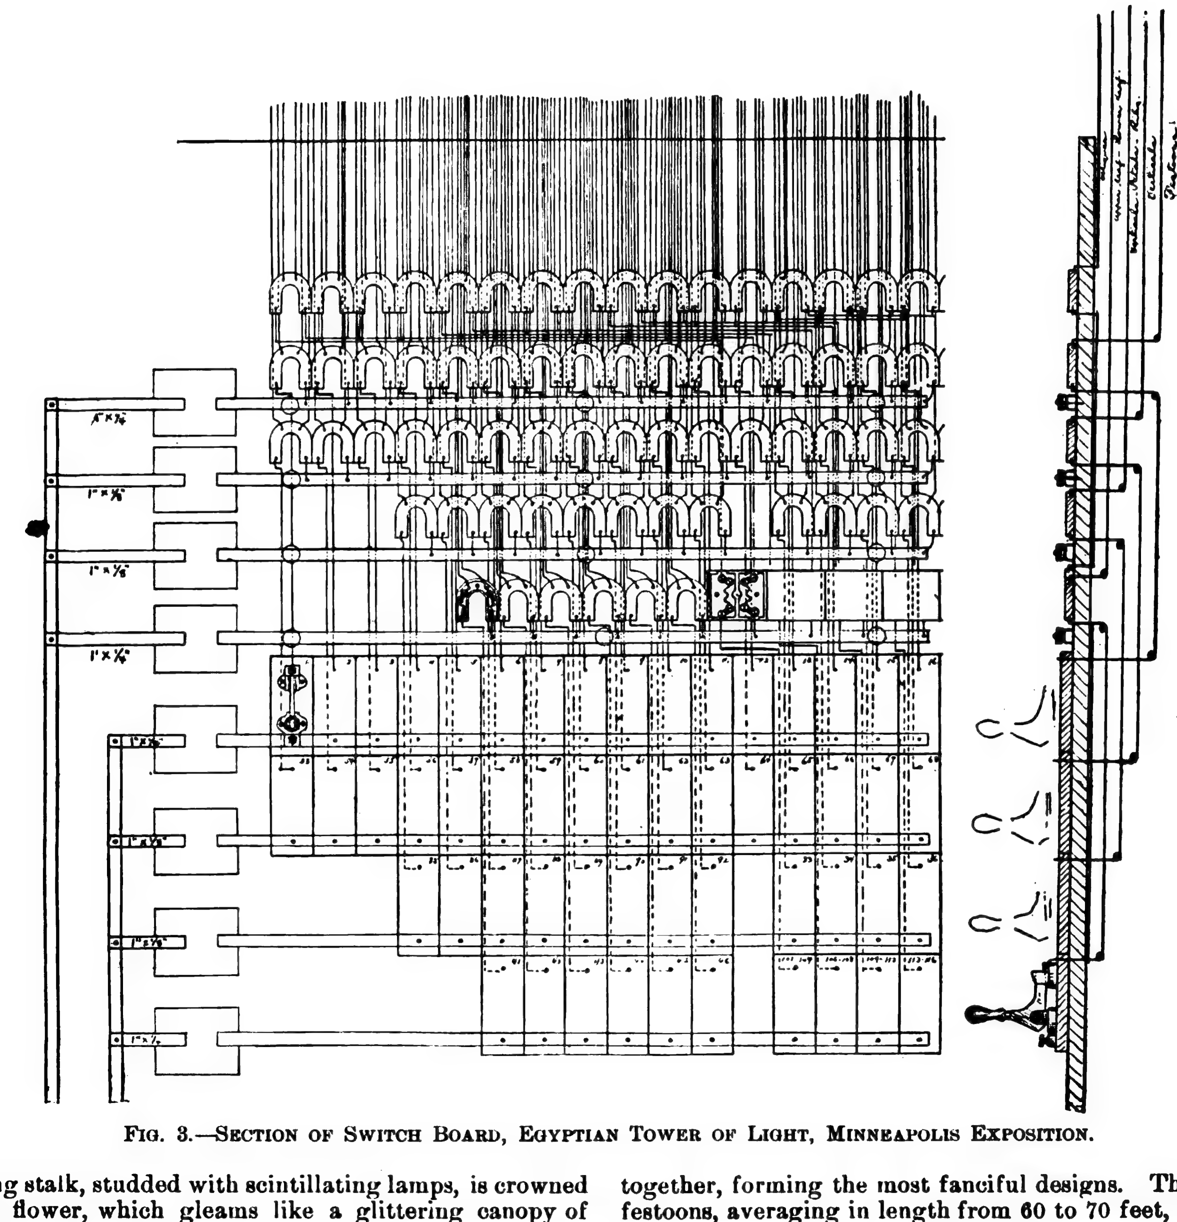

FIG. 3.—SECTION OF SWITCH BOARD, EGYPTIAN TOWER OF LIGHT, MINNEAPOLIS EXPOSITION.

The long stalk, studded with scintillating lamps, is crowned by the flower, which gleams like a glittering canopy of rich light. The petals as they bend down from the corolla are many hued. Radiating from a common centre in the calyx across to the roof of the great light well, are the stamens of the ripened flower. These, represented by festoons, are also of many colors, and as one looks up from below they complete the glory of the fascinating picture. Rushing through a tunnel underneath the falls, disappearing from sight, again to show an instant through the crystal flood, over trestles, and across bridges, is a swift-running miniature electric train.

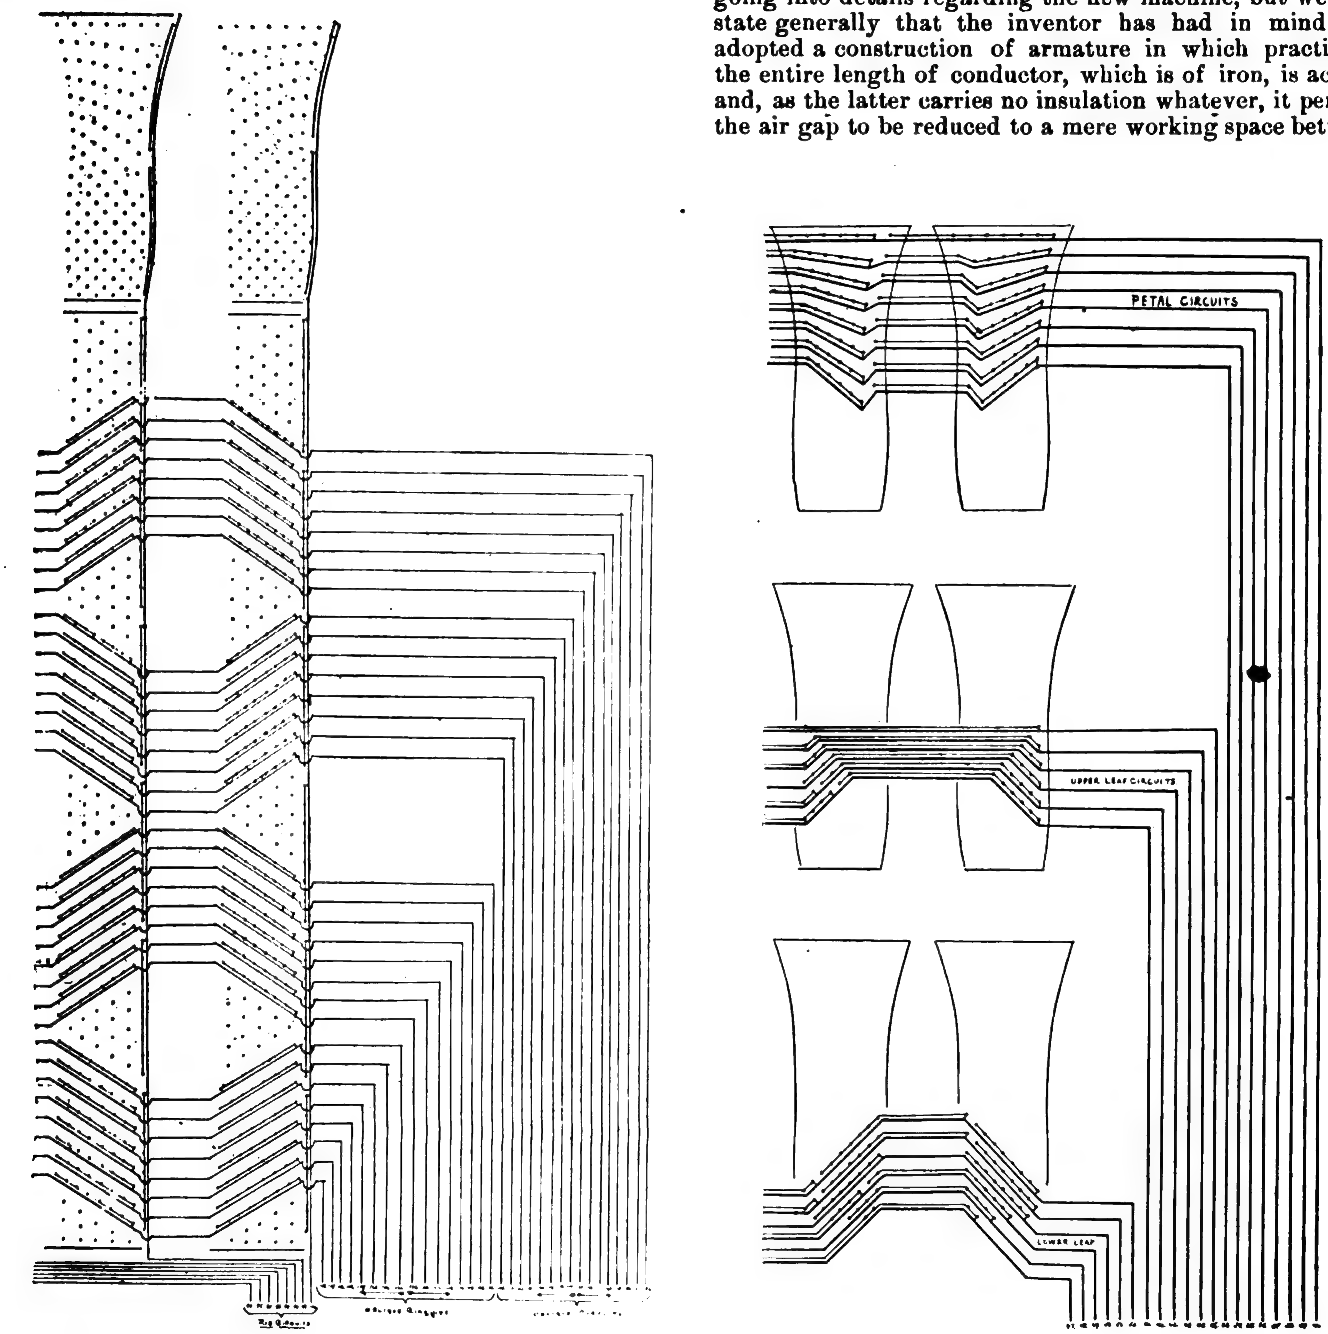
together, forming the most fanciful designs. There are 32 festoons, averaging in length from 60 to 70 feet, in each of which are over 100 parti-colored lamps.

There are two No. 20 Edison generators provided, having a capacity of 900 amperes. The dynamos connect with the light tower through "interior conduit" underground conductors to the switchboard, a part of which is shown in Fig. 3, where the manipulator produces the varied combinations and effects which are the wonder of all, especially when the light is slowly turned on in the festoons, and speeds along its course until the whole bursts into a blaze of light. The plans of wiring adopted for

different parts of the tower are shown in Figs. 4 and 5.

There are fully 10,000 lamps on the tower. Along each of the octagonal corners run perpendicular lines of purple lamps, while in keeping with the botanical structure of the lotus flower, the leaves of the calyx are green. The vertical lines are red, while the festoons and petals are variegated.

The construction of this Egyptian column with its canopy of light shows the capability of miniature lamps for structural effects. It would also have been impossible to have accomplished this feat but for the long



FIGS. 4 AND 5.—PLANS OF WIRING, EGYPTIAN TOWER OF LIGHT.

and careful preparations which were made. This necessity of attention to detail was fully appreciated by Mr. E. W. Hammer, the constructor to whom the plans were entrusted. The work of wiring was done with a special view to safety, and the work done appears as though it were to last for years instead of for six or eight weeks.

This Exposition is but the second occasion in which the miniature lamp has been used commercially in any great number, and the ease with which it can be handled, and the results which can be obtained for decorative and other purposes, in halls, theatres, churches, etc., promises well for the future of this branch of the electric light industry.

A NEW MULTIPOLAR DYNAMO.

WE have recently had occasion to inspect in course of construction a novel type of multipolar slow-speed dynamo designed by Mr. R. Eldridge, of this city. The exigencies of patent applications, now pending, prevent us from going into details regarding the new machine, but we may state generally that the inventor has had in mind and adopted a construction of armature in which practically the entire length of conductor, which is of iron, is active, and, as the latter carries no insulation whatever, it permits the air gap to be reduced to a mere working space between the iron of the armature and the iron of the field magnets. The construction of the machine is being actively pushed, and the inventor hopes soon to give it a practical trial.

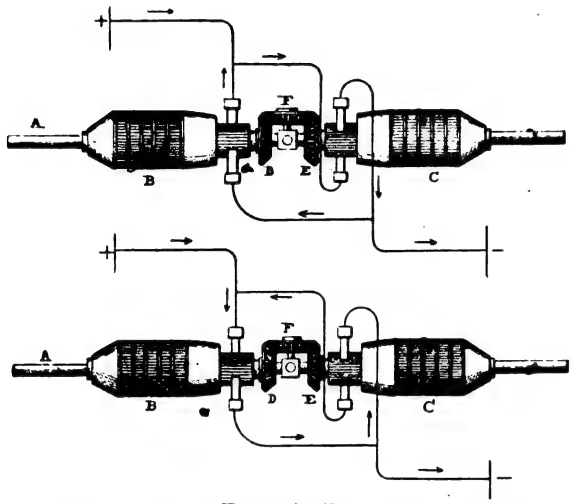
EDISON GENERAL ELECTRIC CO.—The company has appointed Mr. S. B. Paine Edison agent for the New England District, including Maine, New Hampshire, Vermont, Massachusetts, and Rhode Island, with headquarters at Boston.

EDISON'S ELECTRIC CAR GEAR.

Recognizing the importance of the electric railway as a part of the modern applications of electricity, Mr. Edison has of late again devoted attention to this branch and particularly to the method of gearing between the motor and the car axle. The problem involved is essentially that of obtaining any desired variation in speed and direction of rotation with the least waste of energy and by the simplest methods.

Among the various ways in which Mr. Edison has worked out this problem, is one in which he couples two machines together and works them differentially, as it were, converting one or the other into a dynamo or a motor as the exigencies of the service require.

The accompanying illustrations, Figs. 1 and 2, show the principle here adopted. Mounted loosely on the shaft A, so as to turn independently, are two electric motors, B C, the armatures only of which are shown for simplicity of illustration. These armatures are connected with the line circuit and carry on their adjoining ends two beveled gears, D E, which turn with the armatures, independent of the shaft, and which engage with opposite sides of an epicyclic gear, F, mounted upon a stud fixed to the shaft between the armatures. If the two armatures are revolving in opposite directions with equal speed, it is evident that the epicyclic gear F will be simply rotated without exerting any rotary effort upon the shaft A, which will remain at rest. This condition of affairs may be assumed to be reached when the field magnets of the two motors are of equal strength.



Figs. 1 and 2.—Edison's Electric Car Gear.

When it is desired to rotate the shaft in the direction indicated by the arrow in Fig. 1, the field-magnet of the motor B is strengthed, while that of the motor C is made weaker. The effect of this is to accelerate the speed of motor C, and retard that of motor B. The difference in the speed of the motors will result in a rotation of the shaft A in the direction shown in Fig. 1, the machine B, under these circumstances, acting as a dynamo, while the machine C acts as a motor.

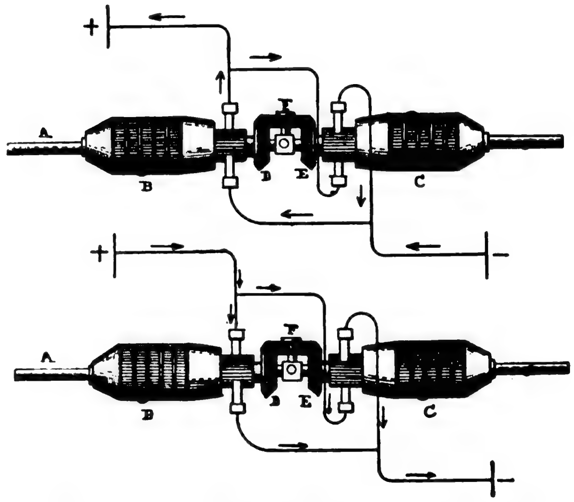
If it is desired to reverse the direction of rotation of the shaft A, as indicated by the arrow in Fig. 2, the relative strength of the field magnets of the two motors is changed, the field-magnet of motor B being weakened, while that of motor C is made stronger. Now the machine C becomes a dynamo, while the machine B acts as a motor, the speed of the shaft A being equal to the difference in speed between the two machines.

Thus it will be seen that a reversal of the direction of rotation of the shaft A may be accomplished without reversing the direction of rotation of the machines, and that the rate of speed of the shaft in either direction may be varied within wide limits, or the shaft may be brought to a standstill without stopping the motors.

Under the conditions shown in Figs. 1 and 2, the current will be taken from the main circuit in proportion to the energy developed, while the machine which is acting as a dynamo will deliver its current through the local circuit, as indicated, to the other machine, acting as a motor, thus economizing the current which is delivered to the machine acting as a dynamo and redelivering the energy, less the percentage due to conversion, for the performance of useful work in the machine acting as a motor. Thus an economical arrangement is produced.

In the application of the idea to the propulsion of street cars, an additional condition will be introduced if it is desired to stop the car while maintaining the circuit-connections of the machines. Considering that the shaft A is a car axle which is being driven in the direction indicated in Fig. 2, and it is desired to stop the car, the field-magnets of the two machines are brought to the same strength, or that of machine B is made stronger, to any degree desired, than that of machine C. The conditions while the car is being propelled forward by its momentum will be as indicated in Fig. 3. The shaft A will then be delivering energy to the machines, with the result of sending current back upon the main line as indicated by the arrows. The machine B becomes a dynamo, and the machine C a motor; but the current taken by the motor will be less than the current delivered by the dynamo. If the car were running in the other direction, as indicated by Fig. 1, the braking of the car would produce the reverse relation of the machines, machine B becoming a motor and machine C a dynamo.

For the driving of some kinds of machinery it is often desirable to produce a greater variation in the speed than can be secured when the motors are capable alone of being driven in opposite directions. In that case the motors



Figs. 3 and 4.—Edison's Electric Car Gear.

may be arranged for independent reversal of their direction of rotation, so that under some circumstances the motors may both be run in the same direction, as indicated in Fig. 4, and while running in the same direction the shaft A will have its greatest speed when the two machines have an equal maximum speed. Thus the speed of the shaft A may be increased from a position of rest to the maximum, which can be secured by running the machines in opposite directions, and then the speed can be further increased by reversing the direction of rotation of the slower machine, so that instead of detracting from the speed it will actually add to it, and the speed will be further increased as this slower machine is brought up to the same rate of rotation as the other, when the maximum speed of the shaft will be attained.

One way in which the principle described above can be carred out in practice, is shown in Fig. 5. By the method of connection here shown, the motor-armatures as well as the field-magnets are connected in multiple arc with the main circuit. A resistance H is located in the field-circuits of the two machines B C, and is adjusted by means of a switch I in such manner that the portion of the resistance on the right of the switch is in the field-circuit of the machine C, while the portion of the resistance on the left of the switch is in the field-circuit of the machine B. The shifting of the switch to the left diminishes the re-

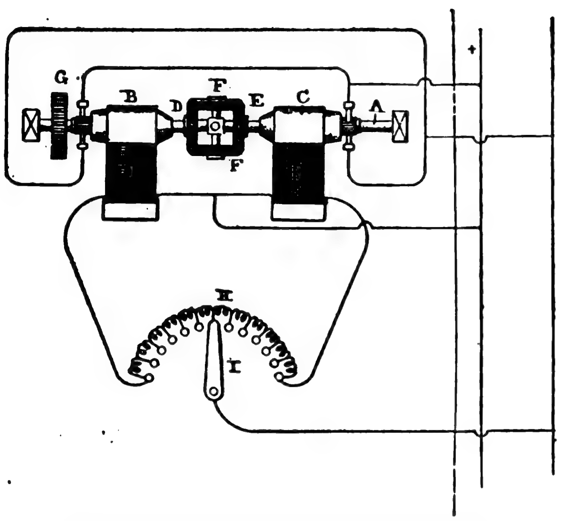


Fig. 5.—Edison's Electric Car Gear.

sistance in the field of the machine B, and increases that in the field of the machine C. A movement to the right produces the reverse effect. If the switch stands at a central position, making the resistances in the two field-circuits equal, the two machines will have an equal speed in opposite directions, and the shaft A will remain at rest.

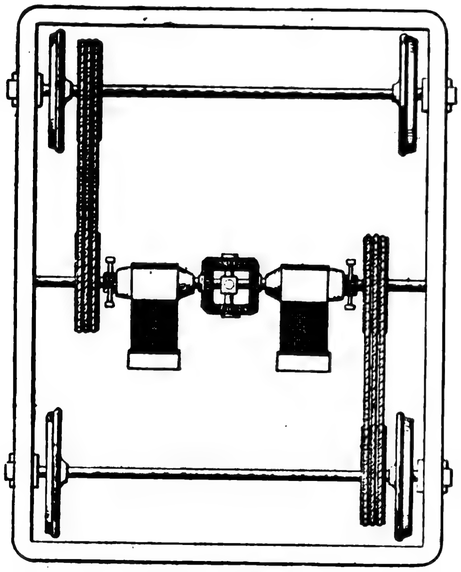

Fig. 6.—Edison's Electric Car Gear.

By throwing the switch to the left the field-magnet of the machine B is strengthened, while that of the machine C will be weakened, resulting in the conditions illustrated by Fig. 1, referred to above, and producing a rotation of the shaft at a speed which is proportional to the difference in the speed of the two machines, and which may be varied within wide limits. By swinging the switch to the right, the field of the machine C will be made strong and that of the machine B weak, and the conditions illustrated by Fig. 2 will be obtained.

The engraving, Fig. 6, shows the method of connecting the driving shaft to both axles by means of rope-gearing, thus equalizing the weight and traction between both axles.

A NEW CURVE INSULATOR.

The successful and economical operation of electric railways depends largely on the proper line construction, *i. e.*, on ample strength of all the parts put under strain, and thorough insulation of the trolley wire from the ground. Owing to the weight of the trolley wire the supporting devices must be very strong, yet they must insulate the trolley line from the supporting wires. This is the more true at curves, where the same strain which is too much for an ordinary iron pole is put on the single centre curve insulator. It is not surprising that some of the forms now in use have not withstood so severe a test in practice, and have either lost their insulating properties or have partly crumbled up. Such a fate seems impossible for the new form

A New Curve Insulator.

which we illustrate herewith, the "Treble" centre curve insulator, designed by Mr. Wm. Sharp for the Great Western Electric Supply Co. This is made of iron pieces bolted together and insulated from each other by hard rubber dashers and bushings. As the cut shows, the three rubber bushings are in series, giving a treble insulation. A rubber sleeve fitting snugly over the insulator keeps this dry, so that the three-fold insulation is obtained in all kinds of weather. The sleeve by enclosing the insulation also prevents any possible deterioration of it. The cut does not show this sleeve, but it shows the disposition of the iron and rubber parts, which are made unusually strong and promise to withstand the severest practical tests.

A NEW ELECTRIC CAR STARTER.

One of the greatest difficulties which has assailed the electrical engineer in designing apparatus for electric street car service is the requirement for an excessive amount of power to start the car from rest. Almost all the cars in service to-day are fitted with about 30 h. p., evidently far too much to keep a car in motion at any speed up to 12 or 15 miles an hour, 10 or 12 h. p. being generally conceded to be sufficient. This extra power is necessary solely to start the car from rest, and electricians will admit that it takes frequently over 40 h. p. to set an ordinary car in motion. Any device which will obviate this difficulty is worthy of serious consideration, and will be welcomed by all street railway men. Mr. John H. Palmer has recently brought to Boston a working model of a device which bids fair to prove an unqualified success, and whose principle consists in having a variable leverage mechanism, obtained by involute wheels, by which an enormously increased leverage is attained on the driving wheels at the moment of starting the car and for some time after. After getting the car fairly set in motion this mechanism is automatically cut out, and the motor continues to drive the car in the ordinary manner, another clutch automatically gearing into the driving shaft an instant before the starting mechanism is cut out. The model works most accurately, and exhibits some very pretty mechanical devices. Experts who have seen it, are agreed that the whole device has been most carefully worked out, and will undoubtedly do all that is claimed for it when put in actual operation. The motor can either be kept running all the time or stopped with every stop of the car, if so desired.

The Turtle Creek Valley Electric Company, of Wilmerding, Pa., is about to add a sixty light arc machine of the new Westinghouse alternate current type to its central station equipment. It already has in service fifteen hundred lights capacity of Westinghouse incandescent dynamos.

THE OPERATION OF THE DOUBLE CORD KEYBOARD AT BROOKLYN, N. Y.[1]

BY GEO. J. DAVISON.

A YEAR ago I addressed a somewhat extended report regarding the workings of the new multiple switch at Brooklyn, as then operated with the single cord keyboard. On account of the troubles therein shown, and because it was essential that we should be able to operate mixed circuits in the multiple board, it was decided to change the keyboard from the single cord, grounded system, to the double cord metallic. This change was completed early in March, 1890, and the new keyboard has, therefore, now been in use for about six months. The equipment is full metallic, with tubular clearing out drops, retardation coils, condensers, split telephones, etc., etc.

The change required the connection of answering spring jacks, which were placed horizontally in the lower part of the switch, necessitating the moving upward of all the spring jacks originally connected. This movement disarranged the switch cable wiring to some extent, and increased the liability to troubles in that particular, but very little has developed. The wiring of the line drops had to be entirely renewed, they having been wired originally for grounded circuits only.

The number of troubles, as shown by the table herewith, is very small, and those occuring were almost entirely of a trivial nature, readily located, and easily removed. In the parts of the apparatus not referred to in the tablulated form, there has been scarcely any trouble. After the change of keyboards had been completed new transmitter cords were put in, none of which has failed; triple receiver cords were necessarily substituted for the double cords; only one of these has failed.

One of the condensers became short-circuited, the result of which was to cause all grounded circuit lines to test "busy" whether in use or not. The split telephones have been very satisfactory, no trouble whatever having been experienced in their use.

Spring Jacks:—We have added 1,720 spring jacks to the 15,600 in use last year, making 17,380 now in use. For the first thirteen months' use there were ten cases of dirty contact; for the past six months there have been 22 cases of this trouble. I think this increased percentage of trouble is due to a considerable extent to the disturbance of the switch cables at the time of changing the system, which set free whatever slight accumulations of dust there was in the cables, no small portion of which found lodgement in and about the spring jacks. None of the spring jacks has platinum contacts the use of which would, I think, lessen this difficulty.

Drops:—There are 1,770 in use, an increase of 110 over last year's report.

The troubles with these have been much fewer than was previously shown, comparing as follows:

	13 Months, 1889.	6 Months, 1890.
Catch	26	3
Shutter	36	8
Armature Trunnion	203	None
Crossed with Core	6	1
Open in Coil	2	1
Burned out	1	5
Broken Wires	20	8
Total	294	26

None of these troubles requires any special comment, the cause of, and remedy for, each being apparent.

Ringing Keys:—The ringing keys are of the pattern known as "long distance metallic," and there are 273 pairs, or 546 individual keys in use. Only five cases of trouble have developed, four of these being a failure to ring, caused by the generator springs not being properly adjusted, being so far away that the depression of the button did not close the contact between the line and generator springs. The remedy was easy and is obvious.

The other case of trouble was where the button, being depressed, would not return to its normal position. This was due to a slight roughening of the sides of the wedge-shaded rubber plunger where the springs rest against it. A little oil applied at the point of trouble was all that was necessary.

Listening Keys:—There are 273 listening keys in use, with which there have been forty-one cases of trouble, no one of which, however, was in the main line circuit, or interfered with the subscribers after a correction had been made. These 41 troubles may be divided into four classes, as follows:

Failing to cut-in operator	9
Failing to cut-out operator	1
Rubber plunger sticking	27
Rubber pin broken	4
Total	41

1. Read before the National Telephone Exchange Assoc., Detroit, Sept. 10, 1890.

Failing to Cut-in Operator:—The nine cases of this trouble occurred in the first two months, and on account of the springs not having been properly adjusted when they were connected. The springs rested against the rubber plunger and did not close the contacts on the operator's circuit. No recurrence of the trouble after properly adjusting the springs by bending them.

Failing to Cut-out Operator:—Only one case of this trouble, caused by the rubber pin of the plunger being so short that the "throw" was not great enough to break the contacts.

Rubber Plunger Sticking:—This trouble occurred twenty-seven times, and, as in the case of the ringing key, was where the plunger remained down, when the cam was thrown forward. It was due, to some extent, to a lack of proper smoothness of finish on the wedge-shaped sides. The plunger is pressed upon by two springs on one side and one on the other, the unequal strain having a slight tendency to make it bind. The difficulty was readily overcome by rubbing a little oil on the sides of the "wedge."

Broken Rubber Pin:—Four of the little rubber pins which are acted upon directly by the cam became broken from some unknown cause. The cams of the listening key make considerable noise when they are thrown forward, but I do not know how this can be avoided.

Tubular Clearing-Out Drops:—Two hundred and seventy-three are in use, which have required attention twenty-three times. All of the troubles, except two, were with the catch. The drops are located directly in the rear of, and on a level with, the cords, the plugs of which in being returned to their normal position occasionally strike against and bend to some extent the rather slender catch of the drops, which, in consequence, fails to release the shutter. The remedy for these troubles, after their occurrence, is obvious. To guard against them the drops should be located elsewhere, which, however, is not practicable in this switch. The "adjustments" referred to were, where the armatures were too loose, requiring the changing of the position of the trunnion binding screws.

Cords:—It appears from the record that only about thirty-five per cent. of the cords in use had failed during the six months. As a matter of fact, a percentage of failures of the cords *actually used* is much greater. Each of the subscriber operators has eighteen pairs of cords available, but habitually uses a much smaller number, a half dozen or so pairs of cords being used for the greater portion of the connections, the other pairs in a lesser and lesser degree according to the volume of business. There were a few failures of the cords at the point of soldering into the shoe, inside of the plug, but the percentage of troubles from this cause is very low.

Almost all of the failures are just at the base of the plug, due to the strain upon the cord in withdrawing the plugs from the spring jacks. The breaking of the tinsels is increased considerably by the perspiration from the operators' hands penetrating the covering of the cords. It is the rule that operators shall withdraw the plugs by taking hold of the same and not by the cord, but it is almost impossible to enforce the rule on long reaches.

The percentage of cord troubles in the double metallic is very much greater than in the single cord, grounded system. In the 13 months' use of 1,200 single cords there were only eight failures, as against 209 failures in six months out of 576 in use in the double metallic. There are two prominent reasons for this increased percentage; first, because as there are two conductors in the metallic circuit cords the liability to trouble is doubled in the same number of cords, and second, because in the double cord system the use of the cords is so much greater. In the single cord system a cord is not used except to complete the connections for which the subscriber, of whose line it forms a part, may call, while in the double-cord system a pair of cords may be used any number of times, in fact, may be used almost continually.

The one case of trouble "conductors crossed in cord" was caused by abrasion of the insulating material. The effect of such a crossing of the line or test is that any grounded circuit subscriber's line tested with that pair of plugs would show "busy" whether in use or not.

Plugs:—The troubles with the plugs have not been many, amounting to thirteen in all out of 576 in use. Four tips of plugs were broken off in the spring jacks, due, however, more to accident and a lack of care than to faulty construction of the plugs.

The removal of one of these tips from a spring jack is a somewhat difficult matter, when it happens to be broken off when the plug is wholly within the jack, and the tip held fast by the line spring. It is then necessary to relieve the tension of the spring by partially, or wholly, withdrawing the screw holding it in place and pushing the tip forward until it is within the sleeve of the "test." From this point I find the most convenient plan of removal to be the use of a short piece of flexible rubber tubing, —placing one end of the tubing firmly over the opening of the spring, a quick inhalation of breath rarely fails to bring it out.

Tips Unscrewed:—The little rivet used to prevent such troubles has come out of nine plug tips, rendering it unsafe to use the plug until repaired.

Referring to last year's report, it will be seen that in the thir-

teen months' record there were 459 cases of trouble with the combination key and 76 with the grounding jacks, a total of 535 in the single cord key-board, or an average of a little over 41 per month. The report herewith for six months shows troubles in the double cord keyboard as follows: Ringing buttons, 5; listening keys, 41; clearing out drops, 23; a total of 69, or an average of 11½ per month. When it is further considered that about forty per cent. of the troubles in the single cord keyboard interfered with the subscriber's conversation after the connection had been made, and that not one of the double cord troubles interfered in this way at all, the contrast is very great.

Add to this, too, the great difference in the ease with which repairs may be made to the double cord system, and that the making of such repairs need not interfere with the operator's efficiency, nor with any subscriber's line, it seems to me that there can be but one conclusion arrived at.

CORPORATE ORGANIZATION.[1]

BY E. J. HALL, JR.

CORPORATIONS have been called "artificial persons," owing their existence to the creative power of the State, and designed by process of law with more or less skill to approximate natural persons in their powers and duties.

When the legislative powers are exercised wisely and skillfully and these artificial persons have been properly constructed, they take their place in society as most useful members, serving the needs of the public in many ways with far greater efficiency and reliability than any natural persons possibly could; for while it may be true that corporations have no souls, it is equally true that they are not subject to paralysis or indigestion.

On the other hand, their design being subject to the fancy of legislative bodies, these artificial persons are sometimes over-developed in some directions and lacking in others, the builder who follows the legal specifications, often finding that parts essential to some material function are wholly omitted, while others are so dwarfed or magnified as to be out of proportion to the symmetry of the intended design.

In the early days of these new members of society the natural persons then composing it had a feeling of, perhaps not unnatural, alarm that if these artificial persons became too big or too numerous they might be troublesome neighbors. What, for instance, if the power which gave them legs and arms should take a notion to add cloven feet, horns and a tail?

This has, from time to time, occasioned the introduction of various restrictions into the specifications, some of them doubtless wise, others unquestionably unwise; but with a realization of the fact that society had not lost, and could not lose, the power to protect itself, has come a better understanding of the benefits to be derived from properly constructed corporations and a disposition to formulate the specifications so that their construction shall be encouraged and their capacity for work utilized to the fullest extent by society.

The tone of the press during the recent labor troubles on the New York Central Railroad reflects a marked change in public sentiment from that existing even a few years ago, and, to some extent, this change is due to a better understanding on the part of corporation managers of the obligations which rest on them to so organize their forces that the public shall be efficiently served, stockholders receive proper returns, and last, but by no means least, that employés shall be justly compensated and fairly treated.

To organize and conduct a corporation so as to fully meet all these obligations is no easy task. In my own work I have been greatly helped by making diagrams of any proposed arrangement of forces, for the purpose of studying from that the exact relations which would exist between various departments and employés if the plan were carried into effect.

Almost invariably the study of a diagram brings out unexpected defects of arrangement or suggests changes which would improve the efficiency of the force. President Sargent has asked me to explain this diagram system, and I am glad to comply with his request, because I believe there is for us no more vital problem than the best method of constructing the "artificial persons" who are furnishing the public with its telephone service, but for whose actions we are all largely responsible. I do not see why we should not go at this just as we would at the construction of any piece of mechanism. Surely it is more complicated and more delicate than any of our electrical apparatus, and, at the same time, its motions are attended with such consequences that we cannot afford to make any mistake.

When we undertake to prepare plans and specifications for the construction of an "artificial person" to conduct the business of a telephone exchange, we must look, first, to the statutes of the State, in which we will find the legal specifications. From them are prepared the charter, articles of incorporation, which, in a general way, define the nature of the proposed corporation and the position which it desires to occupy in relation to the State, while the by-laws, which are to some extent controlled by statute, provide, generally, for the relations of the corporation with its stockholders. By the articles of incorporation and the by-laws provision is made for the control of the corporation by trustees or directors elected by the stockholders, and by certain officers, usually a president, secretary and treasurer, elected either by the stockholders or by the directors. These officers are common to all corporations, and are charged with certain duties by the State and by the by-laws.

It would be interesting to go more fully into the relations thus established between the new corporation, the State which gives it being and the stockholders who risk their fortunes on its success. We will not, however, stop to do so now, because we are considering to-day only the executive forces, the *physical structure* of our "artificial persons." The functions of the officers named will be considered only as they relate to the performance of the work for which the forces are to be organized.

The unit of work, that is, the amount which can be performed by one person, is very small, so we must subdivide until each part of our work receives its proper share of attention; but, as all of the parts are inter-related, it is evident that there must be somewhere a single central authority, for the division means chaos. From this central authority there must be a direct line of communication to every department and every employé; no matter how many departments or employés there may be, this line must be kept in good working order, free at all times from breaks and crosses.

To carry our simile of the artificial person a little further: When, in a natural person, the stomach wires the brain for supplies, the feet must receive orders to move toward them, first one, then the other; they cannot be left to argue between themselves as to which small move first; then the hands must do their work and, at the right moment, the mouth must be ready to do its part, and so each member performs its office as the orders are sent over the connecting lines, and reports from each keep the brain constantly advised of the manner in which its instructions are being carried out.

To construct a diagram of these lines of communication will help us to see how best to arrange the various parts of our artificial person to secure as exact results. For convenience we will call this main line the "Line of Authority," and extend it unbroken from the management to each employé. Other lines there may be, and must be, to unite all the parts of our mechanism into a complete working body, but they must never be mistaken for, or tangled with, the line of authority, or confusion will follow.

On the accompanying diagram which I have made, we can trace now the line of authority originating with the stockholders, extending to the Board of Directors, then to the President, then to the General Manager, and dividing at that point, branches extend to each department chief and through him to his subordinate officers, superintendents, managers, foreman and so on until it reaches the last messenger boy.

The general office is particularly the department of the general manager. Its work consists: *First*—In receiving and recording the orders of the president and directors and transmitting them to the proper persons for execution. With the orders must go the funds and materials for carrying them into effect and the details of the methods to be followed. *Second*—To the General Office must come back the reports and results of all work, which must be recorded and transmitted in proper shape to the Directors. *Third*—Through the General Office all arrangements must be made for *transfers* from one department to another.

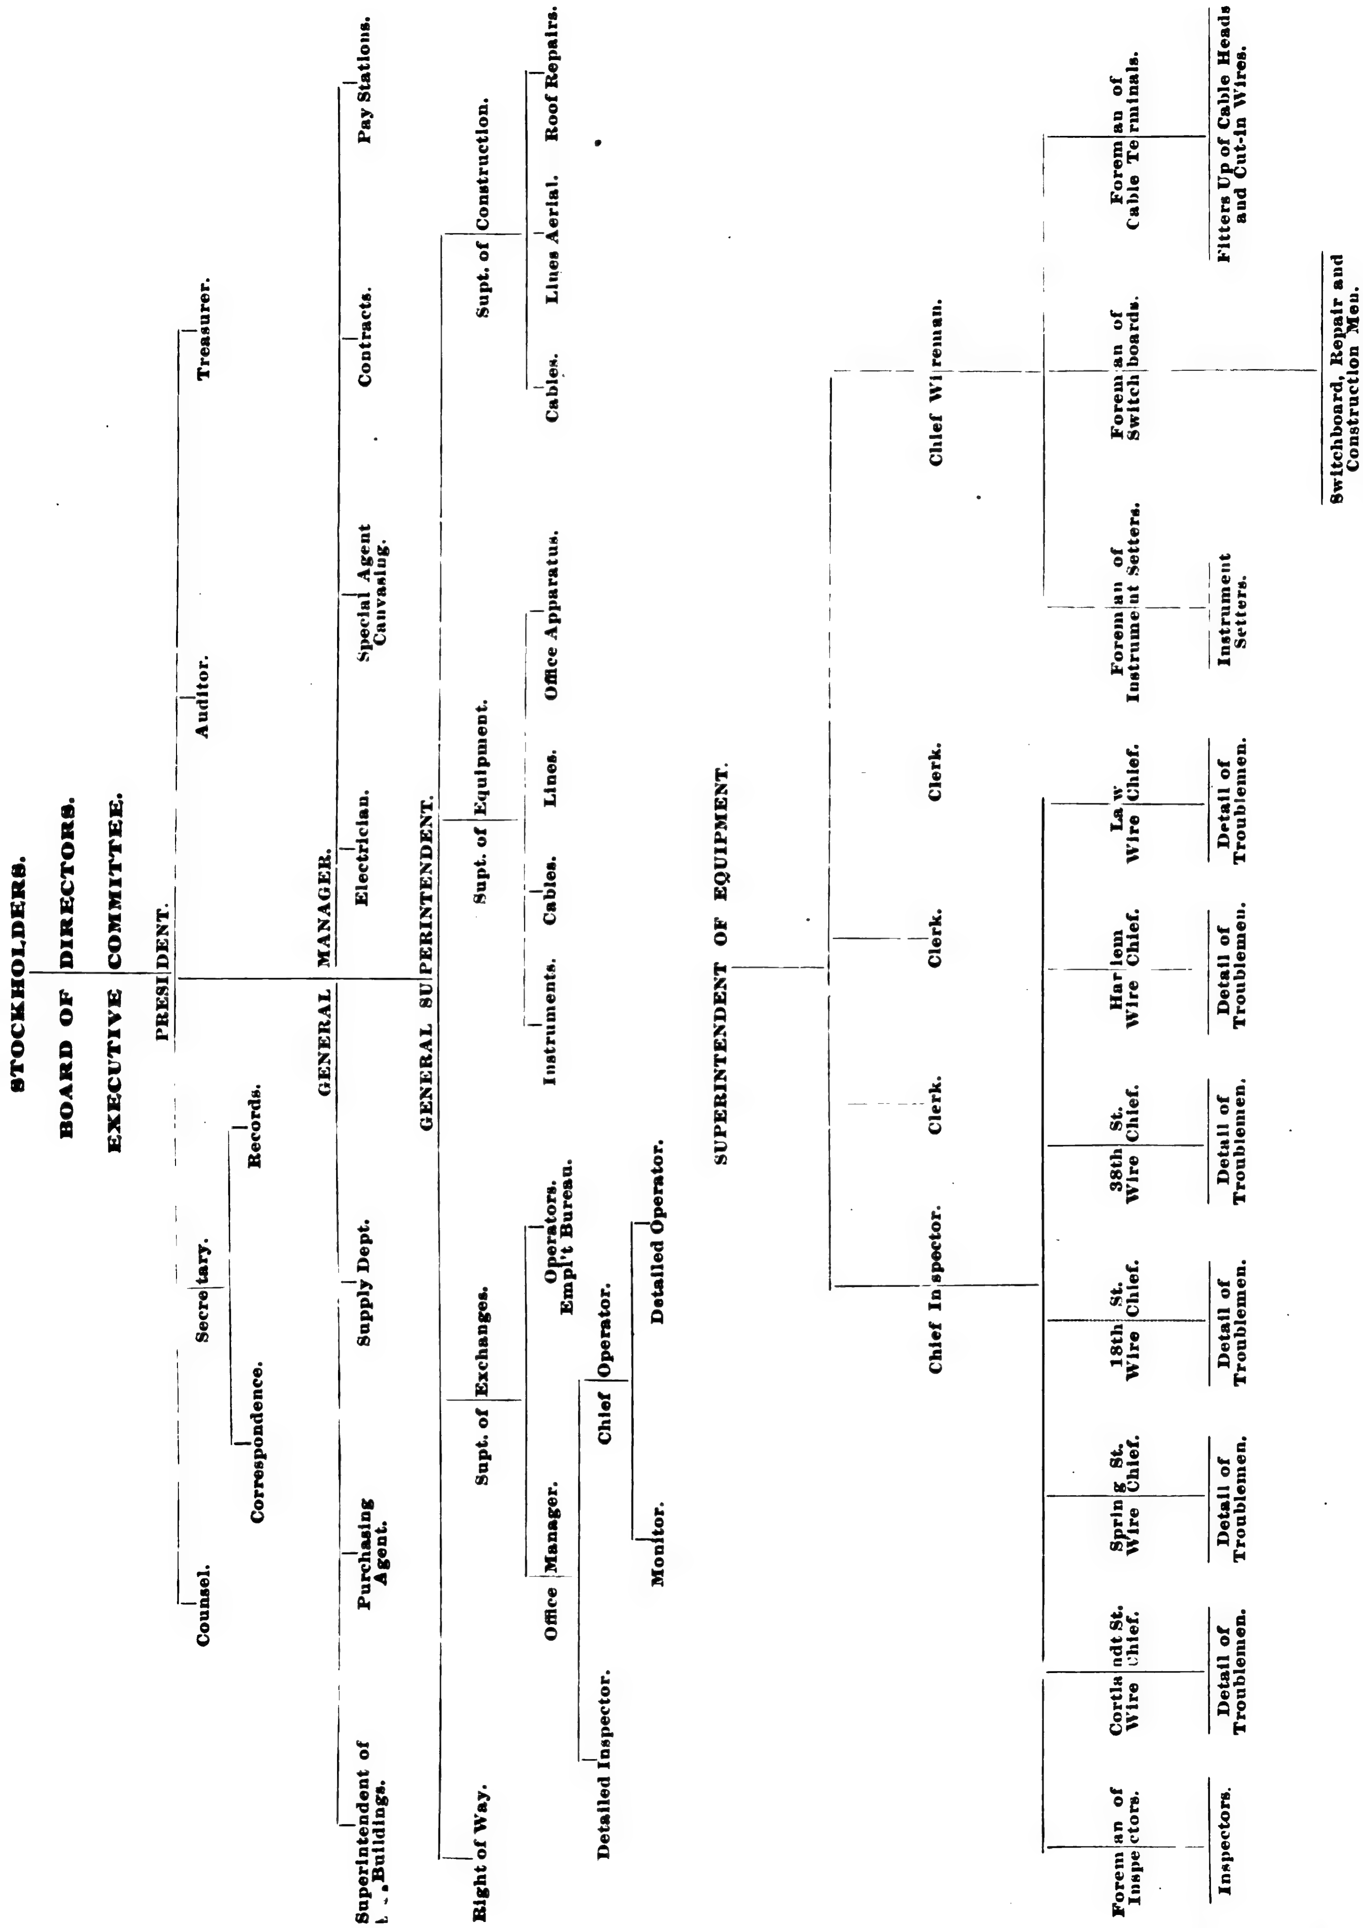
The General Manager acts as the connecting link between the authority which shapes the plans and controls the policy of the company, and the forces which carry those plans into effect. He should be identified as closely as possible with both, and this is often accomplished by making him a member of the Board of Directors, thus enabling him to fully understand the nature of the results to be accomplished, while, at the same time, his close relations with the working forces enable him to keep the Directors fully informed as to the condition of the company's plant and forces, their possibilities and needs for accomplishment of any desired result.

The General Manager, as the diagram shows, has no authority over the Secretary, Treasurer, Auditor, or any employé on the President's line, but such relations as are necessary must be established by order of the directors or the president, unless, as is often the case, the General Manager is also Vice-president, in which case his relations are established by the *latter position*.

This distinction is important, and it applies equally in the case of all relations between officers and employés of different grades when one person fills two offices not on the same "line of authority."

The General Manager should be responsible for the appointment of all employés on his staff or below it, but it does not by any means follow that he should in person select all individuals for appointment; on the contrary, holding a veto power over all, he should select none but his personal assistants, and the heads of

1. Read before the National Telephone Exchange Association, Detroit, September 9, 1890.



Schemes of Corporate and Departmental Organization for Telephone Service.

the departments, for the same reason which makes it necessary for him to control all appointments makes it necessary that—following the line of authority and, conversely, of responsibility—each other officer should, so far as possible, hire and discharge all for whose efficiency he is immediately responsible.

Just here I want to point out the error into which all of us who have charge of a number of men are apt to fall. That is, of doing too much detail work, too much *work* I was about to say ; but it is the quality not the quantity generally at fault. It is often so much easier to do personally than it is to teach others that we fall often, insensibly, into the error of doing routine work which others can do as well, or better ; and having filled our day with arduous labor, go home at night tired but satisfied that the day has been well spent, when, as a matter of fact, we have perhaps lost sight of our duty to keep track of and direct the work of others, and have performed the work of a junior clerk while the interests committed to our charge have suffered in all directions from neglect.

The functions of the Construction and Operating Departments with their various sub-divisions are so well understood by all that it is unnecessary to go into details, and we will follow quickly along the line of authority through the office of the general superintendent to the linemen on one side and on the other to the operator and messengers.

Now to pass on one point of the diagram to another, we must follow back and around on the established lines. There must be no cross lines of authority established, or immediately there is a division of responsibility. This does not mean that there are to be no direct relations between officers and departments except over the route of lines of authority. On the contrary, as I have already said, there must be almost innumerable "lines of relation." These lines may be established in two ways. First, by order of some common superior authority, and second, by an understanding between the employés concerned.

For instance, by order of the president the treasurer might be authorized to use office managers to collect certain accounts or pay certain bills. The treasurer would then have a line of direct relation established with each office manager, but the authority would originate with the president, and his order would pass through the hands of the general manager, general superintendent and superintendent of exchanges to the office managers. Authority given to the treasurer to employ the managers would always be given with the tacit or expressed understanding that the regular duties of the employé called on should not be interfered with, and that the employé's first duty was in every case to his immediate superior.

As an instance of the second sort, it might be arranged between the Construction Department and the Equipment Department that one would do certain things in connection with the other's work ; for example, that the Equipment Department would hang a cable which the Construction Department was responsible for hanging. The test of this transaction would come in case of failure to carry out this understanding. Would it be any excuse for the Superintendent of Construction to say that the Superintendent of Equipment had promised to hang the cable, and had failed to do it ? Clearly not. The diagram shows how such an arrangement could have been made by authority. He took the chances of an arrangement under which he had no control over the other party, and he accepted all the responsibility. In a bad organization this constant shifting of responsibility is always found, and the blame should be with the organizers rather than with the employés, who are probably doing the best they can with the faulty system.

Another fault always found in a bad organization is a defective method of giving orders. Sometimes an organization that otherwise would be good, is demoralized in its work by a careless habit of giving vague verbal orders, a practice sure to result in confusion. Whenever practicable, orders should be given in writing ; they should be brief and clear, and whatever is to be left to the discretion of a person carrying out an order should, if possible, be so stated. Advice and suggestions may be verbal, and often are better so. When an order is accompanied by advice or suggestions as to methods, care should be taken to so separate the order and the suggestions that there may be no misunderstanding.

When verbal orders of any importance are received by any employé he should take the earliest opportunity to reduce them to writing and send an acknowledgment of them, explaining his understanding of their nature, to the officer from whom they were received.

The chart which I have made shows substantially the general organization of a large company, but one which operates a comparatively small territory. Of course a chart prepared for one telephone company or exchange would not be suitable for all others, or, perhaps, for any other; but there are certain functions which are common to all and modifications can easily be made to fit all conditions.

The key note of all successful organizations is sounded in the Bible words : "No man can serve two masters." In the abstract we doubtless all agree with this, but in practice we often make discord instead of harmony among the delicate strings which bind our forces together. It is easy to say that we all arrange our forces so that no man shall serve two masters, but it is far from easy to do it. Especially is it difficult in a small company, where the number of men must necessarily be limited, but where the manifold duties of the service must still all be performed. Even in the larger organizations it is far easier to cross and tangle the lines than it is to keep them straight. The diagram system will aid the manager of a small company to arrange his men to advantage, while to the manager of a large company it will act like the "deadly parallel column" in the newspaper, pointing out all inconsistencies between theory and practice.

Our work of organization and administration is, under the most favorable conditions, perplexing and difficult. Lines must be built, offices equipped, apparatus designed and constructed, records kept, rights of way obtained, reports made, supplies purchased and taken care of, problems legal, financial, scientific and practical solved, and withal we must reckon with human nature in all its varied forms. Each unit of the vast aggregation must be placed where it will be most beneficial to the whole and yet each be so dealt with that personal pride and self-interest shall be considered, faithful service and capacity duly rewarded, the ignorant educated, the idle punished, the vicious and incapable eliminated, and over all discipline, tempered with sympathy and kindness, maintained. Only a thorough organization, wisely administered, can accomplish all this. Without organization the ablest will fail and with it the best will often fall far short of their ideal.

When we have constructed our "artificial person" from drawings which clearly show the location and relations of all the parts, and from specifications which define in exact language the function of each, it may still lack much of the perfection of the natural person, but I am sure it will do its work with far more efficiency and vastly less disturbance than if it be simply an aggregation of unrelated parts tangled together by the old-fashioned "rule of thumb" method.

THE HOUSING AND CARE OF CENTRAL OFFICE APPARATUS.[1]

BY W. R. PATTERSON.

THE cost of the apparatus in a large central office is often greater than the cost of the building which contains it ; at the least, it is equal to a very considerable fraction of the cost of the building.

In renting an operating room for a short term there may be some excuse for taking things as they are found, and working the exchange at a disadvantage in some particulars ; but when a special building is to be erected, nominally as a telephone exchange building, it must be something more than an office building, with the most undesirable part grudgingly spared for an operating room. An outside income from rental of offices and stores is a good thing, unless it is secured at the expense of the legitimate business of the company. The switching apparatus of an exchange system is not a lot of separate instruments, like the outfit of a telegraph office, but it is a complex entity which requires weeks or months to put in position, and the parts of which are not easily renewable or accessible. Therefore, in planning the construction of a building, the fact must not be lost sight of that it is a telephone building, and that its purpose is to protect the central office apparatus and facilitate economical and satisfactory service.

In planning a new building the company's electrician is to be consulted before the architect. The electrician's duty is to plan a switch-board room with reference to the best possible arrangement of the board and all the apparatus connected therewith, having as the only limitation the size and shape of the building lot. The process of evolution of the building must be :—First, the switch-board with its accessories ; second, the finished rooms to contain them ; third, the building of which these rooms form a part. At the third stage, and not till then, except as a consulting engineer, should the architect be called in. Give him the building lot and the finished operating room and its complete equipment as his limitations, and then let him do the best he can with the building.

As to the location of the operating room in the building, precedent is for the top floor. When all the wires were on poles and housetops, the most convenient place for the switch-board was at the top of the building. The use of underground wires is almost universal, at least for leading in from neighboring poles, and this would suggest that a more advantageous place might be found in the lower part of the building. It is impracticable to lay down any hard and fast law, but it would seem that the use of the first or second floor for an operating room was worth considering. Financially, the problem is whether the rental value of the top story, plus the rental value of the space occupied in each story by the cables leading in, plus the interest and depreciation on such cables, is greater, or less, than the rental value of the first or sec-

1. A paper read before the National Telephone Exchange Association, Detroit, Sept. 10, 1890.

ond floor. In the case of a building covering an entire lot, the advantages of an operating room on a lower floor are not so obvious but in a large building, where an interior or rear court is left for light, the operating room may economically be placed on the second floor; building up the court two stories, instead of one, and using the rear of the basement and first floors for storage—so that, for example, the room taken for the exchange room would be in the rear of the second story as against the whole of the top story. Of course, this is only an illustration of what might be done in one case. Electrically, everything is in favor of an operating room near the ground, when, as is the general practice, underground cables are used. One or two hundred feet of cable, made a permanent part of every circuit, is in itself of no importance; but in large cities the amount of cable absolutely required elsewhere, and the possibilities of long distance work with connections into and through other cities, make it important to cut the amount of cable down to what must be used.

All these things, and many others which local conditions impose, being considered, and the operating room planned and its position in the building determined, the next points for consideration are:—Getting the switch-board and other apparatus into the room; connecting the switch-board with the underground conduits; heating, lighting and ventilating the operating room, and protecting it and its contents from fire.

Providing means for getting in and out with apparatus must be considered. In making plans, the best way is to project into space the switch-board, then project around it an operating-room, and then fill in the rest with the best arrangement of rooms and offices. But in building, the process must be reversed—first, the building, then finish the operating-room, and last of all put in its furniture.

Dragging switch-board sections into an unfinished building through a window or a hole left in the wall is poor policy. While the ultimate end of any machine is the junk shop, a piece of work like a switch-board makes more progress towards that end in a few weeks in an unfinished building than in years of service.

Provision must be made for getting cables from the street conduit to the switch-board. The position of the building relative to the conduit, and the number of cables to be accommodated, will determine the best way of getting from the conduit into the building. In general, a tunnel accessible throughout its whole length is best. If the cables are to be taken up through the building to an operating room on the top floor, there are several ways of getting them there. One is through ducts built in the wall; another through pipes fastened to the walls, either inside or outside; another is through a shaft or well-hole in which the cables are accessible. Whichever plan is adopted it should be carried out in such a way that cables of as good specifications as the regular underground cables can be used. In general, the shaft is the best plan, then the pipes on the walls, and least satisfactory, the system of small flues in the walls. The shaft is of advantage, not only in handling cables, but also as a ventilator for the conduit. A good plan for a large exchange, to require a hundred or more cables, is a straight tunnel or passage-way through the building from the conduit in the street to a point under the cable terminal room. From the inner end of this tunnel a straight shaft may be carried through the roof with provision made for clamping the cables upon the sides at short distances, and with a stairway or an elevator in the centre; the cables to run continuously from the street to a terminal room adjacent to and practically a part of the switch-board room. If the operating-room is on the lower floor the large shaft through the roof will be unnecessary—provision being made for a shaft or flue large enough to ventilate the conduit, either by natural draft or by a fan.

Now, as to the construction of the operating-room itself with reference to lighting, heating, ventilating and fire-proofing: First, let us consider the contents of the room. The apparatus therein forms a part of every circuit, and every conversation passes through it. The time is rapidly approaching when all the circuits will be metallic—that is, a circuit will be no longer a single wire, but two sides which must be balanced within a very small limit—balanced not only in resistance but in capacity and insulation. Then, there are spring jacks and keys, contact points, numbering in the aggregate into the hundreds of thousands, poor contact in any one of which will cause poor service on some line. The surfaces on which the springs and contacts are mounted, and to a greater or less extent the insulating material of the thousands of miles of wire used in connections, are hygroscopic, and the insulation of this part of the circuit rapidly falls with the increase of moisture in suspension in the air. A particle of dust under a contact spring either opens the line entirely or throws in more resistance than the whole circuit should have. The extension of underground telephone circuits, the increase of electric light and motor lines, and the continued demand for better service—all require that better work shall be done in the switch-board room than was even suggested a few years ago. This being the case, more thought must be given in the future to the heating, ventilating and care of such a room than they have received in the past. Instead of letting this matter rest and provision be made for heating as a sort of afterthought after the building is planned, and no provision made for ventilating except by open windows and doors, it must be one of the first to receive attention. The heating and ventilating of the operating room must be planned together. Windows and doors as a means of ventilation must be ignored, and windows only used for light. Heating should be by a system of indirect radiation, and the air must be at all seasons of the year of uniform dryness and freed from dust. The coils for heating the air in the winter may be used for cooling it in the summer, circulating cold water or a freezing mixture through them instead of steam. The electrical and mechanical engineer must furnish the detailed plans and specifications for this work, and the architect must accept them, together with the switch-board room and cable conduit, as the things around which the building is to be erected.

When windows are used for ventilation good service cannot be expected. In a city where soft coal is burned, the soot is a cause of high resistance if deposited on the contacts, and making contacts of platinum will not remove it because the separation of the surfaces is a mechanical one and is not due to surface corrosion. This soot is much worse than street dust, since it is adhesive, and the continued closing of contact springs tamps it down on the surface so that only a file or scraper will remove it. On account of its adhesiveness putting contacts vertically will not cure all the trouble, for the reason that the particles of soot will not fall off. Smoke from hard coal is less objectionable, but even this causes corrosion of contact surfaces and renders the use of platinum necessary. Apart from these electrical difficulties caused by dust, its presence, more especially gritty street dust, in the room, causes the rapid wear of cams, plungers, and other parts of the apparatus which require to have a motion which can be affected by friction. A switch-board set so that a draft of smoky or dusty air passes through will arrest a great part of the ponderable particles. The principle of dust arresters used in pipes from saw mills, grinding rooms, and the like, is that the current of dust-laden air has its direction suddenly changed. The inertia of the particles preventing them from changing their direction promptly, they are left, while the air pursues a tortuous course and escapes. The springs and wires act in just this way on a current of air driven through the board. Enclosing the back of the board is good as far as it goes; but it is not enough. It is much easier to keep dirt out of the room than to keep it out of the board when freely admitted into the room.

In cities exposed to frequent fogs, especially along the coast, the insulation of the apparatus will run very low at times, and the deposition of salt on the surfaces makes them more hygroscopic and tends to increase the escape. The only insulating material suitable for most of the switch-board work is vulcanite or hard rubber. This is a vulcanized compound and a continual moistening and drying of its surface results in the oxidization of sulphur to form sulphuric acid. Both these causes result in a permanent lowering of the insulation.

The regulation of the amount of moisture in the air, and its removal above a hurtful limit, has also a direct bearing on the fire-proofing of the board. Of necessity, a great mass of insulated wires must be used to connect key-tables and jacks. The spring-jack connections can, to a great extent, be cabled, and by this means made less inflammable, but the key-boards must be wired with loose wires. There is no insulating material available so far that it is both moisture-proof and fire-proof. Fire-proof qualities are generally made secondary to water-proof qualities, and so the under and back sides of the boards are covered with an inflammable mass of paraffine, beeswax or rubber covered wire. If hurtful amounts of moisture can be kept out of the room the problem of fire-proofing is solved, because dry cotton or silk can be used for the insulation of the wires. A wire closely covered with dry cotton is as near fire-proof as it can be made, and the only objection to be brought against its use is its hygroscopic nature and the consequent low insulation resulting from moisture absorbed from the air.

Precautions having thus been taken to prevent the ingress of dust and moisture with the air, the room should also be constructed with reference to its care and with a view to confining to a minimum the production of dust and dirt within the room. A tile floor, or, at least, one of well-finished hard wood, will assist in this, and the janitor must have learned his trade in a picture gallery rather than on a canal boat. Battery and repair rooms must be entirely disconnected from the switch-board and cable rooms and the operators coming in from muddy streets should not go into the switch-board room to reach their dressing room. Dust-collecting-and-producing carpets, rugs and hangings must be omitted from the furniture, and it may be that sometime the operators will be required to dress in the least dust and lint producing fabrics. Before that time, however, the manufacturers will be expected to produce a cord that will not fray out and add its contribution to the dust.

It may seem that too much importance has been attached to such little things as a regulation of moisture to within a small percentage, and removing dust. But all the precautions advised are no more insignificant than have to be observed in some branches of manufacture, notably the spinning of fine cotton. The telephone itself is made up of little things. The little things in connection with circuit construction, cable work, strong cur-

rent protectors and line tests, have been worked out to a greater or less extent, and no step has been so small as not to show an improvement in the result. The next advance is to be in the proper care of the switching apparatus, and in the construction of exchange buildings, mainly with a view to the protection of the apparatus.

Now, having decided upon the position of the room in the building, your electrical engineer having laid out the floor plan of board and cable room, your heating engineer having provided ducts and rooms for admitting and treating the air, you are ready for the architect. You will have projected into space the rooms devoted to exchange work, and the connection of these rooms with the street conduits, and the complete heating and ventilating plant attached. This is turned over to the architect. He may not be able with these limitations to introduce all the artistic features he would desire in the front, he may not be able to plan such desirable suites of offices as he would, if left to his own devices, he may not be able to plan stores more desirable to tenants than anything else in the neighborhood; but you will have an exchange room which is not an after-thought and which is not the leavings of everything else. In such a room the life of the apparatus will be prolonged, and if originally well constructed it can be depended upon to give uniformly good service.

There may be exchanges working under exceptionably favorable conditions of climate and surroundings where all these precautions would seem unnecessary, but none of them are very expensive and none of them could do any harm.

In existing buildings, where the record of troubles shows a preponderance of open contacts and where frequent cleaning of contact points is found necessary, it would undoubtedly pay to introduce the heating and ventilating plan above recommended. An indirect radiation system of heating is fully as cheap as any other, the only additional expense being the running of the apparatus for ventilation when artificial heat is not required. This expense would not be worth considering if all trouble from open and high resistance contacts could be avoided. That it can be, there is no reason to doubt. If the dirt is kept out of the room it cannot get into the board; if moisture is kept out of the room, it cannot get into the insulation of the wires. Dirt can be kept out of the room and the degree of moisture be regulated just as well in a switchboard room as in a theatre, library or spinning room.

SOME GENERAL REMARKS ON TELEPHONE EXCHANGE CONSTRUCTION AND EQUIPMENT.[1]

BY F. A. PICKERNELL.

THE modern telephone exchange building should be thoroughly fire-proof. False floors and concealed masses of wires should be avoided; for a fire once started in such places is extinguished with great difficulty. In its erection, everything should be sacrificed that in any way interferes with the particular object for which it is built.

In the basement, racks are to be provided for underground cables. Between the basement and terminal room a cable shaft or system of ducts is to be constructed.

On the top floor are to be located the operating, terminal battery and power, cloak and lunch rooms. These rooms should be provided with chemical fire extinguishers, and the manager, fire chief and assistants thoroughly instructed in their use.

In case of fire every effort should be made to suppress it without calling on the Fire Department. If the fire should attain considerable proportions, it could at its worst only consume all the combustible matter in the room, for inasmuch as the operating room is on the top floor, the fire could not cripple any of the supporting columns or beams of the building and cause it to fall. If a small fire were started and the average fireman admitted, he would do more damage with his axe and hose than the fire would in entirely consuming the apparatus.

Before a telephone company is in a position to erect a suitable building it is necessary to make definite estimates of the probable extent of the underground work, the ultimate number of subscribers it will be desired to handle at the proposed exchange, the probable number of trunks to other exchanges, the probable number of extra-territorial lines, the amount of private wire business, the probable average number of calls per subscriber, per day, when the switch-board attains its ultimate capacity. A careful estimate of this kind determines the ultimate capacity of the switch-boards, underground cable runs, etc., and consequently fixes the minimum size of the building.

In order that the building may fulfill the requirements of a modern telephone exchange, a technical expert should be provided with these estimates and his opinion taken before any land is purchased or building erected. He should co-laborate with the architect in making the building plans. Mistakes have already been made by telephone companies in adopting plans of good office buildings and afterwards placing the switch-board wherever room could be found. Such buildings have been found unsuitable for modern telephone exchanges. It does not follow from this that the requirements of a good telephone building are necessarily incompatible with the demands of an office building.

One of the first matters to be considered in planning the building is the handling of the underground cables. The system for bringing in the cables should be thoroughly flexible and permit of the drawing in and out of any particular cable when the point of ultimate equipment is reached. The cables are to be extended through the basement to vertical rows of ducts or to a suitable cable shaft, extending to the cable terminal room. The massing of the cables in rows of ducts extending to two in number should be avoided. Wherever it is necessary to pass from one system of ducts to another system, the cables should be brought into a vertical row, thus rendering each cable accessible.

Before any building plan is adopted, a complete working plan for the handling of the underground cable should be made. This working plan would show the exact location of every cable in the subway, at each turn, and the location of its inside terminal.

It is preferable to head up cables in a terminal containing a sneak current and lightning arrester. The sneak current arrester should operate with the current of .3 of an ampere in 40 seconds, and the lightning arrester should operate when the potential of the wire rises to 300 volts. By using a combined cable head and strong current arrester, economy in space as well as in expense is insured. The strong current arrester should be so designed that the lines can be tested at this point, by using suitable plugs.

The terminal room should also contain a distributing board and chief inspector's desk. The most economical, compact and flexible distributing board that has yet been devised, is that known as the "Hibbard Iron Distributing Board." The cable terminals should be connected with the line side of the distributing board by flexible cable, all connections being solid. The switch-board cables terminate on its other side. For cross-connecting wires, okonite wire No. 20 B. & S. gauge, insulated to $\frac{1}{16}$ of an inch, twisted in pairs, should be used, all connections being solid.

The chief inspectors' desk should be located immediately in front of the distributing board and should be provided with a telephone outfit, Morse key and relay, Wheatstone bridge and galvanometer and loops extending to the tower and battery room, local switchboard and chief operator's desk. It should be provided with testing plugs for use at the strong current arrester.

Near the terminal room should be located a power and battery room, and in this room battery racks should be provided upon which the operators' transmitter batteries and chief inspector's testing batteries can be located. The battery rack should be wired with water proof wire in a permanent manner.

In this room a generator switch-board should be provided, and have terminating upon it loops to the various portions of the multiple board and also the terminals of all generators. Electric motors, water motors, or other suitable power supply, should be located here. Both the terminal room and battery and power room should be so located that it will be possible to enter them without passing through the operating room.

On the same floor and adjacent to the terminal room should be located the operating room. This room should be large and well ventilated, free from elevator shafts, columns or other obstructions. The switch-board should commence at the end of the operating room nearest the terminal room and extend from it in a straight line.

If it becomes necessary to deflect the switch-board from a straight line, it should be arranged so that the operators sit on the inside of the curve. This enables the chief operator's desk to be so located that all parts of the switch-board are visible from this point. The size of the room necessary will depend upon the ultimate capacity of the switch-board. If the switch-board is to have an ultimate capacity of 4,000 lines or over, the extra-territorial trunk section should be the first in the system. It should be equipped with five point spring jacks and three point plugs, so that when a line is in use at the trunk section, it tests busy at the other boards.

If a switch-board is to have a capacity of less than 4,000 lines, the trunk board should be made the last section in the system, and the regular Chicago spring jack used. The reason for locating it last in the system is as follows: Whenever a metallic circuit connection is made at any section, an open leg is attached, which extends throughout the rest of the board, to the answering jack. The open leg is shortest on connections made at the last section. In large boards, this introduces an appreciable amount of cross-talk. By making the trunk line section the last section in the board, all connections made at this board have a minimum length of open leg and consequently the switch-board cross-talk is reduced to a minimum.

The answering jack should be the the last spring jack in the system, thus insuring, in every connection, at least, one of the parties connected having no open leg attached to his circuit. If the answering jack were the first spring jack in the section, every connection would have at least one open leg attached to it extending throughout the whole system.

Next to the trunk section comes the regular multiple board, the number of sections depending upon its present equipment.

1. A paper read before the National Telephone Exchange Association, Detroit, September 10, 1890.

It has been found that sections of multiple board six panels wide, of the hog-trough type, and having an ultimate capacity for 800 subscribers' drops, is the most desirable form of multiple switch-board. On the back of the hog-trough is to be located tubular clearing-out drops and tubular subscribers' drops.

Immediately back of the hog-trough is to be located a cord shelf, upon which both cords are to be placed. In the face of the board, immediately above the cord shelf, is to be placed the answering jacks; above the answering jacks, the subscribers' jacks.

The standard condenser, listening and long-distance ringing keys, with talking contacts of platinum, have been found to give most excellent service. On the frame work, immediately under, and back of, the cord shelf, is to be located an intermediate distributing board. It has been found that it is possible to so distribute the busy subscribers with those that are not so busy, as to make approximately equal the work for all the operators. In order to do this, without changing the number of the subscriber, the intermediate distributing board has been designed. One side of this board is connected to the answering jack and subscriber's drop, and the other side to the cables coming from the multiple board.

By placing two numbers on the subscriber's drop, one on the shutter corresponding with the answering jack, and one on the face plate corresponding with the spring jack number in the multiple board, it is possible to make cross connections at the intermediate distributing board and not change the drop number of the subscriber.

A change of this kind will be effected as follows:—Suppose that the operator upon which subscriber No. 654 terminates, was very busy, and that the operator upon which subscriber No. 235 terminates, was not so busy; and also that the subscriber No. 654 was a very busy wire, and subscriber No. 235 was not a busy wire, it would be desirable to interchange the answering jacks of these two subscribers, for, by so doing, the work of the operators would be more equally divided. This would be done at the intermediate distributing board by cross-connecting the two answering jacks and by changing the face plates on these two subscribers' drops. The office record of circuits should be so constituted as to admit of this dual numbering of drops.

The double trunk system for intercommunication between offices is recommended. Push buttons connecting local operators with the talking circuits are to be placed within easy reach in front of each operator. All incoming trunks should terminate on single cords and be operated by a call wire system. For this purpose the incoming trunk line operator has his head telephone included in the talking circuit from the other exchanges. The trunk circuits should be arranged so that if the calling wire breaks down any other trunk line may be quickly substituted and pending the change the trunk lines operated by drops.

It is also desirable to have the circuits so constructed that when the operator at the originating office disconnects a trunk line, the operator at the receiving office is notified automatically by special signal. This reduces the number of calls on the talking circuit one-half.

In front of the switch-board, in such a position that all sections may be easily seen, a monitor desk should be placed. This desk should have terminating on spring jacks, loops extending to each operator, to the chief inspector's desk, and to circuits in the multiple board.

All operating rooms should be laid with linoleum to prevent noise by people walking about. On the same floor as the operating room a cloak room and lunch room should be provided. The lunch room should be equipped with tea and coffee urns, lunch table, etc. By providing such conveniences for the operators, a better class of women become available and exchange service correspondingly improved.

In closing these remarks, I would call attention to the necessity of providing complete working plans and specifications of the proposed equipment including the cable run before the construction of the building is commenced. Extensive alterations in buildings and apparatus already made in several of our central offices, would not have been necessary had this been done. Such plans are necessary to the successful and economical erection of a modern telephone exchange, as are the plans for the erection of a suspension bridge, or other engineering work.

THE TWELFTH MEETING OF THE NATIONAL TELEPHONE EXCHANGE ASSOCIATION, DETROIT, MICH., SEPT. 9, 10, AND 11, 1890.

The Association was called to order at the Russell House, Detroit, by President W. D. Sargent. The following were in attendance:—

Albany, N. Y.—A. B. Uline.
Atlanta, Ga.—W. J. C. Cole.
Austin, Texas.—F. B. Knight.
Boston, Mass.—I. H. Farnham, W. A. Hovey, H. V. Hayes, J. N. Keller, Thomas D. Lockwood, A. O. Morgan.
Bridgeport, Conn.—Charles B. Doolittle.
Brooklyn, N. Y.—W. D. Sargent.
Buffalo, N. Y.—E. J. Hall, Sr., H. C. Palmer.
Chicago, Ill—E. M. Barton, F. G. Beach, W. Forman Collins, E. D. Crandall, F. E. Degenhardt, Fred DeLand, Mr. Dickerson, Mr. Durburrow, C. E. Mosely, E. L. Powers, Gilbert M. Smith, C. H. Wilson.
Cincinnati, O.—E. V. Cherry, G. G. Hall.
Cleveland, O.—J. P. McKinstry.
Columbus, O.—J. E. Zeublin.
Detroit, Mich.—Paul W. Bossart, F. A. Forbes, W. A. Jackson, J. F. Lerrell, Louis A. Palmer, Frank B. Rae, R. B. Watson.
Elmira, N. Y.—W. N. Eastabrook.
Kansas City, Mo.—Charles W. McDaniels, J. O. Stockwell.
Louisville, Ky.—Capt. H. N. Gifford.
Milwaukee, Wis.—John D. McCleod.
Nashville, Tenn.—O. F. Noel.
New York.—C. O. Baker, Jr., Gen. C. H. Barney, L. D. Beck, W. A. Childs, D. I. Carson, J. J. Carty, J. F. Cummings, Arthur J. Fuller, E. J. Hall, Jr., G. A. Hamilton, A. S. Hibbard, James F. Kelly, F. A. Magee, George T. Manson, J. P. McQuaide, F. E. Pickernell, C. W. Price, Frank W. Price, Henry D. Satnley, C. E. Stump, Thomas R. Taltavall, W. B. Thayer, Jean A. Wetmore.
New Orleans, La.—A. W. Crandell.
Omaha, Neb.—C. E. Yost.
Philadelphia, Pa.—H. S. Huidekoper, E. A. Westbrook.
Salt Lake City, Utah.—D. S. Murray, George Y. Wallace.
Washington, D. C.—J. M. Brown.
Williamsport, Pa.—R. Bailey.

The ladies attending the Convention were as follows:—

Mrs. C. H. Barney, Mrs. W. J. C. Cole, Mrs. A. W. Crandell, Mrs. W. N. Eastabrook, Miss Gifford, Mrs. J. B. McKinstry, Mrs. J. P. McQuade, Mrs. H. C. Palmer.

The calling of the roll showed that there were represented twenty-six active members, three associate members, and six honorary members.

The secretary read his report as follows:

SECRETARY'S REPORT.

I have the honor respectfully to submit my report of this Association for the year ending August 31st, 1890.

At the beginning of the Association year the roll contained the names of 34 active, 6 associate, and 27 honorary members. The changes during the year have been as follows: At the Minneapolis meeting the resignation of the Sunset Telephone Telegraph Company, of San Francisco, as an active member, and of Clark B. Hotchkiss as an associate member, were both accepted, and the Callender Insulating and Water-proofing Company was dropped from the roll of honorary members, it having gone out of business. At the same meeting, the Cumberland Telephone and Telegraph Company was re-elected to active membership, and Messrs. Felten and Guilleaume, of Cologne, Germany, were elected as associate members. Mr. A. G. Day, an honorary member, has died during the year.

These changes leave us with a membership at the close of the Association year, as follows: Active, 34; associate, 6; honorary, 25.

There is now in my hands, to be presented to the Association, the resignation of the City and Suburban Telegraph Association, of Cincinnati, as an active member, and that of J. A. Roebling's Sons' Company, of New York City, as an associate member.

The office of the secretary has remained at 510 West 23d street, New York City, during the entire year. The usual number of inquiries for information have been received and replied to, and the *News Letter* has been regularly issued, semi-monthly, until January 1, 1890, and monthly since that date. The treasurer's report will show that the income of the Association has, during the past year, considerably exceeded its expenses, by reason of a deduction in the latter. There is now in the treasury a balance of $320.99 as against $66.41 at the beginning of the year. All accounts due the Association have been collected, and all debts of the Association have been paid to the end of the fiscal year.

The income of the year was derived as follows:

From annual dues	$1,950.00
From initiation fees	10.00
From sales of extra copies of proceedings,	49.15
Total	$2,009.15

The expenses have been distributed as follows:

For salary of secretary	$1,000.00
For printing proceedings, Minneapolis meeting	245.25
For other printing, *News Letter*, circulars and blanks	129.40
For office expenses, stationary, postage, telegrams, express and newspaper clippings	98.06
For stenographer at Minneapolis meeting,	136.50
For other expenses at Minneapolis meeting,	145.36
	$1,754.57

C. H. Barney, *Secretary.*

On motion the report was accepted and placed on file.

The treasurer's report showed a balance of $320.99.

PRESIDENT'S ADDRESS.

Before nominations are made I will ask the indulgence of the Association to listen to a few remarks that appear to be pertinent to the occasion of the Tenth Anniversary of the Association. On the 7th of September, just ten years ago, the first convention of telephone men assembled at Niagara Falls. The meeting was the result of a circular sent out some time beforehand, signed by representatives of the leading telephone companies in the United States. The object of the convention, as stated in the circular, was, "the formation of a general telephone association to consider the various questions affecting the telephone business and its developments." This meeting was organized by the election of George F. Durant, as chairman, and E. J. Hall, Jr., as secretary. The roll of representatives showed 86 individuals, representing various companies, 6 representatives of the American Bell Telephone Co. and 21 representatives of manufacturing interests; making a total of 113 individuals. A constitution and by-laws were offered, and various reports and papers were listened to and discussed, after which the convention, on the morning of September 9th, adjourned *sine die.* Immediately following this adjournment, and on the same day of which this is the anniversary, the first meeting of the National Telephone Exchange Association of the United States assembled. The present constitution and by-laws were adopted, and the following officers elected; President, Geo. L. Phillips; vice-president, H. H. Eldred; secretary, M. F. Tyler; treasurer, D. I. Carson. The Association then adjourned to meet in Chicago on the first Tuesday in April. The subsequent meetings in Saratoga, Boston, Cincinnati, Philadelphia, and so forth, are a part of the history of our business.

Of the original members, many have left the business, and a few—but all too many—have been taken away by death, notably our universally esteemed first president, George L. Phillips, and others no less dear, and of whom the Association has expressed its appreciation in just and loving tributes to their merits.

Ten years ago how crude the business was! The multiple switch-board was a mere idea; tables were only hinted at; the use of iron or steel wires was almost universal. Insulation was considered of little account by many, and some declared insulators superfluous (laughter), the value of the service was underrated by the public, and our own standards were far below those of to-day. The highest efficiency and reliability is what the public demand of us, and business and prosperity will follow us just as fast as we are able to meet that demand. The standard of to-day requires the use of copper for conductors, overhead as well as underground, and the substitution of metallic circuits for single grounded wires. The underground wires and cables of five years ago do not answer the requirements of to-day, and the same may be said of central office and subscribers' equipments. With improved service comes increased use by the public, and the ability and energies of the best minds in the business may well be taxed to the utmost to keep up with the demand.

This Association has in the past been active in the development and extension of new ideas and improved methods, and it is, therefore, with regret that I call your attention to the lack of interest and the falling off in membership during the past three or four years. The City and Suburban Telephone and Telegraph Co., of Cincinnati, have resigned, and the active membership is now only 83. The secretary's request for papers to be read at this meeting met with no response. The papers which we have were procured by personal solicitation on the part of the officers. It may be said, indeed, that outside of the secretary's statistical report, the furnishing of papers to serve as topics for discussion during the last few years has been done by a very few individuals. If the Association is to be of service in the future, its members generally must take a more active part in the preparation of the papers and reports which form the basis for our discussions. In conclusion, I desire to thank the Association for the kindly manner in which they have treated an inexperienced presiding officer. (Applause.)

The following officers were elected for the ensuing year:—President, W. D. Sargent; vice-president, F. G. Beach; treasurer, H. L. Storke; as member of the advisory committee, vice Capt. Stone, resigned, W. A. Crandall; member of advisory committe for three years, W. A Jackson; executive committee, E. J. Hall, Sr., C. T. Cutter, C. H. Wilson, H. N. Gifford.

The paper on "The Operation of the Double Cord Key Board at Brooklyn, N. Y.",[1] by Mr. Davison, was then read by Mr. J.J.Carty.

In the discussion which followed, Mr. T. D. Lockwood remarked that this was one of the most practical papers that had ever been presented before the Association. Some two years ago he visited Brooklyn, shortly after the single cord switch-boards were set up there, and was much impressed with the attention which was evidently bestowed upon them. When we consider the calls to be received from the subscribers, and consider also that the operator must ascertain whether any of the lines is already in use, and when we consider that the second subscriber must be called, and that the two lines are then to be united for conversation, and that the conversation must be largely guided and supervised, and that finally the disconnecting appliances are to be supplied, it is not surprising that this organism frequently gets out of order. It required the most constant supervision of any electrical instrument that he knew of, for many reasons. Each line has to pass through a great number of contacts, and necessarily so. The instruments for receiving calls have to deal with currents which are not strong, and which sometimes have to pass over unavoidably leaky lines which cannot at all times be kept in the highest order of repair. He thought that the troubles which appeared were not altogether, either in number or in variety, greater than might have been expected if we stopped to consider what the current was, what we were dealing with and of the very uncertain nature of all machinery, especially when it is worked to such a large extent as is a central office switch-board.

There was one other thing which also impressed Mr. Lockwood, and that was the very great improvement which took place this year in comparison with the year 1889. This, he thought, showed constant supervision.

THE PRESIDENT remarked that while it might seem to members that the paper ended a little abruptly, the facts presented were so obvious to the writer that in making the concluding remark he supposed that everybody would see that the double cord switch-board which he had just described was so far superior to the single cord switch-board that he did not need to put it into words. There was far less trouble with the use of the double cord than with the single cord board. The troubles with the single board switch-board lay in their removal; they usually bring in other trouble and prevent the operator from doing the work properly, and altogether create a great deal of trouble, whereas, with the double cord board all these troubles may be gotten at and removed without interfering in the slightest degree with the efficiency of the operator. He thought the record showed conclusively that the use of the double cord—indeed, the use of a key board that is entirely separate from the wires—was the best.

MR. J. J. CARTY said that much might be said about the merits of the double and the single cord boards, but as far as the work was concerned there were no single cord switch-boards which were adopted for mixed circuits. When an exchange comes to consider the question of a new office, whether a board is adapted to a metallic circuit is the first question, and if it is not so adapted it is usually thrown out.

MR. KELLOGG inquired if there was a single cord switch-board in use in the United States to-day, to which Mr. Lockwood replied that there was one at Columbus.

MR. WILSON also stated that there was a single cord board in operation in Chicago in the main office, arranged for single wires and grounded circuits. They also have a single cord metallic circuit switch-board in operation in the stock yards office in Chicago. It filled all the requirements for metallic circuits, but, as compared with the double cord metallic circuit switch-board, it had not been considered so good on account of mechanical details. They now had in operation in one of their branch offices five different metallic circuit key board systems, with which they were experimenting. The spring jack part of the switch-board is the same in all of them, and, as the different systems dove-tail together, they are able to operate the five different schemes in the same office. They had been doing that for six months or more, and from those five different schemes have adopted one for use in their main office, and the apparatus was now being constructed. But the single board scheme had to give way for one of the double board schemes on account of the advantages of the latter over the former.

Regarding the reference to troubles in the spring jack, they find, in Chicago, where they have long underground circuits, that the introduction of a small amount of resistance in the circuit makes a very great difference in the talk, and it was particularly apparent from their office. If the contacts in the switch-board become dirty—not necessarily open, to interrupt the circuit entirely—they noticed a difference between the incoming and the outgoing talk, and had found that a resistance of 200 or 300 ohms in a contact makes a very appreciable difference in the conversation. Some six months ago they organized a labor force to work every night on contacts through the switch-board and measuring with a galvanometer; if a resistance exceeds 150 ohms, including the drop, which is 100 to 130 ohms, the spring jacks are all cleaned. In that way they keep the service reasonably uniform. Their experience showed that after six months' hard work in cleaning up the contacts they still had on an average from five to ten cases of trouble a day, not including open contacts.

MR. GIFFORD—In regard to this report of trouble, I think that the Brooklyn people ought to be congratulated on the small amount of trouble they have. Our trouble in Louisville is that we have considerable dirty spring jacks. We have a detached building that we occupy in a middle of a square. My wire room and shop is underneath, but I have a floor very heavy, four or five inches thick, and very little dust can get through, and when the janitor sweeps our room he sprinkles sawdust so as to avoid raising the dust; but in spite of all our precautions we do have very dirty spring jacks, and it has been the cause of a great deal of trouble,

1. See page 305.

A subscriber will say that he cannot hear anything, and we first examine the battery. If we don't find anything wrong there then there is a suspicion of a loose joint, or an old iron wire, and we go over those things carefully and if we find any trouble it is removed.

MR. GIFFORD after a long experience considered it was necessary to go through and clean out the whole switch board every month. In his exchange of not quite 2400 subscribers, there are from 25 to 40 broken cords every day, and of course they are a serious cause of difficulty. They had tried the ordinary tinsel and then a combination of tinsel and spiral wire. At last they concluded to have a cord composed of about three times as much tinsel as is ordinarily put in, and that gave a great deal of satisfaction.

MR. A. S. HIBBARD remarked, as a matter of observation in exchanges pretty much all over the country, that the dirty jack trouble is more noticed in places West, where they do not burn hard coal and where the whole atmosphere is permeated with dirt and dust; also, in places where an exchange is located near a railroad yard, where smoke and soot from the engines float in through the windows. He thought it might be possible that that was a reason why they did not have so much trouble with dirty jacks in Brooklyn as they have out in Chicago and Louisville. He thought a feature to which attention should be paid was clean floors.

MR. I. H. FARNHAM remarked that in the new Boston exchange provision had been made against the noise of the listening lever by having the lever strike upon a flexible contact instead of on a solid metal base, with considerable improvement.

In regard to dirty jacks he believed it due both to dirt and corrosion. There was a suggestion made two or three years ago in regard to freeing the switch boards from dust which he thought had not yet been adopted, and that was to case up the switch board on the back and supply a gentle current of air so that it would always be outward through all the crevices of the board, and dust kept out in that way.

MR. WILSON said that the difficulty seems to arise entirely from dust and dirt. The moisture in the atmosphere clings to the spring jacks and the dust more readily adheres. The only relief for that is to have an inverted contact point; that is, inverted in the way it is introduced into the spring jack.

MR. BARTON drew attention to the fact that it does not follow, because in the Brooklyn exchange they had a certain number of troubles with their single cord board, and a certain less number with their two cord board, that the troubles, or absence of troubles, are due to the single cord or the double cord. The fact is that the single cord board which was put in in Brooklyn had key tables in which the apparatus was considerably crude in detail, and the difficulties were very largely due to the crudeness in the detail of that board. Now, if Mr. McKinstry, in his Cleveland single cord board, had as many troubles with the subscriber as they had in Brooklyn, then there would be a chance to make a comparison of the systems, because, between the time when the Brooklyn exchange was equipped, and that of Cleveland, there was a good deal of advancement made in the details of construction. The proper way to reach a clean basis on statistics of trouble would be to compare the present Cleveland board with the present Milwaukee board, or the 38th street, New York board, or the board that has just been opened in Denver. The Cleveland board embodied a pretty good degree of excellence in details of construction. The same degree of excellence has been applied in the single cord boards in use by the German government in Berlin, and those boards he thought were fairly satisfactory. The present tendency of the judgment of the exports in this country was in favor of the two cord key table. He added that there was a considerable number of single cord boards, among others, the principal exchanges in Cleveland, one in Cincinnati, one in Providence, one in Columbus, one in Portland, Ore., one in St. Joseph, Mo., one in Topeka, one in Los Angeles, and in other cities. Those boards were tolerably well liked, he thought, by those who had them.

MR. LOCKWOOD said that he had found another trouble with spring jacks. Some months ago he had occasion to spend a couple of days in Albany, and found that one of the spring jack troubles there was not dirt or carbon between the points, and it struck him that perhaps some of the trouble was due to the fact that the insulated contact screw in the lower part of the jack had been made with such a sharp point that it made a dent in the screw in the spring above, and by-and-by that depression was made so deep that when the foot was taken out it was all that the spring could do to make contact with the screw point at all. This, of course, depended largely upon the material used, and in this case the material was not brass, but German silver, and, as there are different grades of German silver, of course care should be taken to get the proper grade.

THE PRESIDENT said that the opinion they formed by the trial of the two key boards was, that, taking all the conditions of the business, the double cord system was essentially the best; that with the single cord system, doing the best one could with it, it is so crowded and so difficult to remedy trouble that occurs in the midst of busy hours, that that fact alone is enough to condemn it. Mr. Wilson's recommendation of the single cord board was something like that of the cripple who had become very expert with his crutches, which in this case are the double cords, which he used when the single cord failed; but no cripple would be willing to continue the use of his crutches if he could use his legs. He did not think anybody wanted to use a single cord board if they had to have a double auxilliary key board to keep it on its legs.

MR. WILSON did not want to be understood as advocating the one cord system for metallic circuits, because he was not. But if he were going to equip a new office, he would use the one cord system. He used the one cord system altogether for metallic circuits in small exchanges where they have multiple switch boards. The advantages are that they equip the switch boards just as they add subscribers. They had quite a number of subscribers, as, for instance, the Illinois Steel Co., which has its general office in Chicago, with about twenty telephones in use; they have three rolling mills in and about the city, and lines connecting them, and all those lines are run into the private exchange located in their general office, and the company gives them three trunk lines from that switch board into the exchange. A special rate is made for that service, and then the telephones in their general office are connected out in such a way that they have what is called the speaking tupe service, that is, they do not have to call their operator to get service. They were putting in quite a good many of those outfits. The subscriber in such cases as these becomes the company's agent in the transaction of his business, and the deduction they get in rates is the compensation paid them for handling the work. In all those places they used the one cord system, and prefer it to the two cord system. If he were going to equip a large exchange with metallic circuits he would use the two cord system.

The convention then adjourned until 2 o'clock.

AFTERNOON SESSION.

The session was opened by the reading of the paper entitled, "Corporate Organization,"[1] by Mr. E. J. Hall, Jr.

The discussion on the paper was as follows:

MR. E. J. HALL, JR.—While this diagram is applicable to the general organization of a company, I ask Mr. Carty to make a diagram showing how he, in following out this line of thought, has organized the department for which he is responsible in his own company. Starting in at the "Superintendent of Equipment," in the general scheme, he has arranged a diagram of the force which he has under his control, and I think it would be interesting to have him explain how he has utilized this idea before we take up the matter for general discussion.

MR. J. J. CARTY—This diagram on the wall represents one of the departments of the Metropolitan Telephone Company. The Superintendent of Equipment is responsible for the condition of the plant. Any trouble with the wires, cables or apparatus in a subscriber's office, or in a central office, comes from here. The chief inspector has under him, first, a foreman inspector, who gives out the daily work to the inspectors who visit the subscribers' stations. The duty of an inspector is to go to a station and see that it is in order, make a note of what condition he finds it in, and what he has done, and hand to the subscriber a printed slip which has on it a request for the subscriber to inscribe on the back of the slip any fault he may have to find. This foreman inspector has a large detail of men under him, and he is responsible for seeing that his men do their work properly. Then, for taking care of the trouble there is located at each of the various offices, what is called a "wire chief." For instance, at Cortlandt street we have a man who sits at a desk called the "trouble desk," and who is equipped with all the necessary apparatus for locating the trouble. If the trouble at any one of the various stations becomes greater than the ordinary staff can properly take care of, the wire chief at that station communicates with the Chief Inspector, and the detail is increased; or, on the contrary, if he gets his work up in a good shape, he reports that fact and the men are transferred somewhere else. The chief wireman receives from the General Superintendent the orders to put in an instrument for a new subscriber, and that order is turned over to the chief wireman, who gives it to his foreman, and the job is assigned to a particular workman. The chief wireman also sees that the line is cut in at the cable terminal and at the subscriber's station. So that the task of getting the line working is in the hands of one man, and when the line is connected up in working order the chief lineman sends the order back through the Superintendent of Equipment to the General Superintendent, and a record of it is made on the books. When a new subscriber is put in at 38th street, the representative of the equipment department there has got the receipt for information connected with that subscriber. For instance, he has to receive a slip and take a note of the cable conductor that that subscriber occupies, and all the other data necessary to go into the record. So that at 38th street there is a complete record of all the terminals terminating there and all the subscribers, and no change can take place without going through the 38th street wire chief. A similar record is kept at each of the branch offices and a record of the entire city is kept by the Superintendent of Equipment. An arrangement of this kind enables you to keep up

1. See page 306.

records of trouble and compare one office with another, and make some important savings in the number of men at each office.

MR. HALL—I think, perhaps, I could go a little further by reference to the original diagram. Mr. Carty has taken the diagram at a point and has shown what is done by the special division force under his charge. Now, the central thought of all that is this, that in that company one man is responsible for the condition of the line and switch board in the company; there is one man responsible for the physical condition of the property; he has no relation with the operators or with the operating service. That is an entirely separate department, but he is responsible for the operators and the subscribers being furnished with suitable apparatus, and apparatus properly taken care of. That simplifies the problem as to who is responsible for any fault in the service. If the fault is one of apparatus or maintenance, then the superintendent of equipment is to blame. He has nothing to do with the construction of that plant, and he has nothing to do with the operation of it. The question might then be raised that, having nothing to do with the construction of a thing, it might not be properly constructed. That is possible, but his skirts are entirely clear, because all he has to do is to report to the General Superintendent that as a certain thing is constructed it is not possible for him to keep it in proper order. Then he is relieved from blame. The general superintendent may refer the matter to the general manager. It may or may not be possible to correct it. If it cannot be corrected, then the superintendent of equipment simply does the best he can with what is furnished him. If it can be relieved, then it becomes a question for superior authority to give proper instruction. In each of these offices are "detailed operators" and under the office managers are "detailed inspectors." That means that while these men are under the office manager he does not employ them. They are simply placed there for the purpose of receiving information as to what is to be done in their work. Written specifications should be made out defining precisely what the superintendent of equipment is to do.

Then, there is another point. The forms and blanks in use are sometimes defective. Now, we had in one company an expert go through the whole organization from the subscriber's order up to the rendering of the treasurer's bill.

The fault does not lie in having too little routine, but in having too much. The only way to do is to start and organize as if you were beginning a new concern, and then if what you have already here corresponds to that, why, all the better.

There has been a suggestion made that the faults of an organization come generally from those high in authority in it rather than from the subordinates. That is very often so. For instance, the president may have personal knowledge of something wrong and he comes straight across and tells the superintendent of construction that he must do this or that. Now that is fatal to a proper organization. It is something the president should never do except in an extreme case. He ought to notify his general superintendent about it and let the order be transmitted through the proper channel.

On motion, the convention adjourned until 10 A. M. the following day.

SECOND DAY'S PROCEEDINGS.—MORNING SESSION.

The first business taken up was the selection of a place for the next meeting, and on motion of Mr. Eastabrook, New Orleans, was unanimously adopted.

MR. W. R. PATTERSON, of Chicago, then read a paper on "The Housing and Care of Central Office Apparatus."[1]

The discussion on this paper was deferred pending the reading of the paper by Mr. F. A. Pickernell on "Some General Remarks on Telephone Exchange Construction and Equipment,"[2] which followed.

MR. WILSON thought, in the discussion which followed, that the only advantage in having an operating room on the second floor would be in the length of cables, and, as Mr. Patterson had expressed it, the expense of the cables, as compared with the value of the second floor, would be the only consideration. But he thoguht the advantages in favor of ventilation and light, and rendering the operating room more exclusive from outsiders, were in favor of the top floor.

MR. HIBBARD remarked that for many reasons the operating-room should be on the top floor. Besides, the operating-room should be convenient to where the cable is hung up, and where the distributing board is. That was quite a point to be desired in a big local exchange. These constitute three links in the successful working of an exchange. The head of a cable, the distributing-board and its entrance to the multiple-board. If it is possible to hold those three points within the reach of the man who has it all in charge, it is like driving a four-in-hand team—he has a good grasp on the business. If, however, one puts in a terminal point in the basement, and a distributing-board way up in a tower, perhaps, and an exchange board in a third place, these links become disjointed, and as a result the team is apt to go badly.

MR. PICKERNELL remarked that one other objection of having the operating-room on the second floor was the noise because of the close proximity to the street. In Cortlandt street if the operating-room were on the second floor it would be almost impossible to operate it. They had to have three sound-proof booths in the front offices there in order to be able to use the telephone at all.

MR. PATTERSON said he did not intend to advocate the first or second floor locations as against the top floor in all cases. So far as dust and noise is concerned, the lower floors would not be so objectionable if the operating-room were placed in the rear, facing on a court, for instance, and lighted by a skylight from above, and the heating and ventilation taken care of by artificial means.

MR. HIBBARD thought that the putting in of dry air into operating-rooms was of essential importance. Nothing wet should be put in and all dirt and dust should be kept out.

MR. GIFFORD remarked that he had a big skylight in the top of his operating-room, and windows besides. He formerly had the shifting-room for the cables up in a little tower on the third floor, but in the last few months he had taken a room of about 15 x 20 on the first floor, and there the underground system came in. That room is just like a hall; the windows are bricked up, and an electric light is placed in it, and nobody gets into that room except one man and the electrician, and he holds them responsible for everything in there.

MR. CARTY thought that they should so organize their staffs that any number could go in the room. He thought it would be a good thing to have the chief inspector located in that room because then he is near the point where he could do his testing.

MR. HIBBARD hardly favored the idea of having a room locked up in which the protectors were placed. One of the points of having it available and next to the operating-room, is this: The most frequent troubles with the electric light wires are to be expected at night. There has been no arrester put in any exchange which will head of all of these kinds of troubles. Each arrester probably does its work as it has been designed in a particular line, but he did not think they had found any that are good all around. Therefore, if a current comes in, any chief operator who is posted is able at once to go to the seat of the trouble and remedy it.

MR. GIFFORD explained that what he meant was that when the room was perfected and finished he should keep it under the care of just one man and make him responsible for the care of it.

The resignation of Mr. C. E. Bailey, as an honorary member, was then accepted.

MR. J. J. CARTY then gave an explanation of his system of "Bridging Bells."

This is a system of looping, the idea being, when more than one station is connected on a line, to loop the intermediate stations in solid.

A line was built in New York containing eight miles of underground cable and four miles of overhead wire, and ten stations looped in solid, and it was impossible to talk over it. The bridging bells were put on the line and the talking over it now is as nearly perfect as it could be. Metallic circuits are employed.

MR. BAILEY remarked that another advantage in the system which he thought would be available in the future was in the way of giving cheaper telephone service on metallic circuit lines to residences. The chief difficulty that he saw about the system was on long extended lines in the liability to damage by lightning. His company have had for a number of years a similar system in operation on quite a number of lines. They had arrived at it by running a shunt wire, commencing at the first station out from the exchange. This shunt wire is passed in through the station, and the calling wire is looped through.

MR. GIFFORD referred to the fact that where one subscriber can listen to the conversation between the others complaints are apt to arise. For this reason also Mr. Wilson, in Chicago, had decided to place no more than five subscribers on one private line.

He also said that the only objection that he saw to the bridging arrangement on grounded circuits is the difficulty in locating troubles on the lines.

MR. HIBBARD commenced this system of bridging in with two or more subscribers on a line, using first the ordinary bell, which gave, of course, very poor service. Then he put in 500 ohm ringing coils. With that system, and with 500 ohms in the central office, they are getting first-class service with five and six on the line.

MR. CARTY—In regard to lightning, I appreciate Mr. Bailey's position out in the country in having the bells burned out, but I would hate to complicate that bell which has been rendered so simple by putting in any of these devices to get a ground in a circuit point. If there was any other way out of it there might be a bridging designed for that particular use. I think if he tried the most approved arrester he would not have any trouble from burning out. In fact, the trouble he speaks of is not necessarily connected with the bell at all. It is the old question of the transmitter being legged on, and the fact that it is 1,000 ohms does not make it any more delicate than these 500 ohm bell arresters used for bridging. I think lightning jumps across largely because of the thickness of the insulation that is a determining factor in making a discharge. I do not think that the retardation of the coils increases the tendency to jump.

MR. HIBBARD—When bells burn out by lightning it is due a great deal to the mechanical way in which they have been wound.

---

1. See page 308. 2. See page 310.

The winding of a magnet of different design has much to do with it. On a long distance line, using a tubular drop, when it was first turned out for us, in 500 ohm drops, we had a good deal of trouble. We found that the wire burned in the outer wrapper generally. That was changed so that the winding was kept away from the iron. No other change was made, and our drops are not burning out as they were before.

MR. CARTY—In some experiments which we made in the development of strong current protectors, it was found that we could make an air cut-out—which is another name for a lightning arrester—and that it would go out at any number of volts at which you wanted to fix it, and they got it down so low that the actual telephone current would jump itself. Now, it seems to me that if Mr. Bailey's bell were equipped with a lightning arrester of that kind it would remedy the difficulty. At least, we should give that a fair trial before we undertake to complicate a bell.

MR. WILSON—We have a metallic circuit from Chicago to Michigan City, about 56 miles. In addition to the two end stations, we have three stations bridged across the circuit. When we first put in that equipment we had great difficulty in locating trouble. We overcame those by simply inserting a little point or switch in the bridge wire. That enabled us to call up the stations and ask them to turn the switch off five or ten minutes, and after they do that we have the old condition of wires without any complication, and that enables us to locate the trouble, whether it is an open line or a grounded line.

MR. CARTY—I might say in regard to the arrangement we have for locating trouble in New York: Everything is getting more and more underground there, and the branches or spurs are necessarily made at the central office. We have arranged for a test-board on the plan of the long distance board with private spring jacks to the board. There will be one of these located in each of our central offices, and the wire chief in charge of the private lines will be located at Cortlandt street. If he finds it is a short circuit he will take off all branches leading from his room, and will then throw them on to a drop and despatch a trouble man on to that branch. If he finds all his own branches are all right, he signals the next office up town, and they have a similar arrangement gone through with until the trouble is located. That can be done in 20 minutes on these complicated lines. We can not only locate the trouble, but get the fault cut off and leave the other part of the circuit working.

MR. WILSON—We are operating all the transmitters in the main office of the Chicago exchange with the Edison current, and we are accomplishing good results. We use storage batteries. We are using at present five cells of storage batteries which have an electromotive force of a little over two volts per cell and give out about five amperes of current. The five cells are connected directly with the Edison current which supplies the office with light, and the storage takes place when we burn the light, and we do not observe any diminution in the lighting throughout the building. There is, therefore, no expense for currrent. The internal resistance of each cell of the storage battery is about .02 ohm. Consequently, as you add transmitters, it simply absorbs more current from the storage battery. The object of having five cells is that it enables us to maintain the storage battery throughout the 24 hours without its becoming exhausted. If we connected all the transmitters, we would necessarily have to turn on light during the day to recharge them. Our experience has shown that with five cells it works entirely automatic. We supply between 60 and 70 transmitters. The arrangement we have contemplates 100 transmitters. We are only operating 60. At the present time we couple about two transmitters, and adjust the resistance until the current in each transmitter is all that it will stand. We also use the Edison current for ringing instead of the small generators.

MR. BAILEY—I have found that the current from all these incandescent plants differs frequently. Where they are supposed to carry 110 they will vary from 90 to 130.

MR. WILSON—The Edison Company have a very large plant in Chicago and they supply motors. The Western Union Company use the Edison current for operating their dynamos, and I think the service gives satisfaction.

MR. GIFFORD—Mr. Forbes uses the same method in the exchange here.

MR. HIBBARD—In watching the generators in the Detroit exchange this morning they had three lamps in the circuit, and you could tell the number of operators ringing at a time by the way the lamps went down and came up and became bright again. He had an electric motor turning the commutator. He had his old equipment for running the ordinary power generator.

MR. WILSON—I would say also that 12 transmitters is the maximum, because the more transmitters you connect on a cell the more current is absorbed from that cell, and you want to adjust the number of transmitters so that the cell will last the 24 hours, or until the lights are turned on again to recharge them. If you are burning lights during the day, with that arrangement it would not be necessary to use so many cells. We propose to have a reserve series of storage cells, and in keeping them stored all the time we will be entirely independent of the source of supply. They will retain the charge indefinitely. I will also add that we are now arranging to take out of the American District plant, which is owned by us in Chicago, the battery which is there—and we now have from 10 to 100 cells of gravity battery located in those offices through the city; and we are arranging to substitute a similar arrangement for all those offices.

MR. BAILEY—The Pennsylvania Railroad Company take current direct from the main at Pittsburgh and Harrisburgh, and use the storage batteries at Altoona. They get very satisfactory current for telegraphic purposes without the intervention of batteries.

THE SECRETARY announced that he had prepared the usual statistical report, compiled from reports furnished by different companies, from the membership of the Association.

After a vote of thanks for the courtesies extended the convention adjourned *sine die.*

After dinner, at 2:30 P. M., Wednesday, the delegates all assembled to take part in a carriage ride and lunch, which had been prepared for their entertainment by the Detroit Telephone Company. Mr. Jackson saw that every one was looked after in good shape and made a prince of hosts. A most enjoyable afternoon was spent, the party first driving around through the beautiful residence part of the city and then out to Belle Isle Park, where a lunch was served at the Casino. After lunch a picture was taken of the group and the whole party then entered their carriages and returned to Detroit.

On Wednesday evening at 8:30 a banquet was held at the Russell House under the auspices, and at the invitation, of The Telephone and Telegraph Construction Company. It was very largely attended by those present at the convention and numerous ladies were present, greatly adding to the charm of the evening, and it went off in a manner worthy of those who had the entertainment in hand. After partaking of the choice menu, the cards of which, by the way, were masterpieces of beauty, speeches and toasts were the order of the evening. President Sargent set the ball rolling with some pertinent remarks, and then called upon Mr. Tyler, of Connecticut, who rose to the occasion and drew a pleasing contrast between the events and progress of the Association from the first meeting until the present. Mr. Crandall, of New Orleans, responded to the toast, "The Ladies," in a truly graceful manner, making a most attractive response. Mr. Thos. D. Lockwood, of Boston, then made some humorous remarks upon a large number of subjects, amongst all of which he was thoroughly at home, and he performed his part, as always, in the very best of shape. Secretary Barney made a short speech full of point, and was followed by Treasurer Storke, who evoked roars of laughter when he related how, during the afternoon drive, Mr. Tyler had been expelled from the Park by the police for walking on the grass and carrying a deadly kodak. Mr. E. J. Hall, Jr., of New York, then addressed the gathering and was followed by Mr. A. S. Hibbard with a song, which was generally acknowledged to be the attraction of the evening. Mr. Hibbard arose, with his neck gracefully adorned with a wreath of smilax, which had been hung about him by his friends near. He then delivered himself of "How I love my Sunday School," in a truly touching and pathetic manner and brought down the house. All the convives joined in the chorus with excellent effect. Messrs. Zeublin, Gifford, Forbes, Vice-President Beach and Joseph E. Lockwood followed in the order named with some interesting speeches. The festivities were finally brought to a close by the singing of "Good Night, Ladies" and "Old Lang Syne," and a most delightful entertainment was at an end.

On Thursday afternoon, at the invitation of the Michigan Bell Telephone Co., a most enjoyable boat ride was taken on the fine steamer "City of Detroit," up the Detroit river through Lake St. Clair and the ship canal through the Flats. Quite a number of ladies were among the party, and as ever, enhanced the pleasures of the trip. An excellent band of music was in attendance. One of the features of the trip was an extempore banjo concert by Mr. A. S. Hibbard, of New York, whose dexterity with the instrument is only equalled by his large repertoire of songs and the spirited manner in which he sings them; in fact he completely paralyzed the regular band for quite a while as he drew the whole crowd on board around him. He was ably assisted by members of the party in the chorus.

Another most attractive feature was room No. 60, where all the male guests received the tip from their obliging hosts to take an observation through the bottom of a tumbler; an invitation which was most cordially accepted. The boat returned to the city at 6:30 p. m. All will carry away with them the lively remembrance of the good time they had in Detroit at the Convention. Too much cannot be said regarding the untiring energy and boundless generosity as kind entertainers of Messrs. W. A. Jackson, T. A. Forbes and J. T. Land, of the Michigan Telephone Co. Throughout the whole duration of the Convention they laid themselves out to cater to the enjoyment of all present.

EXHIBITS AT THE TELEPHONE CONVENTION.

The exhibits made at the Convention were very few but several of the representatives of the prominent supply companies were on hand.

THE NORWICH INSULATED WIRE Co., of 58 Cedar St., New York, exhibited some very handsome samples of their spiral wound paper insulation for telephone cable work. The company was represented by Mr. L. D. Beck, president, and Mr. Jean A. Wetmore, general agent, who explained the peculiar advantages of his cables.

Samples of the regular association standard cable, containing 51 pairs of conductors, both in wet and dry core form, and the cables in different stages of construction, were shown.

This company also have a new method of treating the insulation when employed in telegraph work, which increases the insulation resistance.

They also had a fine display of electric light wires for underground work, either with high or low tension. The paper employed is a fine manilla fibre, which is wound on spirally in reverse layers, ensuring flexibility and centering of the conductor. After being wound on it is compressed by hydraulic pressure and the core is then dried out and finally permitted to absorb a special insulating compound. A large amount of this cable is already in use with the most successful results.

J. H. BUNNELL & Co., of New York, exhibited a number of cells of the Burnley Dry Battery, and were ably represented by Mr. J. J. Ghegan. The advantages of the cell are that it is strong, clean and durable and the connections are so arranged that no creeping salts are developed. It is of very compact form and an interesting experiment of its power was shown by lighting a small 4 candle-power incandescent lamp with four of the cells. It is specially adapted for telephone and open circuit work.

THE NATIONAL CONDUIT MANUFACTURING Co., of New York, had on hand some of their new style telephone conduit, which is made of English Portland cement and crushed granite. Mr. J. P. McQuade had charge of the exhibit and never lost an opportunity of showing up the merits and advantages of this conduit.

THE EDISON GENERAL ELECTRIC Co. were represented by Mr. James F. Kelly, who brought three cells of Edison-Lalande battery with him in behalf of the Edison Manufacturing Co.

THE WASHBURN & MOEN Co., of Worcester, Mass., had on distribution a very neat little book of electrical memoranda, containing quite a fund of useful electrical data and information.

MR. GILBERT SMITH, of The Ansonia Brass and Copper Co.'s Chicago office, had a pocketful of samples of their well known wires and also presented a beautiful little stamp case to his numerous acquaintances.

THE WESTERN ELECTRIC Co. turned out in force, headed by Mr. E. M. Barton, president, who was aided by his able lieutenants, Mr. Hamilton, Mr. Crandell and Mr. Patterson, in making things pleasant for everybody.

MR. FRANK A. MAGEE, of The E. S. Greeley & Co., of New York, was on deck, and, as always, attending to business and forwarding the interests of his company.

THE STANDARD UNDERGROUND CABLE Co. had their genial Western manager, Mr. Fred Degenhardt, of Chicago, to talk for them. He showed some very handsome samples of bunched cables in twisted pairs, the features of which are remarkably low static capacity and high insulation resistance. This is a new form of cable and will be widely used in telephone work.

MR. GEORGE T. MANSON, of the Okonite Company, of New York, and Mr. W. H. McKinlock, of The Central Electric Company, were around ready to tell the merits of Okonite. They brought no other samples but themselves and did not seem to need any, as they are so well known among the fraternity for good fellows that anything they have must be all right also.

MR. W. A. CHILDS was present in the interests of the Law Telephone Co., and was frequently asked for information relative to the big new Law board they are building for Philadelphia.

GENERAL C. H. BARNEY, as the representative of the enterprising new firm of Alexander, Barney & Chapin exhibited the ingenious Field mercury safety cut-out for telephone and other lines, and distributed explanatory circulars.

OUR SPANISH-AMERICAN NEIGHBORS are beginning to see the advantages which electricity possesses as an illuminant. Some time ago, the Westinghouse company sold a fifteen hundred light alternate current incandescent outfit to be used toward dispelling darkness in the Brazilian town of Juiz de Fora. The Juiz de Fora Company is well pleased with its purchase, and has just asked the Westinghouse people to ship two 750 light machines to supplement the present capacity of its central station.

One of the progressive towns of the vast and rich mineral state of Montana is Anaconda. An electric light company has been formed in Anaconda, and the Westinghouse incandescent system has been chosen. The plant will have an initial capacity of three thousand sixteen candle power incandescent lamps, and 60 arc lights.

CORRESPONDENCE.

PHILADELPHIA.

New Lighting Work.—The Electro-Therapeutic Society.—Infringement of Bell Patents.

THE Electric Light, Heating and Power Company, of Philadelphia, Bucks and Montgomery counties, recently incorporated by Hamilton Disston, Charles A. Porter, Peter E. Costello, Thomas W. South and others, of Tacony, has selected a site on the Delaware river below Tacony, where it will at once begin the erection of an electric plant, with dynamos capable of running 500 arc and 10,000 incandescent lights. The grounds are large, and the buildings will be so constructed that they may at any time be increased as circumstances require.

A number of physicians and surgeons have formed themselves into an organization called the Electro-Therapeutic Society. Dr. George B. Massey is president, and Dr. William H. Walling, secretary. The object of the society is to discuss the question of electricity combined with medicine and surgery. Heretofore the subject has been empirical, and it is proposed to take it out of the hands of the irregulars, so that the regularly certified practitioners can make it popular from a scientific standpoint.

The United States Circuit Court yesterday granted decrees to the Bell Telephone Company restraining Edward, George B., Henry F. and Edward Darby, Jr., John W. Stelwagon, Marcus Sternberg, Andrew J. and Charles S. Bair, Israel Fleishman and Morris and Samuel Lippman from using telephones containing infringements on the Bell patents.

PHILADELPHIA, Sept. 10, 1890.

PITTSBURGH.

New Police System for Allegheny City.—Reducing Fares to Three Cents.—Electric Railway Work. — Material Wanted for Fire Alarm Service.

ALLEGHENY CITY is about to put a new police telegraph and telephone system on the streets, the old one having become so defective that it is practically useless at present.

The Philadelphia owners of the Pittsburgh traction road (Widener-Elkins) arrived in this city a few days ago for a conference, when they decided to reduce the fares on their road from five to three cents. It is understood that this cutting of the fare has been resorted to by the company in order to compete with the Duquesne Traction Company, which is building an electric road almost parallel to the traction road.

At a meeting of the board of directors of the Birmingham Traction Company, held a few days ago, it was decided to extend the road from the South Side into Knoxville and Beltzhoover boroughs, a distance of seven miles. The new road will be equipped with electric motors.

A number of the electric cars of the Pleasant Valley street car line, in this city, have been equipped with a raw-hide pinion wheel, by which means the company intends to lessen the noise which is now made by the motors.

Morris W. Mead, superintendent of the bureau of electricity in this city, has ordered a lot of new material for the fire alarm office. He intends to construct a new key and switch board.

PITTSBURGH, Sept. 5, 1890.

BOSTON.

Edison Work in Boston.—The M. C. M. A. Exhibition.—Postal Telegraph Company's Plant.

THE Edison Illuminating Company, of Boston, are making rapid strides with their increase in Head Place, and have just put in two Babcock & Wilcox boilers, and are now engaged in putting in two tubular boilers fitted up with the Jarvis setting, and furnished by the Jarvis Engineering Company. They have commenced on their new brick smoke-stack, which will be 26 feet by 13 feet by 150 feet high, and are laying the foundation for two 500 h. p. vertical engines, which, when set up, will be belted to four No. 60 Edison dynamos. The Edison Company have now completed their underground construction work, and have covered nearly all the important streets in the city.

The 17th triennial exhibition of the Massachusetts Charitable Mechanics' Association opens at the Mechanics' Building, on the first day of October, and the electrical department promises to be very interesting, as numerous exhibits have already been arranged for. Space can now be secured, and various electrical exhibits are arriving every day. The opportunity afforded for exhibiting in the East the most recent developments in electrical engineering is a good one, and should not be missed.

The Postal Telegraph-Cable Company's central office was removed Sunday from 177 Devonshire street to more commodious and elegant quarters at 234 Devonshire street, opposite Winthrop square. The principal improvements consist of increased accommodations, whereby the force of operators can be enlarged from 40 to 90, an increase in the number of switchboards and loops, whereby the rapid transaction of business is greatly facilitated, and the substitution of dynamos for batteries in the generation of the electric current.

Under the old system of batteries the establishment used 4000 cells, but now by using dynamos the same result is gained by means of coils of resistance, which regulate the current for wires of whatever length.

In the basement are two 10 h. p. Westinghouse motors, each run on alternate days by power from the Edison central stations, and, connected with the dynamos, eight small Westinghouse generators, varying in potential from 20 to 300 volts, according to the length of line and number of instruments to be operated.

The entire work has been done under the supervision of Frank W. Jones, the general manager and electrician of the company. In sending and receiving telegrams a quadruplex system invented by Mr. Jones is used. The office is under the management of Mr. E. B. Pillsbury, who is universally courteous to all visitors in explaining the new system, and showing them every detail of construction.

BOSTON, Sept. 13, 1890.

DUPLEX GAS ENGINES.

BY ELMER A. SPERRY.

It was Prof. Fleeming Jenkin who first gave to the world the mathematical demonstration of the increased economy attending triple and quadruple expansion in the steam engine. Prof. Thurston, in this country, in a recent paper, has pointed out the extremely high theoretical attainment of the latest forms. He says in fact that these have now arrived "to so perfect a condition that the range for further improvement is probably very narrow, and the gain still to be made must come slowly and painfully." The first named eminent authority has further made the statement that "the actual achievement of the steam engine has nearly reached the limit of the possible."

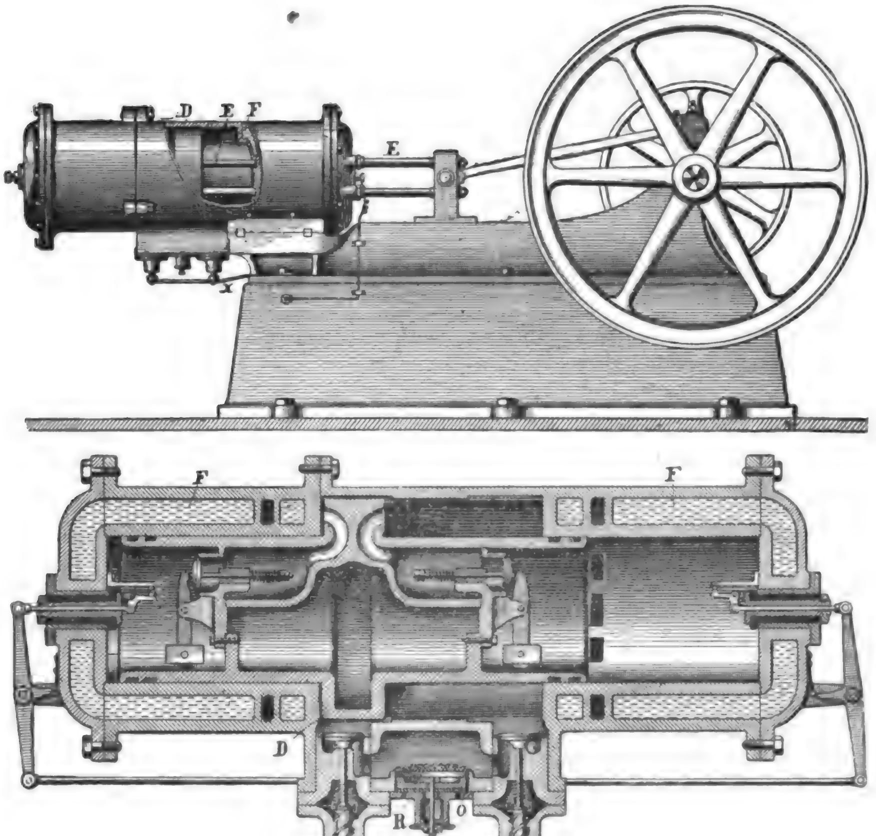
The efficiency of the steam engine when taken as a measure of the recovery of power from the total power equivalent of the heat employed, following the most improved methods, is only about ten per cent. when large units of power are considered. To compare this performance with that of the gas engine, it is but fair that we take equal units in either case. In the comparison of the two motors as heat engines, size for size, the actual performance of the gas engine is over two hundred per cent. better than that of the steam engine, with a vast unexplored region beyond in the case of the gas engine, giving promise of great improvement and higher economy than the most excellent performance yet recorded.

In considering the great problem of transforming heat energy into electrical and mechanical energy it may be well to investigate the laws of operation and working of a system that has already realized so much in the direct line of transformation of heat into mechanical motion.

The gas engine is a hot air engine in which the air as it is drawn into the cylinders is charged with a substance which may at the proper moment yield the heat required to increase its bulk, the confining of which develops the pressures utilized in moving the piston. This increase of bulk on ignition, and the corresponding pressure of the air, is from four to five times. Thus, if the air or mixture in the cylinder at the time of ignition is 40 pounds, the pressure resulting from ignition is about 200 pounds. The ignition does not cause an explosion, as is usually supposed, but, on the contrary, the inflammation goes forward until a certain pressure and temperature is reached, and at this point is arrested, and further inflammation is developed as the piston goes forward and the pressure thereby tends to decrease. The writer has seen cards from gas engines in which constant pressure was developed throughout nearly the entire stroke. This is especially the case with lean mixtures, or below 11½ of air to 1 of ordinary illuminating coal gas.

This system of transferring the furnace, wherein the energy is primarily developed, into the cylinder of the engine itself, and there utilizing directly the benefits of combustion, is undoubtedly the greatest step in advance of the present half century in the direction of high economy and efficiency. There is no doubt that the engine of the future is to have its furnace in its cylinder, thereby eliminating the gigantic waste attending latent heat which is encountered in the case of steam. The high performance of 1.4 pounds of coal per horse power per hour in a ten-horse power engine compares favorably with from 7 to 13 in the steam plant of equal size.

This being true, the question is asked, "Why are not gas engines more sought and employed for ordinary power purposes?" The answer to this question can only be found by a study of the performance of the present gas engine, noticing the difficulties encountered and the limited application to the more exacting power consumers, and the devices resorted to in the attempt to overcome



FIGS. 1 AND 2.—NEW DUPLEX GAS ENGINE.

some of these difficulties. The greatest evil of the present method and cycle of operation in the gas engine is the want of uniformity of speed in the power developed. This is owing to the fact that usually but one out of four, frequently one out of eight, of the strokes or units of power is available for producing effective results. The others are not only non-productive, but actually consume the energy developed in the one. It is true that engines have been produced that make every other stroke an effective stroke; but this system at best produces irregularity that renders it indifferent for driving more delicate machinery, especially electrical generators for lighting purposes. It is true that dynamos may be driven by existing engines to supply storage batteries with some degree of success. But where direct illumination is required, the noticeable irregularity and throbbing prohibits general adoption.

The gas engine of to-day undoubtedly stands in the same position as the steam engine in 1860, when Charles T. Porter first proposed to develop double or triple the power from the same weight of materirl for the same weight of engine, by increasing the number of its power producing elements per minute from 50 strokes, as was the practice, to 250. Or to follow history in steam engineering still further back in the days of Newcombon and Crawley, when all cylinders were sing e-acting and a multiplication of cylinders was required to increase the number of power strokes.

The commercial gas engine of to-day has a single acting cylinder. The difficulties of packing against the high temperatures have been found, and probably will remain, insurmountable. French engineers have sought in vain, through long continued and expensive experiments, to find methods of packing a piston rod against the high temperatures of the cylinder, and thus to produce a double-acting gas engine. The American engineers have heretofore tried, but thus far have failed, to produce a double-acting gas engine.

The most successful practice in gas engines has been followed in producing the engine illustrated herewith, that is, single acting combustion cylinders are used which are placed opposite to each other and form a single mechanical element. Midway between them is a cylinder of larger bore performing the office of a pump for transferring the mixtures to their proper destination before combustion. The compound piston, which reciprocates in these three cylinders, is also a single mechanical element, the two ends of similar size forming plunger pistons operating in the combustion cylinders, in the middle of which is an annular enlargement, which fits the larger bore of the pump cylinder. The differential area so produced between the combustion piston and the pump cylinder is the area which is available for transferring the gases and forms the piston area of the pump cylinder.

It is to this element, namely, the annular-shaped pump piston, that the main piston rods, E, two upon each side, are attached, as may be seen in Fig. 1, thereby eliminating the necessity of packing against the high temperatures; the only packing required in the piston rods is against the low pressures of the cold mixture within the pump. It will be seen in Fig. 2 that the two combustion cylinders are at opposite ends of the compound cylinder. The water jackets are shown at F. Along parallel to the front cylinder are the cored passages, G, in which the two piston rods, E, connecting with the cross head, reciprocate. The packing glands, I, are required to pack only against the small pressure of the gases in the pump cylinder. This pressure is so slight that it may be wholly disregarded.

The law of operation or cycle of the engine is as follows: The pump is double acting and is provided at either end with an induction valve, below which is a screw, by turning which the seating of the induction valve may be varied. This varies the pressure within the pump, and, therefore, the amount of mixture transferred into the combustion cylinder previous to ignition. The ignition is performed by the electric spark, the two igniters being coupled in multiple arc. The mixing device is peculiar, extremely simple, and consists of a valve, O, covering both gas and air passages in a perforated plate. This valve is so large as to nearly fill the circular space in which it is contained, leaving only a very narrow circular slot at its periphery. The gas and air as they are drawn through this narrow slot are given a very high velocity by the suction of the pump at either end. A wire gauze diaphragm, R, stands immediately in front of this passage and completely breaks up the rushing gases as they emerge from the slot. These, as they reunite, form a most intimate and complete mixture.

Experiment has shown that this mixture attains almost theoretical perfection, aiding materially in the perfection of combustion and economy attending the operation of the engine. The compression of the engine is from 35 to 45 pounds before ignition when the engine is working near its capacity, and from this figure down to atmospheric compression when working less than its rated capacity. A governor on the axle is connected by a rod, X, to the two screws beneath the induction valves, and thereby automatic regulation is obtained, which is found in practice to hold the engine within three per cent., from full load to zero.

The actual performance of the engine is very high, being from 19 to 21 cubic feet per horse-power hour. The perfect uniformity of speed is obtained, owing to the fact that every stroke is effective, and a comparatively small weight of engine is required to the horse-power. Chief among its merits also is its low cost of manufacture.

A 13 horse-power engine of this make weighs only about 1900 pounds, and requires but a small fly-wheel, and for purposes of driving dynamos the fly-wheel may be used for a band wheel, about the same practice being followed as in steam engineering in determining the weights of these elements.

The engineering department of the Patent Office looked upon the case with unusual interest owing to the fact of its being the first system of construction which rendered the double acting gas engine feasible, and a patent containing some sixty-five claims was granted upon it.

REPORTS OF COMPANIES.

THOMSON-HOUSTON ELECTRIC CO.

The following item of interest is from the Boston *Herald:*

The Thomson-Houston Company has been selling preferred stock, but not in the market. It has been sold privately, for home and foreign investment, and the proceeds are being used to take up the outstanding notes. A few statistics regarding this company's capital stock will be of interest:

Preferred stock chartered	$ 5,000,000
Common stock chartered	10,000,000
Preferred authorized for issue by shareholders	4,000,000
D'o common	7,500,000
Preferred stock issued, about	8,500,000
Common stock issued	4,500,000

This shows an increase of $2,500,000 in the outstanding preferred stock the present year. Besides the proceeds from stock, the company has yet to receive some $1,000,000 from its debenture notes, and has plans which may soon retire every dollar of floating obligations, except current bills which current income takes care of. A cash dividend upon the common stock in January is quite within the range of probability. The company has orders footing over $4,000,000 on hand in its various departments, and a high authority says it will earn $2,000,000 net in the last half of the year. The same authority says that when the present management acquired the original property it paid $40 per share for stock on which $17 had been paid in, and its earning power was 5 per cent. It then had two sub-companies using its apparatus and paying tribute. To-day the accounts showed about $45 per share actually invested, counting the patents as nothing, and the earning capacity was 20 per cent., and there were 1,000 to 1,200 sub-companies to use its apparatus and pay it tribute. Moreover, its rivals, like the Brush and Fort Wayne companies, were now a part of its assets.

STOCKS AND BONDS.

WESTERN UNION.—The Directors of The Western Union Telegraph Company have decided to pay a dividend of 1¼ per cent. on the capital stock Oct. 15. The income for the quarter ending Sept. 30 is estimated at $2,000,000. The dividend will require $1,077,400, and after paying fixed charges there will be left, it is figured, a surplus of $10,642,383.30. The surplus July 1 was $9,962,983.30.

COMMERCIAL CABLE.—A quarterly dividend of 1¼ per cent. upon the outstanding stock of the Commercial Cable Co. will be paid Oct. 1 for the September quarter.

AMERICAN BELL.—The directors of the American Bell Telephone Co. have declared an extra dividend of 3 per cent, payable October 15.

TROPICAL AMERICAN TELEPHONE CO.—The stockholders of the Tropical American Telephone Company can collect a dividend of 10 per cent. per share Oct. 1, to stock of record Sept. 15. Books will close Sept. 15 to 20. There will probably be dividends also Jan. 1, 1890, and April 1, 1891, as funds are in hand.

THE MODERN MATCH.

Husband (getting ready to light the gas)—"My dear, I wish you would remove all newspapers and other combustible material to the next room. Then send for several pails of water and have them handy." Wife—"Why, what for?" Husband — "I am going to strike a match. Of course it will break, and there is never any telling where the burning end will land."—*Street & Smith's Good News.*

MR. F. O. RUSLING is to represent the Connecticut Motor Co. at the Edison Convention in Minneapolis, and also at the St. Louis Exposition.

FINANCIAL MARKET.

QUOTATIONS ON ELECTRICAL STOCKS.

Mr. F. Z. Maguire, Electrical Securities, of 18 Wall street, this city, reports the following quotations of September 12th from New York, Boston and Washington:—

PATENT NOTES.

INTERFERENCE ON ALTERNATING DEVICE OPERATING BY REPULSION—W. STANLEY, JR. vs. ELIHU THOMSON.

The interference in the United States Patent Office pending for nearly two years between an application of William Stanley, Jr., and the previously issued patent to Elihu Thomson, on the well-known alternating current motive device operating by repulsion, was decided by the Examiner of Interferences on the 4th inst. in favor of Prof. Thomson. The subject-matter of the interference covered broadly the principle which has been treated so fully in the lectures of Prof. Thomson, and has recently been taken up by foreign experimenters and made the subject of published lectures by them also.

INVENTORS' RECORD.

Patents issued Sept. 2, 1890.

Alarms and Signals:—*Automatic Electric Annunciator*, J. W. Luthe and A. E. Jeavous, 435,440. *Push-Button*, G. H. Streickenberg, 435,866.

Conductors, Conduits and Insulators:—*Apparatus for Covering Electric Wires*, A. G. Holcombe, 435,629. *Pole for Electric Wires, etc.*, E. Verstraete, 435,872.

Distribution:—*Automatic Regulation of Electric Circuits*, G. B. Prescott, Jr., 435,545. *Device for Controlling the Current of Electric Generators*, H. W. Leonard, 435,700.

Dynamos and Motors:—*Electric Motor*, H. N. Blades, 435,639. *Means of Making Armatures for Dynamo-Electric Machines*, T. A. Edison, 435,690. *Electric Motor*, H. Groswith, 435,744. *Electric Current Regulator*, E. H. Johnson, 435,899.

Galvanic and Thermo-Electric Batteries:—*Battery-Compound*, E. M. G. Hewett, 435,421. *Process of and Apparatus for Generating Electricity*, T. A. Edison, 435,688.

Lamps and Appurtenances:—*Switch for Incandescent-Lamp Sockets*, W. C. Bryant, 435,578. *Manufacture of Filaments for Incandescent Lamps*, V. M. Hobby, 435,660.

Measurement:—*Electrical Measuring Instrument*, G. W. Walker, 435,550.

Metal-Working:—*Method of Electric Welding*, M. W. Dewey, 435,643 and 435,644.

Miscellaneous:—*Electric Switch*, C. W. Huntington, 435,424. *Workman's Time-Recorder*, F. L. Fuller, 435,582. *Electric Cigar-Lighter*, J. Roberts, 435,668. *Electric-Current Indicator*, A. B. Herrick, 435,695. *Electrical Indicator*, J. W. Howell, 435,896. *Electrical Controlling and Operating Apparatus*, E. H. Johnson, 435,897 and 435,898.

Railways and Appliances:—*Electric Conductor for Street Railways*, L. M. Perkins, 435,447. *Electric-Railway Closed-Circuit System*, Malone Wheless, 435,471. *Block-Signal System*, M. S. Couly, 435,482. *Conduit for Electric Railways*, W. R. Elliott, 435,486. *Electric Conduit*, W. R. Elliott, 435,487. *Means for Supporting Storage-Batteries on Railway-Cars*, H. H. Blades, 435,640. *Electric-Railway Car*, H. H. Blades, 435,641 and 435,642. *Railway Signal*, W. F. Z. Desant, 435,558. *Upward Pressure Contact for Electric-Railways*, J. A. Duggan, 435,559. *Electric Railway*, R. M. Hunter, 435,662. *Railway-Signal*, M. Cortese, 435,801. *Suspending Device for Overhead Electric Conductors*, E. Thomson, 435,870. *Electric Railway*, R. M. Hunter, 435,879.

Secondary Batteries:—*Means for Charging and Using Secondary Batteries*, T. A. Edison, 435,687.

Telegraphs:—*Telegraphy*, T. A. Edison, 435,689. *Telegraphy*, A. Muirhead, 435,851. *Electric Signaling Apparatus*, A. A. Hatch, 435,893 and 435,894.

Telephones and Appliances:—*Telephony*, T. D. Lockwood, 435,438. *Method of and Apparatus for Producing Musical Sounds by Electricity*, G. Breed, 435,679.

Patents issued Sept. 9, 1890.

Alarms and Signals:—*Electric Burglar or Automatic Fire Alarm*, Edmund R. Wilder, 436,030. *Electric Signal for Railways*, George A. Tower, 436,025. *Electric Signal for Railroads*, Frank C. Schroen, 436,154. *Electric Danger and Safety Signal for Railroads*, Edward M. Burt, 436,168. *Railway Signal*, James Richardson, 436,191.

Conductors, Conduits and Insulators:—*Insulator*, J. C. Firth, 436,225. *Insulator Bracket*, H. E. Chubbuck, 436,120.

Distribution:—*Electric Converter*, George Westinghouse, Jr., 436,200. *Pulsating-Current-Battery System*, C. J. Van Depoele, 436,275.

Dynamos and Motors:—*Regulator for Dynamo-Electric Machines*, William Stanley, Jr., 435,992. *Magneto Electric Machine*, Lamotte C. Atwood, 436,-113. *Electric Motor*, Thomas A. Edison, 436,127. *Steam Dynamo Electric Machine*, Edward C. Newton, 436,148. *Adjustable-Current Reciprocating-Engine System*, C. J. Van Depoele, 436,276.

Galvanic Battery:—*Electrolyte for Galvanic Batteries*, Frank K. Irving and Frederick M. Hill, 436,001.

Lamps and Appurtenances:—*Lamp Holder and Switch*, Charles H. Herrick, 435,931. *Electric Lamp*, William D. Graves, 435,967. *Electric Incandescent Lamp*, John S. Potter, David J. Cartwright and Benjamin B. Keyes, 436,316.

Metal-Working:—*Electric Power Hammer*, Charles J. Van Depoele, 436,277. *Electric Soldering Iron*, C. E. Carpenter, 436,119.

Miscellaneous:—*Method of Regulating Electrically Operated Mechanism*, Merle J. Wightman, 435,958. *Rheostat*, Frank Thone, 435,965. *Electric Detonator or Primer*, Henry T. Smith, 436,023. *Electric Switch*, Charles G. Perkins, 436,107. *Cut-Out for Electrical Translating Device*, C. G. Perkins, 436,087. *Lightning Arrester*, G. D. Hoop, 436,238. *Double Pole Snap Switch*, H. H. Crowell, 436,122. *Reciprocating Snap Switch*, J. S. Gibbs and C. G. Perkins, 436,080. *Electric Valve Controller*, H. W. Deeds, 436 219. *Watch Demagnetizer*, C. F. Berlin, 436,205.

Railways and Apparatus:—*Electrical Traction Apparatus*, William Stephens, 435,983. *Portelectric*, John T. Williams, 436,281. *Electric Lighting and Heating Apparatus for Electric Railways*, M. W. Dewey, 436,125.

Secondary Batteries:—*Secondary Battery Plate*, Thomas P. Whittier, 436,050.

Telegraphs:—*Electrical Amusement Reporting Apparatus*, Melvin D. Compton, 435,961.

EXPIRING ELECTRICAL PATENTS.

Reported by F. B. Brock, *Patent Attorney*, 639 *F street, Washington, D. C.*

Expiring in September, 1890.

Automatic Telegraph, G. Little, 142,481; *Perforating Telegraph*, 142,485; *Relay and Sounder*, 142,486; *Battery*, A. L. Nolf, 142,502, September 2, 1873. *Regulator*, T. A. Edison, 143,688, September 9, 1873. *Telephonic Telegraph*, W. D. Sargent, 142,817; *Morse Register*, M. F. Wessmann, 142,825; *Transmitter*, M. F. Wessmann, 142,826; *Regulator*, G. F. Lufbery, 142,925, September 16, 1873. *Battery*, T. A. Edison, 142,999, September 23, 1873. *Key*, D. L. Parkhurst, 143,296; *Multiple Telegraph*, M. Gally, 143,340, 143,341; *Fire Telegraph*, J. H. Guest, 143,-344; *Tool or Machine*, D. M. Smyth, 143,388, September 30, 1873.

[Copies of drawings and specifications of any patent will be furnished by Mr. Brock, at 15 cents each.]

FIRE AT THE BROOKLYN INSTITUTE.

A fire, for which no origin has yet been suggested, broke out on Friday evening last about 6 o'clock in the old Brooklyn Institute building, where so much educational, literary and scientific work has been done. Before the fire stopped the building had practically been gutted, and few things of value were saved by Prof. Hooper. Among the sufferers by the fire is Prof. Vander-Weyde, who had in the building a most interesting and valuable, as well as irreplaceable, collection of electro magnets, telephones, batteries and other electrical apparatus.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

INDURATED FIBRE FOR SUBWAYS AND CONDUITS.

REFERENCE was made in the last issue of THE ELECTRICAL ENGINEER to the use of indurated fibre pipe for underground telephone work in Philadelphia, where, according to Dr. S. M. Plush, it has proved very satisfactory and has stood severe tests during a period of over 18 months. This material now bids fair to assume considerable importance in subway work, and deserves the attention of the electrical public. It is made by a patented process from long wood fibres, separated, washed free from all saps and gums, molded while in a pulpy state into the requisite size and shape and then subjected to great hydraulic pressure. After this it is treated and hardened by a special chemical process that renders it impervious to moisture, acids or gas. It is, moreover, extremely tough and durable, and will withstand enormous crushing strains. The tensile strength is about 1,100 pounds to the square inch. Its weight is about one-fifth that of iron for equivalent service in pipe form. It will resist over 200 degrees of heat, is remarkably insensible to the rigors of winter, and is easily handled as well as readily reamed and threaded.

The method adopted for the use of this pipe for electric light subway work is practically as follows:—The manhole chambers have a bottom of asphalt concrete upon which is placed a flooring of indurated fibre in a slab about an inch or more in thickness. The walls of the chamber are similarly treated. The wires are carried through these manholes in rubber tubing, which fits tightly on either side of the chamber over a nipple with screws over the ends of the pipe. A packing of phenicite helps to exclude moisture and seals the whole hermetically. This phenicite is a plastic compound capable of resisting very high temperatures in connection with electrical work. The pipes used are generally 1½ inches inside diameter with ½ inch shell, and are joined together with collars, in which they are fastened by means of screw threads. The junction box, made of the same material, is about 12 inches long, 6 inches wide and 5 inches deep. The ends are tapped for screw threads and the main pipe screws into them on either end. The box has a removable cover which is fastened with iron machine screws, countersunk. The heads of the screws are treated with wax or similar preservatives to prevent oxidization. The inner edge of the box is grooved and a perfectly tight connection is made by means of linen gaskets thoroughly saturated in phenicite.

The service pipes, when it is necessary to make an angle, are fitted with screw threads and are made a little smaller than the cover apertures through which they pass. They are fastened by jam nuts, placed respectively on the inside and outside of the box cover and made tight by gaskets served with phenicite.

To make it unnecessary in new construction or repairs to remove pipe protecting service wires, the service or side pipes at the threaded part are made slightly larger than the main part of the pipe, in order to allow the outside jam nut and the cover to slip back over them, when unscrewed, for the purpose of exposing the main wires.

The operation of connecting from the main wire to a house or to any point at right angles is as follows:—A trench is dug from the street main to the point requiring service and connection is made at the service point. This service wire is then strung through pipe and collars of the same material, until the junction box in the street is reached. The service wire is connected with the main wire passing through junction box. The service pipes and collars are then screwed tight, each joint being carefully cemented with phenicite.

The pipes are laid in a concrete of cement, sand and gravel, the faces of the boxes being left free of the concrete for easy removal.

The junction boxes occur every 50 feet and are placed one above another, either in direct line or staggered. A number of pipes are used as service pipes along the route and can be changed over at manholes, bringing another set of apertures in the next section or block. The phenicite is used to insure perfect joints and to facilitate construction. It is also applied to the surface of the conducting wires as a lubricant to facilitate drawing them through the conduit, thereby preventing injurious abrasion or strain.

Such, in brief, is the method adopted in subway work for lighting wires, with modifications for telegraph and telephone wires, or for combination of all three services.

This system is now being introduced by the Indurated Fibre Pipe Co., of 40 Wall street, this city, with factory at Mechanicville, N. Y. Mr. J. L. Brownell is president; Mr. Jonathan Brownell, treasurer, and Mr. H. J. Medbery, secretary. As mentioned above, it is already in successful use in Philadelphia, where 40 miles are laid. In Detroit, the Detroit Electric Light Co. have about 20,000 feet, and the local Edison company some also. The Pennsylvania Railroad Co. have it laid in five different places, each with conditions of its own, and it is highly reported upon. The Badger Illuminating Co., of Milwaukee, and the Mt. Morris Electric Light Co., of this city, are both using it; and the Fort Wayne Electric Co. have adopted it for all their work. It has also been used for work in the Bonair Hotel, at Augusta, Ga., by the Edison company, and in the new hotel at Fifty-ninth street. Mr. Medbery informs us that he has never had a single unfavorable report on it, but that in every case it is working well. Specimens that have been underground for four years were exhumed and tested recently and showed no change whatever, being as good as when laid.

MOTOR BUSINESS OF THE EDISON GENERAL ELECTRIC CO.

A SHORT time ago the hint was thrown out in THE ELECTRICAL ENGINEER that the "small motor" field open deserved to be worked all the year around. There seems to have been a general impression that the great harvest time for small motors is the hot season when fans are in the briskest kind of demand; and that when the summer draws to a close, the central station superintendent can rest on his laurels in the power department and concentrate his energies upon the lighting business. In fact, nothing could be more of a mistake than this. Even so far as fan motors alone are concerned, the opportunities of sale are certainly excellent during the winter months, when in hot and crowded rooms ventilation is required that cannot be obtained by the opening of windows; and when, in various places, quite as much in January as during July, agitation of the air is required to keep it pure and fresh. There are, moreover, numerous fields of work that have yet been untouched or barely scratched. In the household, for example, the little motor that can do so much to lessen the work and alleviate the worries attaching to domestic duties, is almost a total stranger, even in towns and cities where the electric circuits are well nigh as familiar and common as waterpipes. What are 50,000 small motors among the millions of families of this country? What would even 500,000 be? And, then, there are the countless small industries where a quarter or a half of a horse power available in this handy form proves the most valuable of aids and acquisitions; yet how small is the number of minor establishments where the diminutive "jack of all trades" has been set humming his cheery tune! Nothing could tend more to the diversification of industries and the perfection of handicrafts than the possession of these compact little mechanisms.

Recognizing these facts and many others that belong to the subject, the Edison General Electric Co., through its stationary power department, of which Mr. H. Ward Leonard is the chief, has just issued a special announcement, to be found elsewhere, in our advertising columns, on the work it is ready to do in connection with the development of the small motor business. This special circular of the Company calls attention to the small motors it is handling, and gives a variety of information as to their size, speed, etc. It also gives data in regard to the Edison generators, which are being found not less useful for power work than for lighting. Altogether the company is to be congratulated upon its enterprise in this line and upon what must be regarded as its timely movement in arousing the activities of central station companies for a winter campaign.

A WORD OR TWO ON ACCUMULATORS.

AN interesting batch of circulars reaches us from the Accumulator Company, of 44 Broadway, this city. One of them consists of a number of recent testimonials dealing with a variety of uses to which the cells have been put. Thus Potter Palmer tells of the work done in the big Palmer House in Chicago and at his private residence. Another letter from Mr. G. Clark describes their use in connection with motor fans used on Atlantic steamships for ventilation purposes. One letter comes all the way from Honolulu, telling how, in the far off Sandwich Islands, James Campbell, C. B., has tempered exile by putting a storage plant into his residence at Waikiki. Lieut. Bradley A. Fiske tells how the cells he had on board the U. S. S. "Chicago" were often roughly handled, used as targets by expectorating seamen, and washed off with salt water, but were very satisfactory in all his experiments. Mr. F. Jarvis Patten, the well-known inventor, deserves quoting in full. Under date of July 22, this year, he writes: "I have used your storage batteries constantly since November last at my laboratory here as well as in Philadelphia. I have used the '15M' cell of your most recent and improved form for driving the distributor motors in my multiplex telegraph system also for past month. I have used 60 cells of your smallest size battery, originally designed for medical apparatus only, in lieu of about 125 cells of ordinary gravity battery, for telegraphic transmission over the 100 mile circuit I use daily between New York and Philadelphia. With reference to the first lot, large size, used for motors, I am pleased to inform you that notwithstanding very irregular use, these cells have given me thorough satisfaction during the eight months I have had them in use, being more reliable for a con-

stant E. M. F. than the dynamo circuit I use for charging them. The line battery to small cells occupying six cubic feet of space take the place of more than 100 cells of gravity, and require far less attention than the latter, and, so far as observed, give better results. I consider your improved forms of storage battery far superior to any I have seen in use, and with proper care in handling, as to charging and discharging, they are an exceedingly convenient and reliable source of current." The yachtsman, W. H. Starbuck, has been able, with the help of the cells, he writes, to get excellent illumination for the "Tillie"; and last, but not least, one or two of the phonograph companies make report of the results they have obtained in using stored electricity to obtain stored talk.

With this pamphlet goes a circular dealing specially with the use of accumulators for street car propulsion, and the packet is completed by a dainty folder, bearing the compliments of Mr. D. H. Bates, and addressed to various classes of persons likely to require accumulators. It will be strange indeed if all this literature, evincing as it does a keen appreciation of the value of printer's ink, does not prove effective with the public it is addressed to. It may be added that the envelope has "Stored Electricity" on it in large letters.

THE ELECTRICAL EXHIBITS AT THE MINNEAPOLIS INDUSTRIAL EXHIBITION.

BESIDES the magnificent Egyptian tower of light described on another page, the Minneapolis Exhibition this year contains a number of notable electrical exhibits. Among these is Mr. Edison's personal exhibit on the second floor of the building, extending the entire length of the light well, and from the light well to the wall. Here can be seen working models of all of Mr. Edison's inventions which are attracting a great deal of attention from the thousands of visitors in the building every day. The phonographic dolls, as shown in a spacious theatorium, give intense satisfaction to all who hear them, as they are the very latest type made, having a natural voice and a vocabulary of over one hundred words apiece. The phonographs proper are finely exhibited in the art department, under the intelligent care of Mr. A. T. E. Wangeman, of Mr. Edison's laboratory. This is a very popular resort, and those hearing the fine records exhibited are delighted with them.

Besides these personal exhibits of Mr. Edison, the Edison General Electric Co., under its representative, Mr. W. S. Howell, has a fine exhibit of its products, consisting of dynamos, motors, bare and insulated wires and cables, underground conductors and electric light fittings, which make an attractive display.

One of the exhibits which is attracting a great deal of attention is that of the Thomson Electric Welding Co., which has a full display of its apparatus for various classes of work in operation, welding everything, from a pin to a pipe four inches in diameter. Mr. Gorton, the electrician from the Lynn factory, has charge of the exhibit.

The Interior Conduit and Insulating Co. have a very neat exhibit of their tubes and conduits, which is very interesting to Minneapolis people at the present moment from the fact that many miles of their conduits are being used on the immense system of electric railroads, now being placed in operation in Minneapolis.

Another most interesting exhibit is that of the Carpenter-Nevins Electro-Heating Co. Beginning by experimenting in a small way a few years ago, the gentlemen comprising this firm have utilized the heating properties of electricity for sad irons, griddle cake pans, coffee and tea-pots, clothes boilers, vats, and many other appliances for household and laundry use where heat is necessary.

WESTERN THOMSON-HOUSTON SALES.

The following is a list of the sales made by the Chicago office of the Thomson-Houston Co. during August:—National Forge & Iron Co., E. Chicago, Ind., 20 arc; A. H. Andrews & Co., Chicago, Ill., 600 direct incandescent, 110 v.; McDonnell & Church, Lowell, Mich., 30 arc; McDonnell & Church, Lowell, Mich., 300 alternating; Consolidated Piedmont Cable Co., Oakland, Cal., 30 arc; H. A. Foster & Co., Pontiac, Ill., 100 direct incandescent, 110 v.; H. M. Loud & Sons Lumber Co., Au Sable, Mich., 50 arc; Mt. Pleasant Electric Co., Mt. Pleasant, Mich., 30 arc; St. Louis Republic Co., St. Louis, Mo., 300 direct incandescent, 110 v.; Peninsular Electric Light and Power Co., Houghton, Mich., 50 arc; Albion Electric Light Co., Albion, Mich., 650 alternating; Citizens St. Railway Co., Indianapolis, 30 arc; H. H. Brown, Canon City, Col., 650 alternating; Dernberg, Glick & Horner, Chicago, Ill., 45 arc and 100 direct incandescent, 110 v.; Cicero Gas, Water and Electric Light Co., Oak Park, Ill., 1300 alternating; Yazoo Water Works and Electric Light Co., Yazoo, Miss., 650 alternating; Yazoo Water Works and Electric Light Co., Yazoo, Miss., 50 arc; Watertown Electric Co., Watertown, Wis., 50 arc; Western Electric Construction Co., Denver, Col., 400 arc and 5200 alternating; Maryville Electric Light and Power Co., Maryville, Mo., 30 arc and 650 alternating; Marysville Electric Light Co., Marysville, Kan., 650 alternating; Brookfield Electric Light Co., Brookfield, Mo., 650 alternating; Springfield Electric Light and Power Co., Springfield, Ill., 1300 alternating; Oakland Gas, Light and Heat Co., Oakland, Cal., 50 arc; Edison Electric Light and Power Co., Little Rock, Ark., 10 h. p., 110 v.; Capital Electric Co., Nashville, Tenn., 10 h. p., 500 v.; Elastic Metallic Packing Co., Omaha, Neb., 1½ h. p., 500 v.; H. D. Preston, Kansas City, Mo., 10 h. p., 220 v.; Kalamazoo Electric Co., Kalamazoo, Mich., 50 arc; Famous Manufacturing Co., E. Chicago, Ind., 300 alternating.

WESTERN ELECTRIC DOUBLE CARBON LAMPS.

The Western Electric Co. are going right ahead with the manufacture of their well-known double carbon arc lamps, and will shortly place upon the market a new form of lamp which is superior to anything heretofore got up by them in that line. They announce it as follows in a circular which is signed by Mr. C. A. Brown:—"We solicit your orders for double arc lamps. Our double lamp has no finely geared clock work; no close fitting sliding solenoid cores; no steel pinions or pivots to rust and stick; no gearing to clog with dust. It is practically and theoretically the simplest and best constructed double arc lamp, and the only double arc lamp manufactured for both high and low tension currents. We offer to furnish companies using low or high tension systems with new double arc lamps guaranteed to work satisfactorily, and with guarantee against loss on account of suits for alleged infringement of patents."

WESTINGHOUSE ELECTRIC RAILWAY WORK.

The Westinghouse Electric and Manufacturing Company Railway Department, under the management of Mr. J. L. Barclay, so well known in street railway circles, have now got comfortably settled in their magnificent suite of offices in the Pullman Building, Chicago. The offices are situated on the west side of the building on the ground floor. As you enter is a handsome reception hall, to the left of which is located Mr. Barclay's private office, and behind this a handsomely furnished reception room. Back of this again is a large room where a double truck on running gear and other adjuncts of the Westinghouse system of electric street railway propulsion will be placed on exhibition. On the right of the entrance hall behind a handsome oak railing are the desks of Messrs. Stewart, Osgood and Atkinson, the well-known traveling representatives of the company. In the reception hall, Mr. Reid, who has general charge of the office work, is located, and behind him are the general offices of the company. The whole suite is handsomely furnished and beautifully equipped and lighted with incandescent lamps on tasteful fixtures. The whole planning of the offices reflects the greatest credit on Mr. Barclay, under whose management it has been carried out.

THE EVANS FRICTION CONE.

The Evans Friction Cone Co., of 85 Water street, Boston, inform us that they have just taken the contract for fitting up the entire plant of the Derby Gas Co., Birmingham, Conn., with their system of driving dynamos, which has already become a familiar and valued feature in so many stations. The plant is to be driven in this manner, partly by water power and partly by steam, and the station will be a model one in every respect.

FIBRONE AS AN INSULATING MATERIAL.

The attention of the electrical public was recently called in these columns to the merits and uses of "Fibrone" as an insulating material. It is a solid and plastic substance, presenting many of the most desirable characteristics of hard rubber. It is a perfect non-conductor, absolutely water proof, and proof against the weaker acids. It can be made to withstand concentrated acid solutions and all actions of alkalies, and is therefore particularly useful for battery jars and covers.

Experiments have been made with this substance by several authorities, and more recently Fibrone was submitted as an insulating material to a most severe test in the Merchants' and Manufacturers' National Laboratory of New York.

The result of these experiments plainly showed that Fibrone does not flake off, blister, crumble, crack, expand or contract under ordinary temperatures, and for special purposes is made also to withstand a high degree of heat. Mr. Louis Steinburger, President of the Fibrone Manufacturing Co., of New York, and inventor of this new and valuable material, asserts that it can be made if required absolutely fire proof. It can be sawed, planed, drilled, tapped or turned in a lathe, the same as hard rubber, and be made heavy or light. It can be given in any of the handsomest, delicate and bright colors, and is a very artistic imitation of any natural wood, rare marble, stone, bronze or metal.

On account of its exceedingly low cost, Fibrone has already entered into competition with hard rubber in almost all kinds of

electrical fittings and will be found most economical and valuable either in sheets or in the shape of battery cells and covers, switch boards, tubes, rods, bell boxes, rosettes, etc.

The admirable plasticity of Fibrone is demonstrated by the finest specimens of artistic decoration *en relief* made with this material. We have recently seen a variety of handsome electrical details made from it, including a line of onyx push buttons.

THE NOVELTY ELECTRIC SUPPLY MANUFACTURING CO.

The above company, of 264 West Fourth street, Cincinnati, are very busy at present, having several orders on hand. One from the Northwest Thomson-Houston Co. for iron poles amounts to $12,000. They have equipped what they claim is the most complete electrical repair shop in the United States, and are making a specialty of rewinding armatures and fields for electric railway and electric light plants. They have just closed a very important deal with the C. & C. Electric Motor Co. for handling their motors in Southern Ohio, Kentucky and Tennessee, where they have the exclusive agency. They also carry in stock a full line of combination fixtures, wood and iron poles, etc., and 50,000 Perkins incandescent lamps; everything, in fact, pertaining to electric light, electric railway, telegraph, telephone and house work. Their business is already much larger than they anticipated.

THOMPSON, REED & CO.

Westchester County, N. Y., is fortunate in having its electrical railways in the hands of such experts as Thompson, Reed & Co., of 32 Liberty street, New York city. The system of territorial supervision and inspectorship applied to such a business is an index of the great importance it has assumed in public opinion and esteem.

MORE ELK-HEAD ELECTROLIERS.

A few weeks ago in describing and illustrating the large Chicago house of the Great Western Electric Supply Co., our cut showed one of the novel elk-head electroliers made by this firm. This has attracted much attention at their store, and is now one of the electrical features at the Chicago Exposition. The firm has recently received nineteen mounted deerheads from the Yellowstone National Park, which will also be made into electroliers. We understand that most of these are already sold, and will be sent out as soon as they are wired up.

THE EXHIBIT OF JAS. W. QUEEN & CO. AT ST. LOUIS.

One of the most striking exhibits, as indicating the great advance of home manufactures, is that displayed by Queen & Co., of Philadelphia. This enterprising firm show a full line of their standard electrical test instruments, and for the benefit of those who may not have the opportunity of viewing the exhibit, we will say a few words regarding what may be seen.

First should be mentioned the collection of resistance boxes, which is probably the finest assortment of American make ever placed on exhibit. The "Queen" standard resistance boxes No. 16, standard megohm box (P. O. box), No. 2, and a full line of their new portable testing sets make a showing that will interest every electrician. These testing sets appear to possess valuable peculiarities, used only by Queen & Co., and we hear it whispered that there is a great demand for them.

Ammeters and voltmeters for all classes of work are attractively shown. Well known types are to be seen, such as the Ayrton and Perry, Deprez-Carpentier, Cardew, electrodynamometers, and also Queen's new magnetic vane meters, which, while but recently placed on the market, are finding many friends. They are adapted for central stations, electric railways, marine plants, isolated plants, etc., and the low prices at which they can be obtained place them within the reach of all.

Reading telescopes, galvonometers, speed indicators, testing batteries, and other instruments, together with those mentioned above, go to make up an exhibit that reflects great credit upon Queen & Co.

Mr. Foree Bain has been in the city the past week with regard to the electric railway work in Minneapolis, upon which he is engaged as consulting expert by the local company.

Mr. E. G. Bernard, special agent, reports recent Sawyer-Man plants sold by him as follows:—Victor Mills, Cohoes, N. Y., 300 lights; Wymanskill Mills, Troy, N. Y., 150 lights; Austin Stairs & Co., Amsterdam, 150 lights; Brandywine Mills, Norfolk, Va., 150; Chesapeake Mills, Norfolk, Va., 100; H. M. Quackenbush Rifle Factory, Herkimer, 150, and residence, 60; W. McClyman, Schenectady, 60; Rose Hill Farm, Geneva, 75. The mill in Norfolk made his forty-ninth knitting mill.

"A. B. C."

Already the windows of the big new store of Alexander, Barney & Chapin, at 20 Cortlandt street, arrest the attention of the passerby, and this a good augury of the notice they will receive when filled up with a tasteful display of electrical novelties. At the present moment one of the windows is covered with a huge sign announcing that the firm will begin business there about October 1; and at the top is a diamond enclosing the letters A. B. C. This diamond is the trade mark of the new house, and its selection is excellent. It will soon be as well known throughout the country as any that has ever been used in the electrical business.

The firm inform us that they have already conducted some important negotiations to a successful issue, and there is no doubt that when they start they will carry one of the finest lines of electrical supplies and novelties in the country.

THE SAWYER-MAN CO.

It is understood that, consequent upon the resignation of Mr. P. H. Alexander, the management of the Sawyer-Man Co. has been entrusted to Mr. G. W. Hebard, who has already entered upon his additional duties at the big lamp factory in West Twenty-third street.

WESTERN TRADE NOTES.

Mr. A. S. Manning, assistant engineer of the Chicago office of the Thomson-Houston Co., has just been presented with a handsomely engraved gold headed cane by the traveling experts of the company.

Mr. Harry Small, of the Thomson-Houston Company, has returned from a trip East, where he visited Boston and the company's factory at Lynn, Cape May and other points of interest.

Mr. Ernest L. Clark, secretary of the Illinois Material Company, has just closed one of the largest pole "deals" ever consummated at Moline, where he will immediately ship 35 carloads.

NEW ENGLAND TRADE NOTES.

J. A. Grant & Co., the well-known Eastern agents for the McIntosh & Seymour engines, have removed from their old quarters, at 243 Franklin street, Boston, to 8 Oliver street, where they have much more commodious offices to carry on their largely increasing business. Mr. Grant reports that the factory at Auburn is extremely busy, and that they are taxed to the utmost to keep up with their orders.

The Eastern Electrical Supply and Construction Co. has been formed with capital of $50,000, with headquarters at 65 Oliver street, Boston. They will be sole Eastern agents for the well-known goods of J. H. Bunnell & Co., of New York, and will handle exclusively for the United States the zincs made by the Carr Metal Co., of Fall River, Mass. They will also control the Auxiliary Fire Alarm for Massachussets, besides other specialties which they are not ready yet to name. The company is strongly backed by gentlemen well known in electrical circles, and Mr. G. H. Buckminster, for four years with the Electric Gas Lighting Co., will attend to the wants of customers as head clerk. When the company is fairly started, it is their intention to go into the electric light and power construction business, as well as furnishing all kinds of telegraph, telephone and electric light and railway supplies.

The Jarvis Engineering Co. are enjoying quite a run of business at present in Armington & Sims engines and various boilers, furnished with the famous Jarvis setting. Among their recent sales may be mentioned 100 horse-power engines for the Lawrence Gas Company, Lawrence, Mass.; two tubular boilers, 15 h. p. each, for the Edison Illuminating Company, of Boston; two 250 h. p. Heine boilers for the Chicago Edison Company; a 100 h. p. supplied to the Ball Engine Company for use in an electrical plant in Manchester, Va.; a 1,000 National h. p. heater for the factory of the Thomson-Houston Electric Company, of Lynn. (This is the largest heater the Jarvis Company have ever installed, and weighs over two tons.) They have also shipped a 50 h. p. engine for the Middlesex Machine Company, of Lowell, Mass., for an isolated electric light plant in a new building in Andover, Mass. The Jarvis Company are preparing to install a 60 h. p. Armington & Sims engine in the Mechanics' Hall, Boston, for the exhibition which opens in October, and which will drive a Thomson-Houston dynamo by means of the Evans friction system.

The Rowell American Switch Co., of Boston, have installed one of their patent switches for operating from electric cars, at the corner of Causeway and Canal streets, Boston, which is giving great satisfaction. Two ordinary street cars have been fitted with the necessary apparatus to operate the switch, and it is receiving a thorough and severe test. The switch is attracting a great deal of attention from electric railroads, and the company is having numerous inquiries from roads all over the country. The cost is quite small, and the switch is certainly much required, and will doubtless ere long be extensively adopted.

EDITORIAL ANNOUNCEMENTS

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

VOL. X. NEW YORK, SEPTEMBER 24, 1890. No. 125

The honor of a scientific discovery belongs, not to him who first sees a thing, but to him who first sees it with expert eyes, not to him even, who drops an original suggestion, but to him who first makes that suggestion fruitful of results.—George M. Beard.

CONDUIT ELECTRIC RAILWAYS.

AT the convention of the New York State Street Railway Association, held in Rochester, last week, electricity as a motive power was the leading topic. It may be said to have been the only topic, and all electrical engineers must feel gratified at the manner in which the merits and benefits of electricity were eulogized by the street railway men themselves of their own volition. Both the speech of the president and the paper of Mr. McNamara were warm in recommending electricity to those interested in street railways all over the country; and both characterized the overhead trolley system as the best method possible and obtainable at present.

A few weeks ago we discussed the figures of Prof. Adams, compiled for the Census Bureau, showing that in 56 leading American cities electricity is only used on 8.26 per cent. of the street railroads, while, as we pointed out, taking the country as a whole, the percentage rises at once to not less than 25 per cent. of roads and mileage. This difference can only be accounted for on the ground that it is impossible to overcome the strong antipathy entertained in many cities towards poles and overhead wires. Even where these street fixtures are tolerated, there is objection to an extension of the system for new classes of service. In fact, the public, worked up by the sensational stories of reporters in search of the ghastly and picturesque, has come to look upon every street corner with a pole on it as a possible Calvary; and here in New York, this very week, we have the mayor of the city seeking to palliate a gross piece of carelessness on the part of a lineman who, unfortunately, gave up his life on the pole he had climbed. If this be the condition of affairs, as it is, and if it still be, as it is, the determination of electrical inventors and engineers to operate nearly every one of the street railroads by electricity, resort must be had for the bulk of city work to other methods than those of the overhead wire and trolley.

Hence it is that storage battery traction is now receiving so much attention, the failures of the past acting simply as a stimulus and an incentive. There is more activity in that field to-day than ever before. But in the meantime, the conduit system of direct supply, which had fallen into desuetude, especially since the attempts in Boston, has again been resorted to, and it is believed by many that electric traction in the larger cities is to fullfil its mission through the agency of the conduit. We publish in this issue a very complete description of a new system that deserves attention not only on its own account but because of the special circumstances attending the development of street railways in Washington, where it has been put in successful operation experimentally. In legislating on this subject for the District of Columbia, Congress has decided that there shall be no resort to the overhead system. If electricity is to be employed it must be in some other way than that; and the legislation has been made absolutely prohibitive. At this juncture, the conduit system described in our pages has been brought forward, and as it is one in which only the sections under the traveling cars deliver current, the others being dead, it can readily be understood that Washington is very much interested in the matter. The question is one, however, which, as we have shown, concerns some forty or fifty other cities, to say nothing of numerous towns ranging upward to 50,000 inhabitants; and we do not think we are mistaken in saying that the conduit system, after having thus been relegated to obscurity as a direct method of supplying current to the car, will very shortly come to the front again in a commanding manner.

THE USE OF STREETS BY PRIVATE CORPORATIONS.

A SPECIAL committee of the city government of Boston was appointed recently to report upon plans for securing some return to the city for the use of the streets by private corporations operating under franchises and ordinances. The subject is an interesting one, and the conclusions and data of the committee deserve not to be overlooked. The committee report that they found that the local telephone companies of Amsterdam pay to the city, annually, 21½ per cent. of gross receipts; in St. Louis, 5 per cent. of gross receipts; and in Philadelphia, $1 annually for each old pole, and $5 for each new pole, used for the support of wires. Street railway companies also pay large amounts for their locations. In Amsterdam they pay 5 per cent. of their gross receipts, annually; in Baltimore, 9 per cent. of gross receipts, with an additional tax on each car; in Newark, 2½ per cent. of capital stock; in Providence, a certain fixed sum; in St. Louis, a percentage of gross receipts on a sliding scale; while in New York State all street railway franchises are now sold at auction for the highest offer above a certain fixed percentage of gross receipts. The method most generally adopted

is to require the payment to the city of a percentage of the gross receipts.

The committee come to the conclusion that no scheme of taxation is desirable that induces the corporation taxed to lessen the amount of convenience it furnishes to the public. Thus, for instance, a tax of so much per car would tend to reduce the number of cars put into commission, and the public would suffer from crowding. On the whole, the committee dislike such a method as the above, which obtains in Baltimore, for example, and incline to that favored in Philadelphia, where the tax is, for instance, on each pole. Thus, they would require a corporation to pay a fixed sum for each mile of track, or for each pole put up, or for each mile of subway occupied. Here, again, however, there is danger. In New York, the local companies find the rate of $1,000 per mile of subway duct rental excessive, and a tax on top of that would certainly prove a most serious burden on their business. It is stated that so far Boston has enjoyed less revenue than any other city from the privileges it has granted. Granting that the privileges have a fair market value, it is hard to see that Boston has suffered particularly from its generosity to the corporations that supply its people with light, means of locomotion, and other things.

IMPROVEMENTS IN TELEPHONY.

The improvements which are steadily going on in telephone work are evidence of the fact that this branch of applied electricity is in the hands of men who realize that telephony involves engineering in all its branches to a degree unfortunately lost sight of in its early days. With the high standard of construction which is now being observed both in the office and outside of it, marked improvements must follow, and with them come others which add enormously to the value of the line as a working medium. One of the most valuable of these, recently brought out, is that of the simple device due to Mr. J. J. Carty, by which the talking capacity of a given line to which a number of instruments are connected is enormously increased. Our readers may recall that in the early days of telephony, when individual call devices occupied the attention of numerous inventors, the limit to the number of stations which could be placed on a single line was soon reached on account of the retardation caused by the bell magnets, which were placed in series. In Mr. Carty's arrangement the high resistance bells are all placed in shunt across the line, and the defects heretofore experienced are entirely absent. The results already obtained in practice leave no question as to the general adoption of this system. Its value, however, exists further than in the mere improvement in transmission obtained by it, which comes out most strongly in the application for long distance service. By the use of this arrangement it is evident that there is considerable saving in the length of conductor necessary to connect stations, especially those lying at a distance from the main line. Thus, instead of running a double loop to such stations, a simple metallic circuit may now be used in the same way as branches are run from incandescent circuits. The device is one of those simple improvements which are far reaching in their effect.

Electricity at the World's Fair.

The various appointments in connection with the Columbian Exposition at Chicago are now being made. One of the first is that of Mr. Gardiner C. Sims as chairman of the Committee on Electricity and Electrical Appliances. This is an excellent choice by the Commission in many respects. Mr. Sims is a man of great ability, independent wealth, unchallengeable probity, and wide practical acquaintance with the arts. He is an enthusiast on the subject of electricity, and has done much to promote its interests. He may be depended upon to make an excellent chairman of the committee. He is also a member of the Commission committees on manufactures and tariffs and transportation, upon each of which he has been placed because of his intimate knowledge of these important subjects.

Suicide or Otherwise.

A lineman was killed in this city a few nights ago. He went up a wet pole, with bare hands, to see to a lamp that had been affected by the storm, and proceeded to work upon the live circuit. In reporting upon the case Dr. Wheeler, as expert of the Board of Electrical Control, held that the man was responsible for his own death because he failed to wear the rubber gloves provided. In other words, he neglected the most simple and reasonable precautions, and paid the penalty. Mayor Grant, however, is not satisfied, but wants to have it made out that the man was a martyr to duty. It seems to us a very great and deplorable pity that a public official so highly placed as the mayor should thus endeavor to condone and extenuate carelessness of this kind.

The Edison Meter.

The paper read at Minneapolis, by Mr. Kennelly, before the Edison Association, confirms the faith of the Edison Company in the electrolytic meter of Mr. Edison, and gives some interesting information with regard to the latest type of that meter. It is also interesting to note that Mr. Edison has taken up the mechanical registering meter in order to fill a demand which no doubt exists in many quarters for it as a form which consumers frequently insist upon.

Open Circuit Transformers.

In a recent issue we described the latest type of Mr. Swinburne's open circuit transformers and gave the arguments which have determined Mr. Swinburne in the adoption of this type. Principal among these, as will be remembered, is the point claimed by Mr. Swinburne that, although somewhat less efficient on full load than the closed circuit transformers, the open circuit type has a considerably greater all-day efficiency. In this issue Mr. Tesla takes up the question and discusses Mr. Swinburne's arguments, with which he does not agree, and cites his reasons therefor. Mr. Tesla's remarks, taken in connection with his letter, also in this issue, referring to a criticism of his recent work in alternating motors, make an excellent résumé of the discussions which have been going on lately with regard to this subject.

THE WHELESS UNDERGROUND ELECTRIC RAILWAY SYSTEM.

WHILE the progress which overhead electric railways have made in this country commands the admiration of the world, and has just been commented on by Sir Frederick Abel, in his presidential address before the British Association, those who have studied the situation closely cannot fail to have discerned the increasing objection which is entertained to the employment of overhead wires in cities. This feeling,

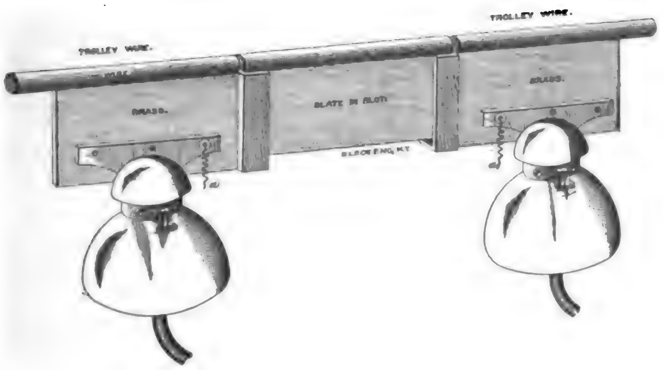

FIG. 2.—ENDS OF ADJOINING SECTIONS IN CONDUIT.

heretofore confined to electric light, telegraph and telephone wires, has now spread to electric railway conductors, and in some of our largest cities electric railways have thus far been practically barred out, while in others now operating overhead systems the extension of such work has been stopped by municipal ordinances. As an example, we need only take the city of Washington, D. C., where, by recent enactment, the running of overhead electric railway wires is now prohibited, though the Eckington and Soldiers'

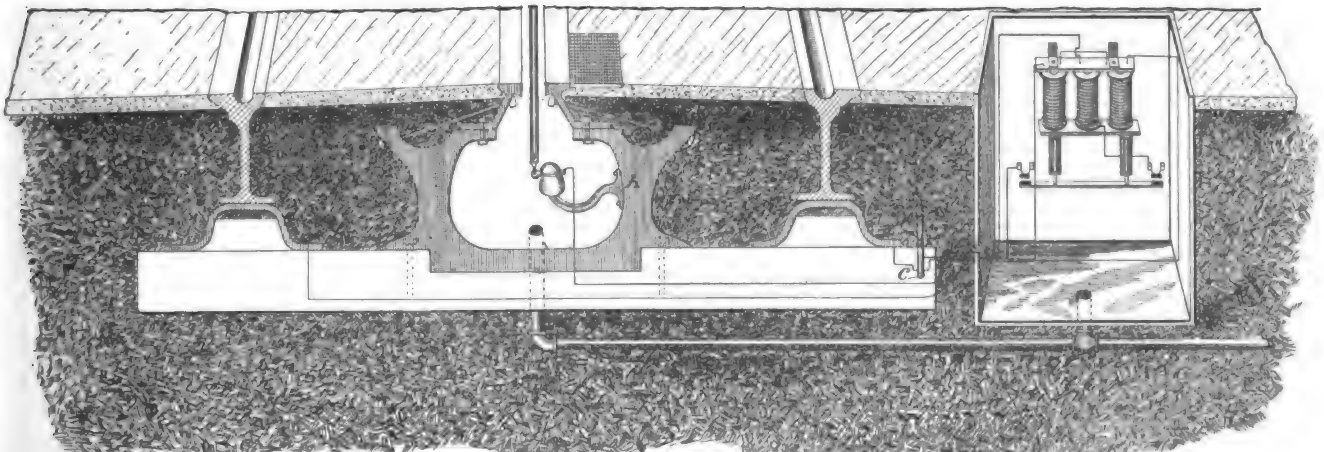

FIG. 3.—SECTIONAL VIEW OF CONDUIT, WHELESS SYSTEM.

Home Electric Railroad, in operation there, is one of the most substantially built and successful roads in the country.

A practical, feasible system of railway conductors, placed entirely underground, will, therefore, in point of fact, open up an immense field, as yet untouched, and add a new stimulus to electric railway operations.

The conditions which confront the constructor of an electric railway conduit system are by no means easy. They involve factors including not only electrical but mechanical details of the utmost importance. We, therefore, desire to draw the attention of our readers to a system of this nature, which has been in successful operation at Washington since last November, and which is the invention of Mr. Malone Wheless, of the Wheless Electric Railway Co., of Washington, D. C.

The road, which has been constructed to demonstrate the practicability of the system, starts near the power-house of the Eckington and Soldiers' Home Electric Railway, and runs for a distance of about one-sixth of a mile, including several abrupt curves and a grade of 11 per cent., thus presenting in a bunch all the severe conditions met with in actual practice.

Mr. Wheless has set himself the problem of furnishing a system which shall at once be safe and afford the least opportunity for leakage—one of the main difficulties to be

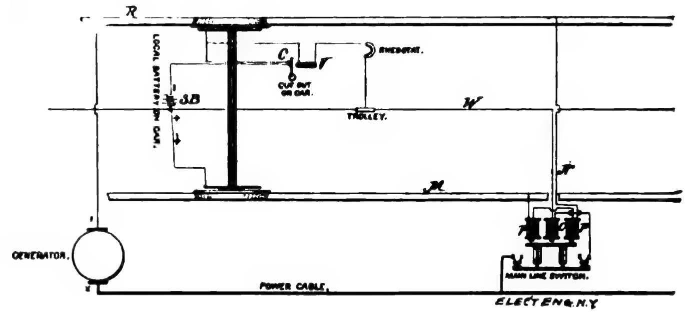

FIG. 4.—DIAGRAM OF CIRCUITS, WHELESS SYSTEM.

overcome in underground work. For that purpose the main current is carried in an insulated cable buried between the tracks, if a double track road, or by the side of the track, if a single track road. This cable extends the entire length of the road, and is the ordinary cable used in electric light work. From this cable the current is automatically switched into the conductor in the conduit. This latter conductor, however, is not continuous, but is built in convenient sections, of, say, 300 feet; and at the end of each section a small switch box is placed in the ground, through the medium of which current from the main insulated feeder is automatically sent into the section of conductor in the conduit over which the car happens to be passing at the time. It follows, therefore, that only a small fraction of the exposed conductor is in circuit at any one time, all other sections being dead. This, therefore, ensures safety and reduces any leakage to that minimum due to the section over which the car momentarily passes.

With this somewhat general description, as preliminary, we propose now to enter into a description of the details by which these desirable results are accomplished and which we were recently afforded an opportunity to examine. The car

itself, as it stands on the track, is shown in the accompanying engraving, Fig. 1, and evidently does not differ in outward appearance from those now in general operation. The conduit in this instance is laid in the centre of the track, and within it a bare wire is supported on insulated fastenings. As before stated, this wire is run in three hundred foot lengths, each length constituting a section. The lengths of the sections can, of course, be

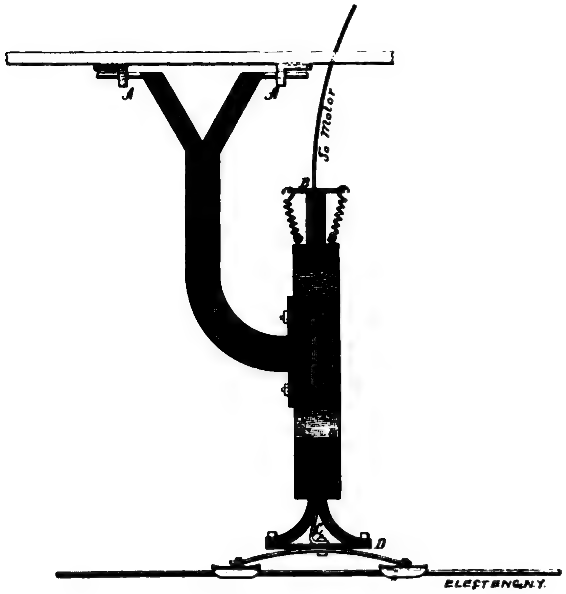

FIG. 5.—TROLLEY AND CARRIER.

made longer or shorter as the necessities of any peculiar construction may demand.

The engraving, Fig. 2, shows the ends of the sections as they appear in the conduit. The two ends of the section, marked "trolley wire," approach each other to within five inches, and are then separated by a block of slate, which is fitted in a slot and makes a continuous coupling between the ends of the wire. The object of inserting the slate is to afford a bearing for the slider and to prevent its jamming on the ends of the sections in passing over them. The ends of these sections are supported by metallic straps which fasten around the insulated hood, the hoods being made strong enough to carry any pressure required from the weight of the trolley and the line. The broken ends of the bracket upon which the hood is screwed are fastened to the side of the conduit, as shown at A in Fig. 3.

The lines shown in Fig. 4, which extend from the sections are passed under the rail and into the switch-box. It is into this line that the current is passed when the armature in the switch-box, which will be described presently, is drawn up; the armature connects the conductor from the trolley wire to a conductor from the feeder cable, C, which is also passed under the switch-box.

A clear comprehension of the operation of the switch-magnets will be obtained from the diagram, Fig. 4. From this it will be seen that when the car enters the section a local battery on the car, consisting of four accumulators, S B, vitalizes the two extreme poles, P P, of the magnet in the switch-box by traversing the rail, M, and returning by the conductor, N, to the opposite rail, thence through the cut-out, C, to the negative pole of the battery. When this is done the armature is instantly drawn up and the current from the feeder cable is let in through the carbon contact points and passes around the centre coil, O, in the switch-box to the trolley wire, W. From this wire it passes to the trolley, then through the rheostat, thence around the magnet V, instantly drawing back the plug at the cut-out, C, and opening the local circuit and battery before entering the ground through the rail, R.

The cutting out of the local battery on the car is evidently a most important feature, as it prevents a draining of the storage cells, and in actual operation these cells are only called upon for current for a fraction of a second as the car passes from one section to the next. This saving on the cells makes it necessary to charge them only once in several weeks, and, as there are only four cells used, they can be put in at any convenient time.

The car repeats the operation just described at every section; thus there is no dead point on the line, as the shoes of the trolley, shown in Fig. 5, are set at such a distance apart that they span the ends of the sections, and the current can be taken to the car through either shoe should the car happen to stop directly over a section.

When the car stops, the current is instantly cut off from the wire in the conduit, owing to the fact that the armature in the switch-box is held up by the main line current passaround the centre magnet, as already described, and as shown in Fig. 4; and in addition, when the rheostat is thrown off, the main line current is cut on the car and the armature, C, instantly falls. The local magnet in the switch-box could not, of course, hold up the armature after the main line current has opened the local circuit on the car.

The engraving, Fig. 6, has been made directly from a photograph of one of the switches now in use on the road. The carbons shown on the ends of the armature have apparently an indefinite life and would only need replacing on account of actual breakage. This feature, as applied to electric railway work, is decidedly novel, and certainly makes closing and releasing of the sections certain, provided there is no bad work mechanically. The current from the cable enters this switch from the line on the lower left hand side of the switch, and its route through the switch can be easily understood by reference to Fig. 4. This form of switch has been in daily operation for over four months and the carbon contact points are apparently in as perfect a state of preservation as they were when first put in.

The trolley used on the car is shown in Fig. 5. It is supported from a beam on the bottom of the car and is given a lateral play by means of the sockets, A, and a perpendicular play by the traveling guide, B. The lateral play is given it to permit of passage around curves, and the perpendicular play allows the guide to hold the shoes on the wire by being forced down constantly by springs on the

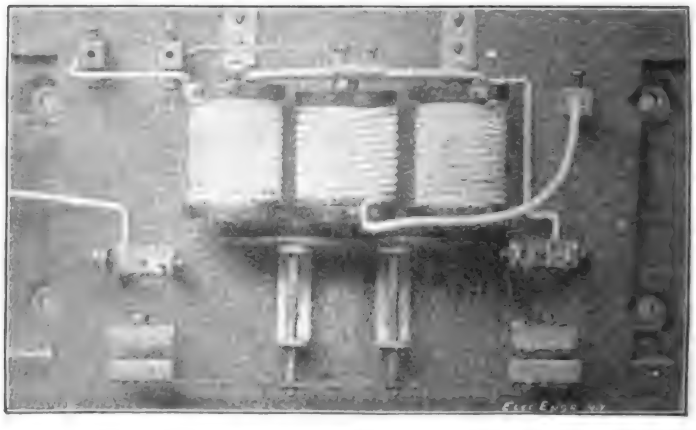

FIG. 6.—SWITCH FOR CONNECTING FEEDER WITH WORKING CONDUCTOR.

top of the guide. The current enters the motor through the two steel friction shoes and passes along the metallic bar connecting them together. From the bar the current passes to the line C, thence through the centre of the traveling guide, coming out at the top and thence to the motor. The frame of the trolley is made of steel and is insulated from the shoes by a heavy piece of insulation, D. The trolley shaft is about half an inch thick, which allows it to fit comfortably in the slot in the conduit. In this way it is difficult for the shoes to leave the wire, and a continuous contact from the shoe to the wire in the conduit is given.

The local cut-out on the car is shown in perspective in

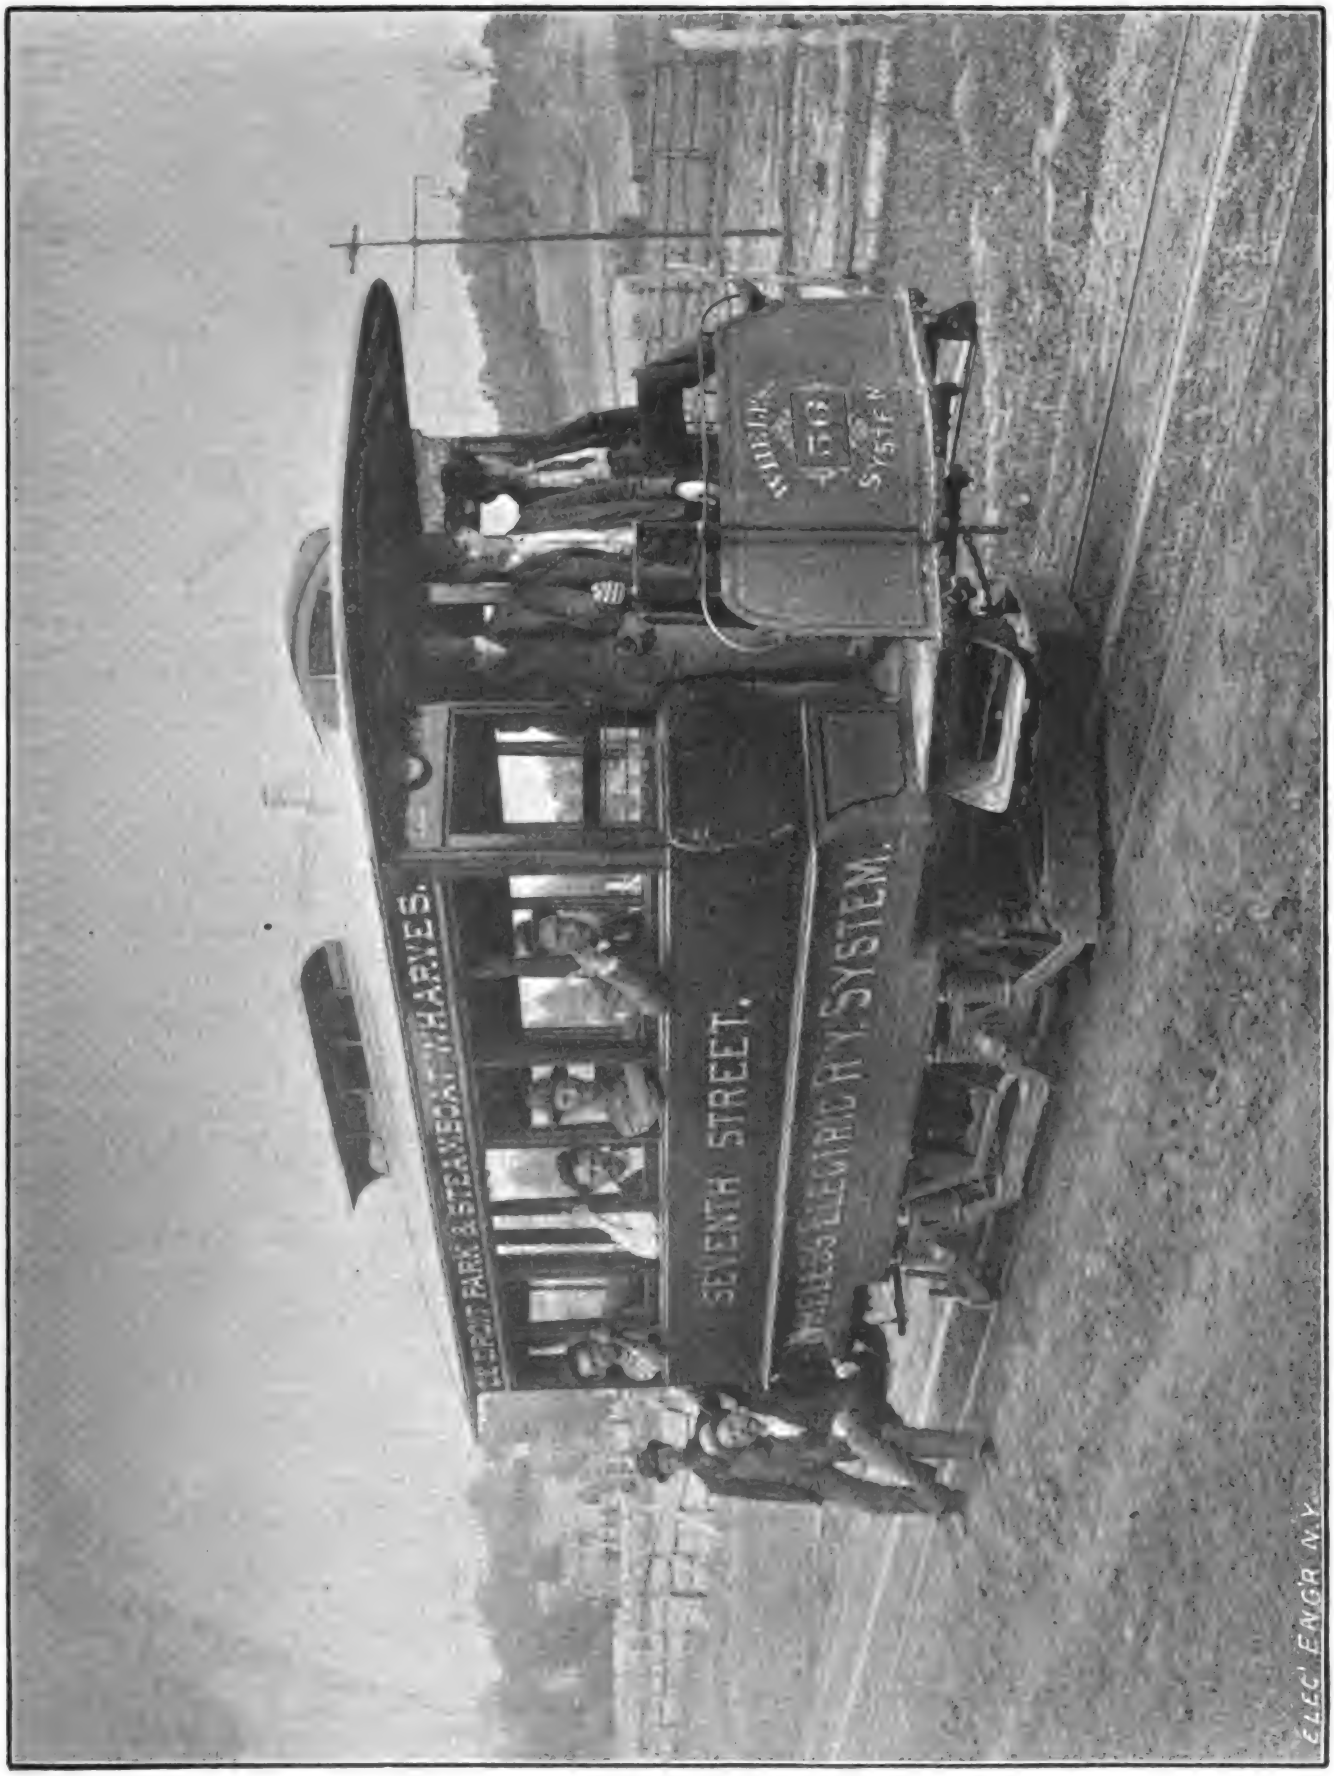

FIG. 1.—THE WHELESS CONDUIT ELECTRIC RAILWAY SYSTEM, WASHINGTON, D. C., SHOWING CAR, CONDUIT, ETC.

Fig. 7. This cut-out is placed under the bottom of the car, and is indicated at c, in the diagram, Fig. 4. Its use, as already explained, is to open the battery circuit on the car after the storage battery which the car carries has performed the function of raising the armature in the switch-box, letting in the main line current to the motor. The main line current, on entering the motor, passes around the magnet, and, drawing up the armature, cuts the local line at c, and holds it open as long as there is any current passing through the motor; in other words, as long as the car is moving.

To stop the car the rheostat must be thrown off, as usual, and when this is done the power current is cut, and, of course, the magnet, shown in Fig. 6, becomes dead and the local line is closed again. The local circuit would then immediately draw up the armature in the switch-box again if it were not for the fact that the local line on the car is still held open by the rheostat arm. When the latter is again thrown on to start the car, it plugs the local, and the car is at once started, as already explained. A sectional end view of the conduit employed in the Wheless system is shown in Fig. 3.

As will be seen, the conduit yokes are seated upon the cross-ties, the rails being elevated to convenient heights by the steel saddles which support them. The conduit is built

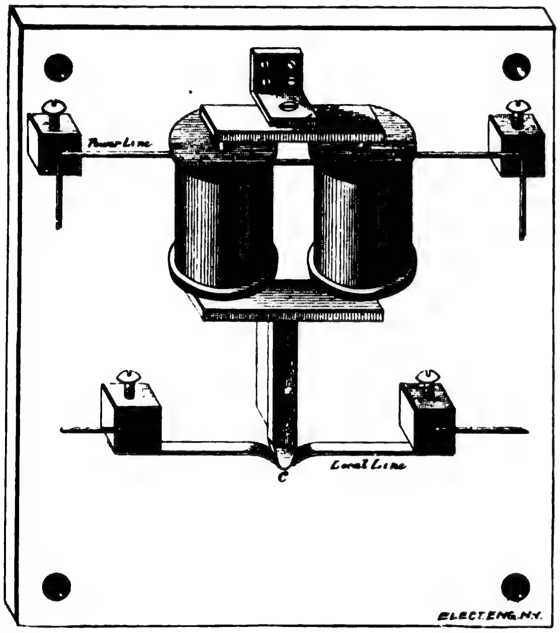

FIG. 7.—LOCAL CUT-OUT ON CAR.

with suitable drains, at convenient points; the drains also passing under the switch-box at the side of the track. The body of the yoke which rests on the tie is made of cast-iron, faced with steel angle plates bolted to the top of the yoke and supported by strong bars laid out to arms extending from the side of the yoke. The conduit has openings at convenient points for entering it and removing accumulations of dirt.

Recent tests of this system in its practical workings show a car of great power and efficiency. Fifty-two men were placed on the car and it ascended the 11 per cent. grade at a speed of six miles per hour. The car was then stopped on the grade, and, on being started again, gathered its speed, with this weight upon it, inside of thirty feet.

Where heavy grades are to be ascended, a separate feeder cable can evidently be used on the grade, so that as soon as the car starts up the grade it ceases to take current from the cable supplying other cars on the route, thus preventing a drop in potential.

These details embody the main features of Mr. Wheless' system and present a solution of the railway conduit problem, which deserves consideration by those who look towards the general introduction of electric railways in our large cities. The trials which we witnessed ourselves, a few days ago, involved every condition of operation met with in actual practice and were made during the recent abnormally heavy rains. While also entirely free from the mishaps usually accompanying the demonstration of new work, these tests went to convince us that the early extension of electric railway work on the conduit system is now to be looked for.

ON THE DISCHARGE OF ELECTRICITY THROUGH GASES AND ON THE FALL OF POTENTIAL.[1]

BY A. HEYDWEILLER.

SIR WILLIAM THOMSON first observed that the difference of potential necessary to cause the passage of an electric spark through a gas (air) between very close, smooth electrodes, is not proportional to the distance between them, but increases more slowly than this distance. Maxwell gives two explanatory notes on this point. The author wishes to corroborate that one which states that this may be due to a condensation of the air at the surface of the conductors, so as to produce better insulation, the two condensed strata being brought up to one another when the two electrodes are very close. A further question is as to what is the result in a non-homogeneous medium, as, for instance, between the surfaces of concentric cylinders, or two spheres external to one another. In the numerous experiments made on this point, no attention has hitherto been paid to the fact that the greatest and least values of the fall in potential at discharge are easily calculated from the size and distance of the electrodes and from the residual potential. This calculation shows also that the maximum tension is not nearly the same in all cases; but the mean (so called, absolute) values of the fall of potential taking place at discharge at the two electrodes in all cases with increasing distance, shows an analogy with that taking place in homogeneous fields. The limiting value of the fall of potential increases with increasing curvature of the electrodes.

The conclusions to which the author arrives are :—

(1) It is possible to explain the peculiarity of fall of potential on a spark passing through air between smooth electrodes, on the supposition of air being absorbed on the electrodes; but they must be larger than this layer of condensed air; further, it decreases with increased curvature.

(2) The mean fall (*i. e.*, the arithmetical mean of the differences at both electrodes) is, in non-homogeneous, as in homogeneous, fields, independent of the distance.

(3) The mean fall increases with increased curvature.

(4) From this mean fall, the maximum charge of a sphere in air may be calculated.

ELECTRIC RAILROADING AT COLORADO SPRINGS.

The Colorado Springs Rapid Transit Railway Company are rapidly completing their system of electric railways, the greater part of which is suburban. Four lines of single track road radiate from the centre of the city to the following points:—Rosswell, 3⅛ miles; Austin Bluffs, 5 miles; Cheyenne Canon, at the foot of Cheyenne Mountain, 5.4 miles; Manitou Springs, at the foot of Pike's Peak, 6 miles; Spruce street extension, 1¼ miles; besides which there is a city loop. The total mileage of the system will be about 22 miles. The power station has an aggregate capacity of 300 h. p. and consists of 2 Heine Safety boilers, each of 150 h. p. capacity, fitted with Murphy's patent grate setting and stoking device; 2 Allis-Corliss engines, each of 150 h. p. capacity, belted directly by means of link belting to line shafting, fitted with Hill patent clutches, driving four 50,000 watt Edison generators. Eighteen motor cars are in use. All lines are completed, except the Manitou, which is at present only operated to Colorado City, 2⅛ miles distant, but work is being pushed rapidly and will be completed in 30 days.

1. *Wiedemann's Annalen.*

ELECTRICAL ENGINEERS.

CARL HERING.

Carl Hering, B. S., M. E., was born at Philadelphia, Pa., in 1860, and is one of the five sons of the late Dr. Constantine Hering, the well-known founder of homœopathy in America. He is of German descent; his parents were born in Germany, but lived in America the greater part of their lives. He received his collegiate education at the University of Pennsylvania, in Philadelphia, entering in 1876. Physics and mechanical engineering were his favorite branches. He took the course in mechanical engineering under Prof. Wm. D. Marks, and graduated with honors in 1880, taking the degree of Bachelor of Science and Mechanical Engineer.

In 1881, he was elected Instructor in Mathematics and Assistant in Mechanical Engineering in the University of Penna., which position he relinquished a year later to become Assistant in Physics in the same University under Prof. George F. Barker, at that time one of the principal consulting electricians of the Edison Co. His object in taking this position was to study electrical engineering, which was, at that time, just beginning to become an important branch, but which was not yet being taught anywhere as a special course. While there, he published his first article, a table of equivalents of electrical and mechanical units of measurement. A year later he decided to go abroad to study the subject there. He was at that time (1883), elected Commissioner of the Franklin Institute of Penna., to the International Electrical Exhibition at Vienna, at which exhibition he was made an active member (the only one from the United States) of the International Jury, or Scientific Commission as it was called, who undertook the elaborate scientific tests of the exhibits. This work, which was started on very elaborate plans, continued several months after the closing of the exhibition. Thence he went to Darmstadt, in Germany, to continue his studies in electrical engineering at the Polytechnikum, under Prof. Kittler, who had been one of the principal experts at the Vienna Exhibition tests. This college was at that time one of the few institutions where electrical engineering was being taught as a special course. Shortly after beginning study there, Prof. Kittler appointed him his assistant, which gave him additional facilities for experiment and research. In 1884, he returned to the United States to become acting electrician for the International Electrical Exhibition in Philadelphia, held under the auspices of the Franklin Institute. He was also made one of the active members of the Scientific Commission appointed to make the tests and reports of the exhibits. In the latter capacity he urged the importance of a comparative life test of incandescent lamps, which had been wanting in the Munich and the Vienna tests to make them of value. Though this test was at first opposed and ridiculed by many of the prominent and well-known members of this Commission, it was finally started by Mr. Hering, through the efforts and aid of Prof. Marks, who appreciated the importance and value of such a test and who did not fear the work involved. Owing to the elaborate preliminaries and the repeated delays, the tests were not started until after Mr. Hering's departure abroad, on business, but they were subsequently carried out on much more elaborate plans through the untiring efforts of Prof. Marks, assisted by others. These tests, now well known as the Franklin Institute Duration Tests, remain the only ones of the kind that were made at an exhibition. Among the new testing instruments prepared by Mr. Hering at this exhibition was a galvanometer for measuring volts with an accuracy of one-tenth of a per cent. and a range of from 1 to 3,000 volts; also a means of measuring a current of 3,000 amperes, from the Forbes unipolar machine. In the fall of 1884, he returned to Germany to become electrical engineer for one of the large firms there. He then returned to Philadelphia, as consulting electrical engineer for a large company there, after which he started a practice of his own in that city, which he carries on down to the present time. In 1886 and 1887, he took charge, temporarily, of the course in electrical engineering at the University of Penna. In 1889, he was sent to Paris by the United States government to make the report on the electrical exhibits at the Paris International Exposition. Here he was made one of the two United States members of the International Jury, to award the prizes in Class 62 (Electricity), his very able colleague being M. Abdank-Abakanowicz. He was also elected delegate from the Franklin Institute to this exhibition for the class "Electricity," and was one of the representatives of the American Institute of Electrical Engineers, at the International Electrical Congress in Paris. At the close of the exhibition, he received the decoration "Officier de l'Instruction Publique," known as the "Gold Palms," from the French Government. In the spring of 1890, he was elected by the American Institute of Electrical Engineers as the representative whom they were asked to appoint, to act as one of the committee of three judges to award the prizes at the St. Louis Electrical Exhibition of 1890.

Carl Hering.

In addition to practising as a consulting electrical engineer in Philadelphia, Mr. Hering is devoting himself specially to testing and general expert work. He is the author of a number of papers and tables on electrical subjects, and of two books on dynamos. He is the inventor of several improvements in dynamos and storage batteries. He will be remembered by our readers as one of the oldest contributors to The Electrical Engineer, His valuable book on "Dynamo Electric Machines" is based on articles that appeared in these pages.

CARTY'S BRIDGING BELL SYSTEM FOR TELEPHONE LINES.

The system of bridging bells invented by Mr. J. J. Carty, the electrician of the Metropolitan Telephone Company, which was explained in his address on the subject at the recent Detroit telephone convention, deserves more than the passing notice which, pending diagrams and more explicit details, was contained in our report of the proceedings of the convention.

The practices which have been so successfully applied in telegraphy were at first applied to telephone circuits, but by no means with the same result, and no more striking instance of the different needs of the two branches of electrical engineering is afforded than in the arrangement of a number of stations on one line. As Preece says, in his

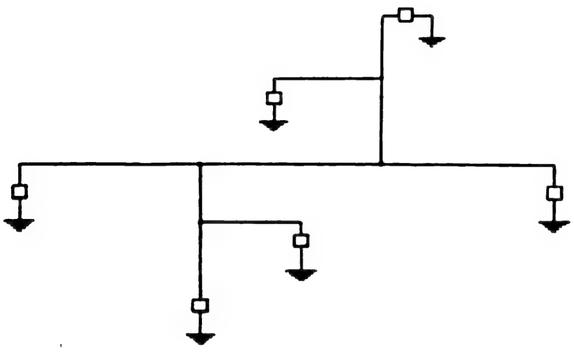

Fig. 1.

work on the telephone, "Nothing is easier than to place several telegraph stations on the same wire, while in telephony the conditions are entirely altered." The ordinary practice in telegraphy is to loop the various stations in the line, and this has been tried in telephony, with the result that the limit of speaking was soon reached, owing to the immense amount of resistance thrown in circuit with the addition of each additional magneto-bell, the counter E. M. F. of the magnet coils of course vastly increasing the actual resistance of the wire in the instruments. The bridging system has also been tried, but still with unsatisfactory results, and it has remained for Mr. Carty to design a bell—for here lay the crucial point of the problem—which permits of a far greater number of stations being placed on one line than has hitherto been attempted, and with the most successful results as regards both speaking and ringing.

In planning his magneto—which is now known as the "Metropolitan" bridging bell—Mr. Carty has kept in full view the peculiarities of the alternating current and the beauties of multiple arc working, which have been so thoroughly taken advantage of in electric lighting. The essential points of the bell are that the generator armature is wound to a very low resistance, the loss in E. M. F. which would otherwise follow being avoided by employing extra strong permanent field magnets, and that the ringer magnets are wound to a thousand ohms actual resistance with No. 33 wire, involving a great number of convolutions and, consequently, a high coefficient of self-induction. In this way the resistance of the bell circuit to the telephonic current may be 10,000 ohms, or even higher, and it is obvious that, even though every station on the line is connected so as to form a shunt across from one arm of the circuit to the other, it is a shunt of such an enormous resistance as compared with that of the speaking circuit that the talking is in no way impaired. The resistance of the speaking circuit may be considered as merely the resistance of the line plus that of the receivers and one transmitter secondary coil, as the other can always be cut out by the listener by means of the button provided for that purpose. It will be noticed that in planning out his system Mr. Carty has improved upon the ordinary multiple arc circuit as found in electric lighting, as every station on a line equipped with bridging bells is not only a receiving station but also a transmitting station; if such an arrangement had been proposed a short time ago probably few would have thought it possible.

The accompanying Figs. 1 and 2 illustrate the application of the bridging bell to both grounded and metallic circuits. On lines of either class, the bell is working with the best of results. In New York city several important private lines, one of them containing as many as twenty stations, have been equipped in this manner. All of these lines are busy throughout the day, and the users are highly satisfied with the clear speaking. In San Francisco an iron wire fifty miles long, containing eight way stations, was formerly arranged on the looping-in system, and it was impossible to speak from end to end of the line. The bridging bell has lately been applied to this very sick telephonic patient, the bells being legged on to ground as shown in the diagram, and the way line now works as well as the through line which is run on the same poles. It would appear also that the bridging bell is a panacea for all telephone complaints, as the reports in this instance state that, whereas with the old arrangement there was considerable trouble from cross-talk between the two wires, now there is but very slight induction.

An item of considerable importance which is liable to be overlooked in discussing the electrical advantages of the bridging bell is the saving, brought about by its adoption, in the expense of construction and maintenance of lines. As a general rule, when a number of stations are to be connected in one line they are so scattered that the most convenient method of reaching them is to run branches out from certain centres, generally local exchanges, the route of the main part of the line being determined by that of

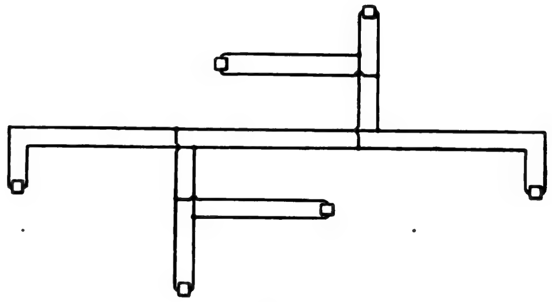

Fig. 2.

the trunk lines or underground cables belonging to the general system. With the stations looped in it would obviously be necessary, in the case of a grounded circuit, to run two wires, one lead and one return; or, if a metallic circuit, four wires would be required. With the bridging system only one wire is used in the first case and two in the second, as is shown very clearly in the diagrams. Consequently, there is a great saving in cost of material and construction, and also in maintenance, and Mr. Carty's device possesses the double advantage of being vastly more efficient than the methods it supplants, and also considerably more economical.

THE MONTE SAN SALVATORE ROAD.

A steep cable railway has lately been built up the slopes of Monte San Salvatore, near the Lake of Lugano, Italy. The power for working is obtained from a stream in the vicinity, and is transmitted electrically to the operating station. The water is led through a long iron pipe to two Girard turbines coupled direct to Oerlikon dynamos. The road is about a mile long and has grades varying from 17 to 60 per cent.

THE INTERIOR CONDUIT SYSTEM AND RULES IN PHILADELPHIA.

THE method of wiring buildings by means of the interior conduit system has attracted considerable attention in Philadelphia among electrical engineers, architects, insurance inspectors, owners of property, and others. The Interior Conduit and Insulation Co. has recently found it necessary to establish an agency there, in charge of Mr. B. Frank Johnson, and we are glad to have the opportunity of showing here the very handsome and striking sample board that he has placed in his office in the Provident Building there. It is a graphic representation of the system, as run through any building, and the samples displayed on the lower panels illustrate the different finishes that the tube is capable of receiving, such as old oak, brass, copper, nickel, china gloss, etc.

Taps. A separate tube must be laid for each wire except in case of "taps" or "branches" for not more than fifteen (15) amperes; in which case conductors having only a cotton insulation separating them will be required.

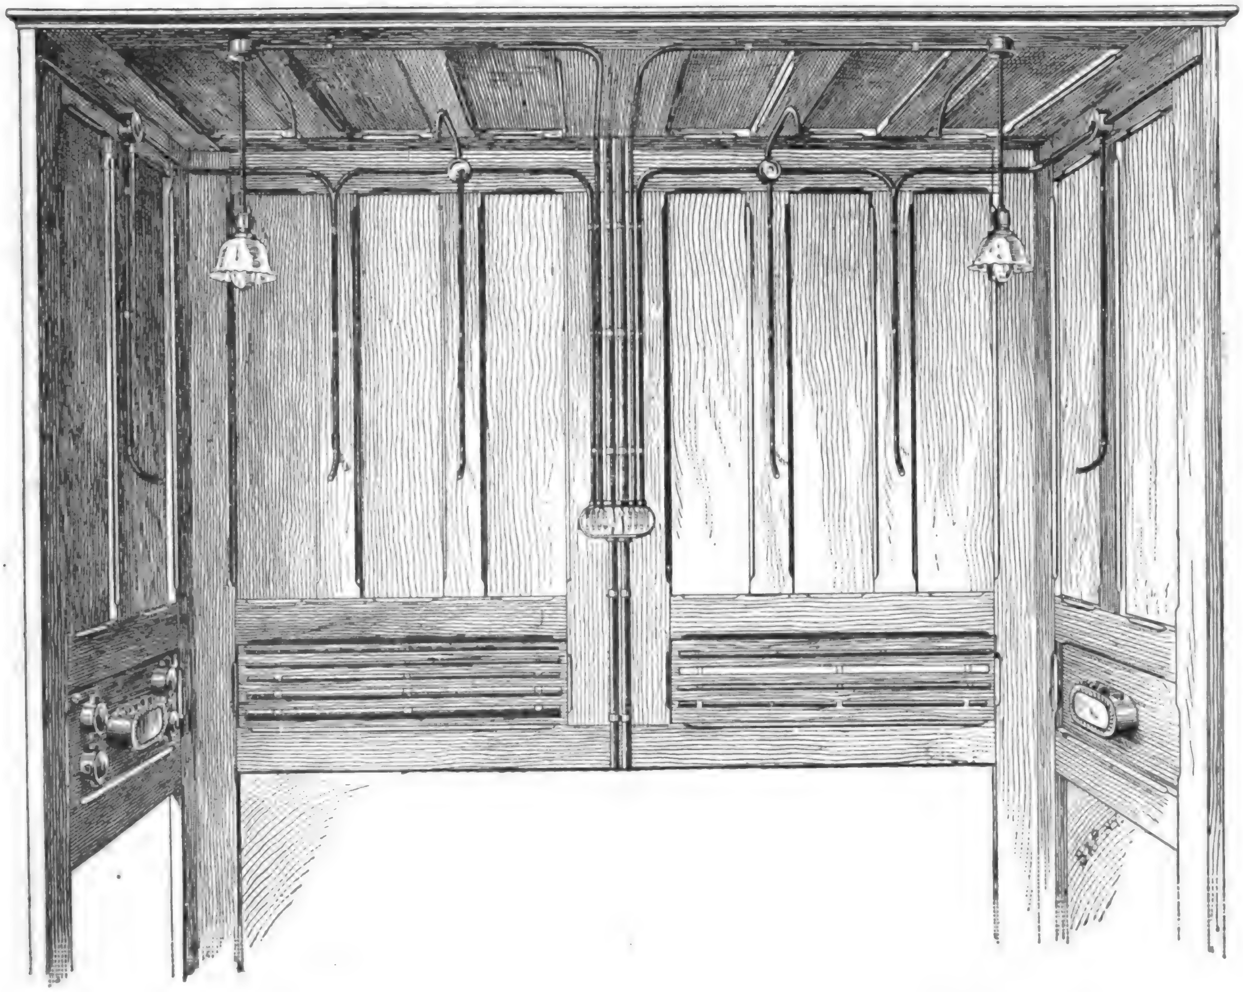
Wire. Rubber-covered wire must not be placed in the conduit where two (2) wires of the same or opposite polarity are run in the same tube.

Conduit. The conduit must be continuous from one junction-box to another, or to fixtures or switches.

"Clips." The tubing must be held in place by brass "clips" and in no case will staples be allowed.

Outlets. At all outlets the tubing must project through the plaster at least one inch and the tube left in such a way as not to be disturbed by the plasterers.

Joints. All the joints are to be made with the insulating compound of the Interior Conduit and Insulation Co., and carefully "wiped," so as to prevent moisture from entering. "P. & B." paint or any other material than the compound named must not be used. Before making joints the ends of the tube must be cut perfectly square so that they will butt together.



BOARD ILLUSTRATIVE OF THE METHODS AND DETAILS OF THE INTERIOR CONDUIT SYSTEM.

In connection with this work in Philadelphia, a very important set of interior conduit specifications have been drawn up and put into force, with the approval of the Philadelphia Board of Fire Underwriters; and as the matter is one of such general and vital interest, we print them below in full:

System. The building is to be electrically conduited and the conduit system of the Interior Conduit and Insulation Co. to be used throughout the entire building.

Sections. The building is to be divided into —— sections, as marked on the plans, and a separate set of tubes run for each "riser" in each section for the mains, said tubes to be one inch inside diameter.

Size of Tube. All tubing must be of sufficient size and so placed that the wires may be drawn, withdrawn and re-inserted at will.

Elbows. No more than four (4) elbows will be allowed between outlets, and should it become necessary to have more than four (4), an intersection box must be used. After the tubing is completed between outlets, a fishing wire, with a ball attached to the end, must be inserted, so as to make sure that no compound obstructs the tube.

Junction Boxes. Four (4) circuit main junction boxes are to be placed in each section on each floor throughout the building and from which all "taps" or "branches" in that section are to run.

Cut-outs. Four (4) circuit porcelain cut-outs are to be used. These cut-outs are to be placed in the junction

boxes and each branch wire leading from the cut-out must be protected by a safety fuse.

Inserting Wires. After the building is electrically conduited and before inserting the wires, powdered soap-stone must be blown into the tubes.

Inspection. The Conduit System, when completed, must in every way pass the inspection of the Philadelphia Board of Fire Underwriters, or, if so requested, the same to be inspected and passed by the Conduit Co., or both.

SWINBURNE'S "HEDGEHOG" TRANSFORMER.

BY NIKOLA TESLA.

SOME time ago Mr. Swinburne advanced certain views on transformers which have elicited some comment. In THE ELECTRICAL ENGINEER of Sept. 10. there are brought out further arguments on behalf of his open circuit, or, as he calls it, "hedgehog" transformer, claiming for this type a higher average efficiency than is attainable with the closed circuit forms. In regard to this, I say with Goethe, "Die Botschaft hör' ich wohl, allein mir fehlt der Glaube—I hear the message, but I lack belief."

Many of Mr. Swinburne's arguments are in my opinion erroneous. He says: "In calculating the efficiencies of transformers, the loss in the iron has generally been left completely out of account, and the loss in copper alone considered; hence, the efficiencies of 97 and 98 per cent. claimed for closed iron circuit forms." This is a statement little complimentary to those who have made such estimates, and perhaps Mr. Swinburne would be very much embarassed to cite names on behalf of his argument. He assumes the loss in the iron in the closed circuit forms to be 10 per cent. of the full load, and further "that in most stations the average use of lamps is less than two hours a day, including all lamps installed," and arrives at some interesting figures in regard to efficiency. Mr. Swinburne seems not to be aware of the improvements made in the iron. The loss with the best quality of iron will, I believe, not reach 6 per cent. of the full load by an intelligent use of the transformer, and there is no doubt that further improvements will be made in that direction.

As regards the second part of his assumption, I think that it is exaggerated. It must be remembered that in most central stations or large plants due care is taken that the load is favorably distributed and in many cases the wiring is such that entire circuits may be shut off at certain hours so that there is during these hours no loss whatever in the transformers.

In his "hedgehog" form of transformer Mr. Swinburne reduces the iron considerably and comes to the conclusion that even in small transformers the iron loss is under one per cent. of the full load, while in the closed circuit forms, it is, according to him, 10 per cent. It would strengthen this argument if the iron would be dispensed with altogether. Mr. Swinburne does not appreciate fully the disadvantages which the open circuit form, operated at the *usual period*, entails. In order that the loss in the iron should be reduced to one-tenth, it is necessary to reduce the weight of the iron core to one-tenth and subject every unit length of the same to the same magneto-motive force. If a higher magneto-motive force is used the loss in the core will—within certain limits, at least—be proportionate to the *square* of the magneto-motive force. The remark of Mr. Swinburne, "If the iron circuit is opened, the sides of the embracing core can be removed, so the loss by hysteresis is divided by three," is therefore not true; the loss will be divided by $3 \times \frac{F^2}{F_1^2}$ where $F_1 > F$. If the iron of the open circuit form is made up in a closed ring the advantage will be at once apparent, for, since the magnetic resistance will be much reduced, the magneto-motive force required will be correspondingly smaller. It is probable that, say, four Swinburne transformers may be joined in such a way as to form a closed magnetic circuit. In this case the amount of iron and copper would remain the same, but an advantage will be gained as the total magnetic resistance will be diminished. The four transformers will now demand less excitation and since—under otherwise equal conditions—the gain depends on the square of the existing current, it is by no means insignificant. From the above comparison it is evident that the core of such open circuit transformer should be very short, by far shorter than it appears from the cut in THE ELECTRICAL ENGINEER.

Mr. Swinburne is in error as to the motives which have caused the tendency to shorten the magnetic circuit in closed circuit transformers. It was principally on account of practical considerations and not to reduce the magnetic resistance, which has little to do with efficiency. If a ring be made of, say, 10 centimetres mean length and 10 square centimetres cross-section, and if it be wound *all over* with the primary and secondary wires, it will be found that it will give the best result with a certain number of alternations. If, now, a ring is made of the same quality of iron but having, say, 20 centimetres mean length and 10 square centimetres section it will give again the best result with the *same number of alternations*, and the efficiency will be the same as before, provided that the ring is wound *all over* with the primary and secondary wires. The space inside of the ring will, in the second case, be increased in proportion to the square of the diameter, and there will be no difficulty in winding on it all the wire required. So the length may be indefinitely increased and a transformer of any capacity made, as long as the ring is completely covered by the primary and secondary wires.

If the wires be wound side by side the ring of smaller diameter will give a better result, and the same will be the case if a certain fraction of the ring is not covered by the wires. It then becomes important to shorten the magnetic circuit. But, since in practice it is necessary to enclose the transformer in a casting, if such a ring be made, it would have to be protected with a layer of laminated iron, which would increase the cost and loss. It may be inclosed in jars of some insulating material, as Mr. Swinburne does, but this is less practicable.

Owing to this, the constructors of the most practical forms, such, for instance, as the Westinghouse transformer, to which the Swinburne reasoning applies, have been prompted to enclose the wires as much as possible with the laminated iron, and then it became important to shorten the magnetic circuit, because in this form only a part of the magnetic circuit is surrounded by the wires, as well as for other practical considerations.

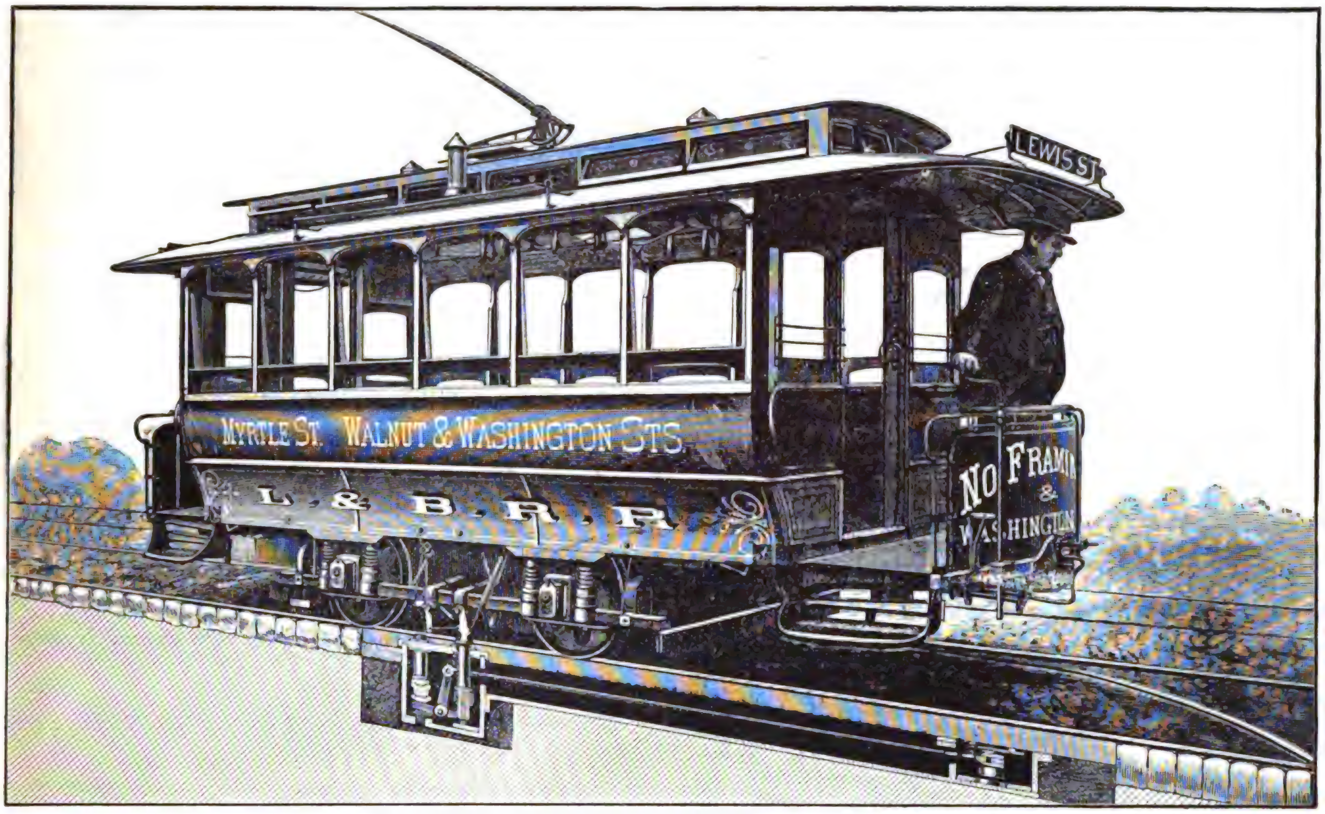
In practice it is desirable to get along with the least length of copper conductor on account of cheapness and regulation. Mr. Swinburne states that in his transformer the loss in iron is under one per cent. of the full load; all the balance of loss must, therefore, be in the copper. But since, according to him, the wires are of larger section, his transformer can hardly be an improvement in that direction. The gun-metal casting is also objectionable. There is no doubt some loss going on in the same, and besides it increases the resistance of the wires by a factor $\sqrt{\frac{S}{S_1}}$ where S is the total cross-section of the core and S_1 the section of the iron wires. There is one important point which seems to have escaped Mr. Swinburne's attention. Whether the open circuit transformer is an improvement, or not, will depend principally on the period. The experience of most electrical engineers has resulted in the adoption of the closed circuit transformer. I believe that I was the first to advocate an open circuit form, but to improve its efficiency I had to use a much higher period; at usual periods the closed circuit form is preferable.

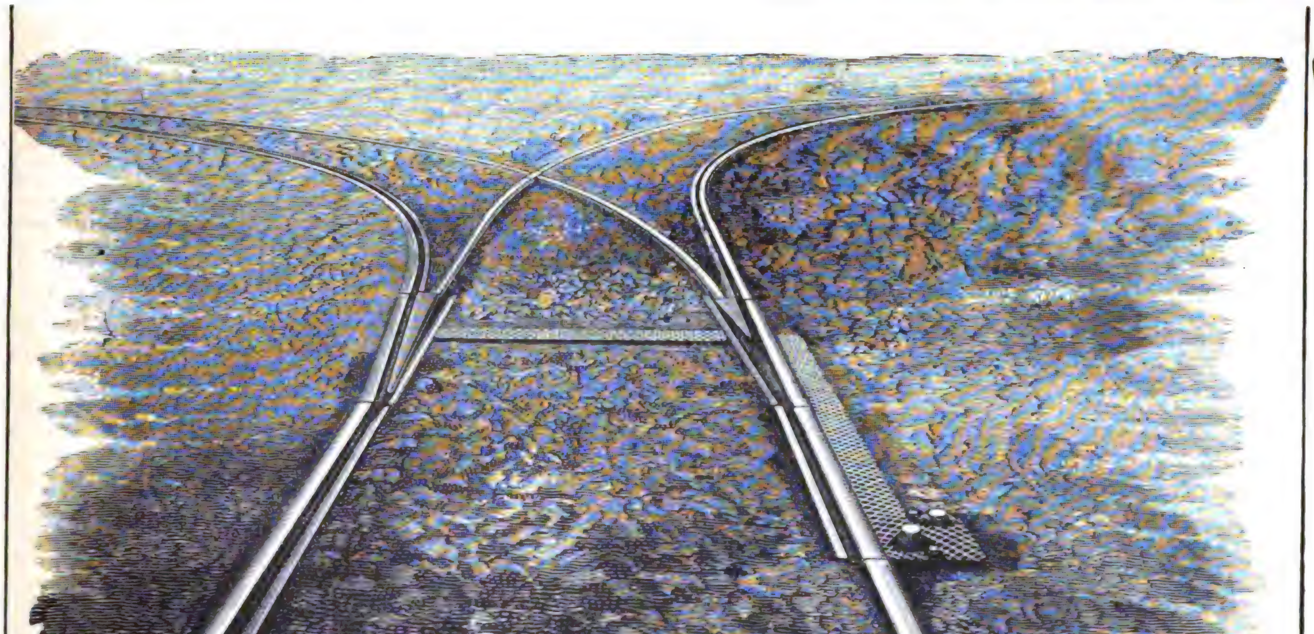
Mr. Swinburne makes some other obscure statements upon which I need not dwell, as they have no bearing on the main question.

THE ROWELL AUTOMATIC STREET RAILWAY SWITCH.

We illustrate on this page an interesting and useful device which has now been in successful operation on the Lynn & Boston Railroad Co.'s electric line, for a period of over eighteen months, and including two winters. It is of simple and durable construction, costs little for installation, and is under easy and complete control of the driver.

The switch is operated by two upright arms or plungers, in a box at the right-hand side of track. These upright arms or levers are connected to arms upon a rock shaft, which moves the switch tongue by a rod and crank. The plungers referred to are operated upon by either of two arms, the lower end or tread being a segment of a circle hung from the axle box, or the bar connecting them, and when not in use, are drawn up close to the truss of the car, by a spring, and are brought into an upright position, so as to strike the plunger and set the switch, by a lever in front of the driver, to be operated by the hand, or a pedal attached to the lever, as may be preferred.





Figs. 1 and 2.—The Rowell Automatic Switch as Used on the Electric Road, Lynn, Mass.

Fig. 1 represents an electric car in the act of setting the switch; also a longitudinal section of the switch mechanism. It will be noticed that the switch-setting attachment on the car is hung below the springs, on the bar connecting the axle boxes. This always remains at a fixed distance from the track. The arm always strikes the plunger,

and the movement of the switch-tongue is positive and sure. On this car the motorman brings the arm in position by a pedal.

Fig. 2 represents a section of road-bed with a left-hand switch, with cross connection in position, at the corner of Washington and Boston streets, Lynn. The box containing the switch mechanism is always placed on the right-hand side of the track, but the left-hand switch requires a cross connection, as above. This switch is being introduced by the Rowell American Switch Co., of Boston.

ELECTRIC STREET RAILWAY MOTORS.[1]

BY JOHN W. M'NAMARA, PRESIDENT ALBANY STREET RAILWAY.

SOON after the road-bed of the Albany railway was completed, and during the summer of 1864, when the directors and projectors of that road often saw four horses vainly endeavoring to draw the passengers contained in a twelve foot car up a grade of eight per cent. on State street, their attention was very naturally turned to the solution of the problem of transmitting the power of steam to the car.

Device after device was tried, but all proved failures, but still the directors never lost hope that at some time the problem would be solved. The successful use of the cable in San Francisco stimulated the stockholders to an effort to secure capital enough to construct a cable road; but the large amount of capital necessary to lay a cable road, and the want of faith in its working in this climate during the winter months, proved formidable obstacles.

More than twenty years had passed since the road was opened, and horses were still being used to draw the cars, when the attention of the managers of the road was called to certain experiments made by Mr. Leo Daft, who had for many years been a resident of two adjacent counties. Those of the managers who saw what the Daft electric motor did, felt that the day of emancipation for the State street car horses was rapidly drawing nigh. The experimental roads which are familiar to us all were earnestly examined, and the time when the obstacles to smooth operation would be overcome hopefully expected.

The time came much sooner than the most sanguine of us dreamed of; Baltimore, Scranton, Meriden, Richmond, Hartford and Boston followed in rapid succession, Scranton and Meriden demonstrating that it was possible to operate electric motors in winter. Our sister city, Troy, joined the electric band, and our sister company, The Watervliet Turnpike and Railroad Company, also contracted for electric equipment, before the Albany Railway could determine which of five systems was the best and make a contract. It was finally made with the Thomson-Houston Electric Company on the 30th day of November, 1889, and cars began running on the State street line April 28, 1890, and on May 1st all the horses on that line were withdrawn.

None of our drivers had had any training until the evening of April 27, 1890, yet we were able to begin running schedule trips with three cars the next day. Over four months' experience has taught us that the electric motor is efficient and reliable. We have yet to learn, by experience, that it will ascend State street an eight per cent. grade at the rate of five miles per hour in winter, as it has during the summer. We have also to learn, by experience, for it seems to be impossible to learn it in any other way, whether operating cars by electricity is more economical than by horses.

At the time of the introduction of the electric motor, the ordinary street car drawn by horses was the most convenient vehicle in public use. It was easy to enter one and easy to alight from one. The various makers had vied with each other, until one was able to step as easily from the street into a car, as he could ascend two steps of his own stairs. The early builders of electric cars endeavored to retain this feature of the street car, and placed the motor proper *on* the car, communicating motion to the axles by means of sprocket chains and wheels; but the mechanical difficulties, and the noise made by the chains and wheels led to their abandonment, and the motor or motors were then placed on the axles and *under* the car, where we find them to-day.

At first the easy-of-access feature was retained, but as the necessity for larger motors and more room for them became apparent, the car body was gradually raised until it is too high for children and elderly people to enter readily and a great deal of time is consequently used in receiving and discharging passengers.

The car body has been raised at the expense of comfort without, it seems to me, improving the condition of the motor. It is still under the car, near mud, dust, snow and slush, and is as difficult to get at as it ever was.

With these exceptions the electric motor of to-day is well nigh perfect, but these exceptions, as time goes on, will become more serious. When the novelty of being regularly and rapidly carried to their homes and places of business ceases, then passengers will call attention to the difficulty of entering and leaving cars.

The size of the motor, especially for use on grades, should not exceed the standard—sixteen feet for box cars and about twenty-five feet for open cars. On level and suburban roads, where the headway is not less than twenty minutes, larger cars with eight wheels might probably be economically used; but for populous cities where headway is less than five minutes, the old standard car body is, in my opinion, the best.

How the motor is to be arranged with reference to the car body so as to admit of easy access to it for examination and repair may, or rather must, be left to mechanical and electrical engineers. That we will continue to drag them in the dust and mud very long I cannot believe.

I think the opinion of all who are unprejudiced is, that the overhead single trolley under contact systems are the most reliable and efficient. With good overhead construction the loss of power in transmission is but slight, and the conductors are always where they can be seen and kept in place.

The ideal motor is one which is independent of every other motor or other engine, and contains everything necessary to make it go. This motor exists and seems to work fairly well on grades of not more than five per cent; but that it is capable of doing the work now being done by motors of overhead system is still problematical. However, as we have already witnessed such wonders in propelling cars by electricity, may we not hope for a storage battery electric car which shall be equal to any now in use?

We are justified, I think, in recommending to all who think of changing from horse to electric motors, or to all who think of building new roads, the overhead single trolley system. All the manufacturers of motors and generators have their systems in use in cities which can be readily visited, and the merits of all can be compared.

The question as to whether the electric motor is as economical as the horse car cannot yet be answered, and need not be answered. Just as certainly as the horse car supplanted the omnibus, the electric motor will supplant the horse car. The horse car, however economical, must go, and the electric motor, no matter how expensive, must come.

ON THE NEW STANDARD EDISON ELECTROLYTIC METER.[1]

BY A. E. KENNELLY.

SINCE the last meeting of the Association, the new and improved pattern of the Edison meter has been decided upon, received Mr. Edison's approval, and has been completed by the Edison General Electric Co. It has already been introduced into two stations, Brooklyn and Winnipeg, and the reports upon its behavior in each case are excellent.

There are four standard sizes of these 3-wire meters, Nos. 1, 2, 4 and 8; designed to supply 40, 80, 160 and 320 lamps respectively. Meters of larger capacity than these are made specially. In all sizes, however, the bottles and plates are alike and of the pattern shown; the spools are alike, making the resistance of the bottle circuit the same in every meter, and the drop of potential in the shunt at full load is the same; namely, four-tenths of a volt.

It is arranged that in the smallest, or No. 1 meter, each milligramme of weight transferred represents one ampere hour of supply, and the transfer is ten milligrammes per hour on full load. Similarly, every meter transfers ten milligrammes per hour at full load, so that each milligramme of transfer in a No. 8 meter represents 8 ampere hours, and in a No. 4 meter, 4 ampere hours, the number of the meter being the index of the supply in each case.

This greatly simplifies the system, reduces the weight of bottles that have to be daily transported, reduces the stock that the station has to keep on hand, makes only one balance requisite instead of two, and with reasonable care the use of a separate multiplier for each size of meter is not found to be an inconvenience. The objection has been urged against the system that there is danger in making one milligramme of transfer stand for so large a unit as 8 ampere hours in the No. 8 meter, since an error in weighing, or in the proportions of the meter, would result in an error in the bill eight times as great as the same discrepancies would produce in a No. 1 meter. Even granting the validity of the objection, however, it is evident that since meters are introduced in the capacity proportionate to their duty, the error in the No. 8 meter bill will only bear the same ratio to the whole amount charged, that the smaller No. 1 error bears to its bill. As a matter of experiment, however, taking, for instance, a series of tests made with the meters by Mr. R. S. White at Brooklyn, the records of a set of Nos. 1, 2, 4 and 8 meters worked in series and at intervals for a week on half load for the smallest, or five amperes, one-sixteenth of the load for the largest, showed

1. A paper read before the Assoc. of Edison Illum. Co.'s, Minneapolis.

practically the same result, the No. 8 meter under-indicating about 2 per cent.

This high degree of relative accuracy, setting aside all question of care and skill, is secured by three things. The first is a higher degree of absolute accuracy in general. The old pattern meter is universally admitted to be a faithful and accurate instrument, but the intrinsic accuracy of the new pattern is about three times as great. The only chance for error in the operation of the electrolytic meter, accidents aside, is the variation of resistance in the bottle, whereby the true ratio between the currents in the bottle and shunt circuit is upset. The extent of such a disturbance, of course, depends upon the relative proportions of resistance in bottle and spool. Suppose it were possible for the new bottle to even double its resistance and to become 5 ohms instead of 2.5 at normal temperature. In circuit with a spool of 46¼ ohms, such a change would only upset the balance and make the record in defect 5 per cent. In the old pattern meter, the doubling of the bottle resistance, were such a variation to be expected, would make the readings 15 per cent. in defect.

The second preventive of error in the larger sizes is due to the uniformity in the size of plate. A cause of discrepancy has always existed in a slight gain of the plates in weight independently of the current's action and due to their oxidation superficially. With care this source of error has always been minimized, but with the old meters it increased with the size of the meter, since a larger plate offered a larger surface to oxidization. In the new pattern it is, of course, a fixed amount in all sizes, and owing to the small area of plate is in any case very small.

The third precaution against error in the larger sizes is the use of duplicate bottles in the Nos. 4 and 8, as mutual checks which are not required in the Nos. 1 and 2.

Another improvement is in the plates. These are castings of pure zinc alloyed with two per cent. by weight of pure mercury. This amalgam has the advantage of being more readily brought into good condition for use than the rolled plate; the trouble of varnishing is also saved. The only other noteworthy change has been in the solution, which is about twice as dense as in the old bottles.

Mr. Edison has recently completed a mechanical meter on the pattern of one of his early patents in that direction. This instrument is a small motor delicately constructed. The armature commences to rotate as soon as one lamp in the supplied circuit is turned on. The rotation accelerates as more lamps are lit, until, at the full load of 20 lamps, the speed is 600 revolutions per minute. A counter, worked from the armature shaft, records the number of rotations, and on duly proportioned dials, the supply. The field magnets are kept charged by a feeble current from the mains, while the main current passes through a shunt as in the electrolytic meter, and from the shunt terminal, wires pass to the armature. The drop of potential in the shunt at full load is 1.5 volt. The model, though complete in itself, will be slightly modified in detail to suit commercial use, and will then be available for such cases where a mechanical meter is desirable. Mr. Edison does not consider that a mechanical meter can possibly be as cheap or as reliable as the electrolytic meter, first, owing to the necessary frictional error, which makes the record too low for very light loads and low speeds; and, secondly, owing to the mechanical wear and tear of the working parts which will need attention and exchange from time to time; but there are cases in which a direct reading mechanical meter will be an advantage, and he expects that from the tests and behavior of this model it will serve the purposes.

CONCLUSIONS DRAWN FROM ONE YEAR'S EXPERIENCE WITH THE STANDARD EDISON METER.[1]

BY R. S. WHITE.

DURING the year's work with the new standard meter we have taken 4,088 incandescent, 853 arc light and 244 motor readings—a total of 5,185, and have obtained uniformly good results. In a large number of cases customers have kept tally of lamp hours—and in every instance expressed themselves as satisfied. A considerable number of tests have shown marked accuracy. The greater dispatch and care with which the meter work can be performed has been abundantly shown. The use of small and uniform plates secure, by the balance method, doubled accuracy in weighing and the elimination of the oxidation error. In brief, our experience with the standard meter shows improved ease and economy in operation with more uniform and accurate results. In so far as a chemical meter "fills the bill," little remains to be said.

It may be interesting to note the use of four Aron meters on our circuit for the past year. The frank, open countenances of these meters have won the favor of the meter man and the confidence of the customer. It is suspected also that the company would accept their advances with better grace were it not for their haughty treatment of the financial question involved.

We may conclude then that it is in the line of a direct reading dial meter that we are to look for the next advance in the commercial treatment of the meter question.

1. Read before the Association of Edison Illuminating Companies, at Minneapolis, September 17, 1890.

A NATIONAL CODE OF INSURANCE RULES AFFECTING ELECTRIC LIGHT AND POWER INSTALLATION.[1]

BY W. J. JENKS.

IT has often been noted as one of the evidences of the incomplete development of the present system of electric light and power construction that the rules enforced by the underwriters in different sections of the country are so widely different as to make it impossible for a construction firm in Boston to be at all certain of being able, without further education, to do work in Philadelphia acceptable to the insurance inspector, or for a supply man in Chicago to be sure that he is furnishing material which the underwriters of Cincinnati will approve.

From the time of the formation of the original rules for wiring of buildings for incandescent lamps (resulting from the conferences of the New York Board with the practical people of the Edison Company) to the present, all codes used by the insurance fraternity have, while annually growing nearer to a standard, embodied so many uncertain quantities and individual notions that it has been hard to predict what a year might bring forth in modification of existing requirements. Very much has been done by the earnest efforts of the inspectors of the New England Exchange, and the New York State Board, as well as by the practical labors of the Philadelphia fire patrol and the Chicago city officials; but it has been reserved for the present year to evolve a plan which promises to speedily revolutionize the chaotic condition of matters of this kind by harmonizing all the minor distinctions which exist in the codes heretofore enforced by the insurance inspectors of different sections in one National Code, which, by reason of the authority by which it is supported, will be adopted by a large majority, if not by the entire fraternity, of the insurance men in the United States.

At the Kansas City meeting, February last, the National Electric Light Association chose a committee for the purpose of conferring with the insurance people, and, if possible, of setting on foot such measures as might result in this uniform code. The action by which this committee was brought into existence is expressed in the vote taken at that session.

Pursuant to this plan the secretary of the committee, Mr. George Cutter, of Chicago, entered into correspondence with the representatives of the active executive insurance associations, and with the leading electric light companies of the country, and the result of his persistent and intelligent endeavors in this direction appeared at a meeting of the committee and the representatives of the two interests which convened at the Stockton Hotel, Cape May, August 16th, three days in advance of the first session of the convention of the National Electric Light Association.

The committee held its first meeting on Saturday evening, Mr. Cutter in the chair, and the names of the remaining gentlemen present were as follows:

C. M. Goddard, inspector New England Insurance Exchange, Boston, Mass.; E. C. North, chairman electric light committee, New England Insurance Exchange; S. E. Barton, president of the Electric Mutual Insurance Company, Boston; Wm. Brophy, chief inspector Electric Mutual Insurance Company, Boston, and representative of the Mutual Fire Insurance Companies of New England; F. E. Cabot, inspector Boston Fire Underwriters' Union; W. H. McDevitt, inspector Philadelphia Fire Underwriters' Association; J. P. Barrett, city electrician, Chicago, Ill., and also representative of the Chicago Board of Fire Underwriters; W. A. Anderson, secretary New York Board of Fire Underwriters, and also secretary of the National Board of Fire Underwriters; W. De L. Boughton, chairman electric light committee, New York Board of Fire Underwriters; H. O. Kline, chairman of the electric light committee Underwriters' Association of the Middle Department, Philadelphia, Pa.; J. J. Babcock, chairman light committee Insurance Association of the State of New York, Binghamton, N. Y.; C. E. Bliven, chairman electric light committee, Western Union Fire Underwriters' Association, Chicago, Ill., and representatives of the Fire Underwriters' Association of the Northwest; J. S. Alfred, inspector Southern Tariff Association, Atlanta, Ga.; R. H. McMath, representative St. Louis Board of Fire Underwriters; J. R. Lovejoy, Thomson-Houston Electric Company, Boston, Mass.; P. H. Alexander, Westinghouse Electric Company, New York; W. J. Jenks, Edison General Electric Company, New York.

Mr. Cutter was chosen secretary, and the chairman stated the object of the meeting as being the securing of a harmony of ideas between the electric light and insurance interests.

An extended discussion of the proper basis of a code of generic or fundamental rules, extended through several sessions, and resulted in an outline representing practically the unanimous views of the gentlemen present. Exhaustive statements of the reasons for the positions assumed in this initial code were made by the electric light representatives and agreed to by the insurance inspectors as embodying the results of their experience. A special

1. A paper read before the Association of Edison Illuminating Companies at Minneapolis, September 16, 1890.

committee presented at the second session a code of by-laws as the basis of a permanent organization, which was, early in the deliberations of the meeting, decided upon as the only practical method of securing and perpetuating an influence sufficiently positive and controlling to be permanent. A concise summary of a few of these by-laws will illustrate the scope of the work to be done, the solidity of the basis upon which the organization was effected, and the standing of the insurance representatives composing the organization is a guarantee of that important work in that executive direction in which former efforts have been lacking.

The name decided upon was "The National Electric Insurance Bureau," and the object is stated by the by-laws to be "the harmonizing of the electric interests and the fire insurance interests in the United States."

It is also provided that in addition to the membership indicated by the names of those in attendance, one member may be chosen by the National Telephone Association, one by the Western Union Telegraph Company, one by the Postal Telegraph Company, one by the National Association of Fire Engineers, one by the Underwriters' Association of the Pacific Union States, and such other insurance representatives as may apply for membership, and be deemed eligible.

It was settled that as a method of completing an organization for the opening year, the gentlemen of the committee chosen by the National Association, and representatives of the other organizations above named, having been called together by the original committee, should be members of the bureau until the next meeting, or until their successors were chosen.

Officers were elected as follows: President, Major C. E. Bliven, Chicago; secretary and treasurer, George Cutter, Chicago; executive committee, Messrs. Bliven, Brophy, Lovejoy, Jenks, Anderson, McDevitt and Cutter.

A committee consisting of Messrs. Barrett, Goddard and McMath was chosen to gather information regarding city and state laws bearing upon electric interests.

After a very careful discussion of the best method of obtaining the primal object of the meeting, namely, a uniform code of rules which shall be national in their application, the following members were chosen a committee to outline such a code: Messrs. Bliven, Cutter, McDevitt, Cabot and Jenks.

The deliberations of the meeting consumed six sessions, and an adjournment was made on Monday evening, Aug. 18th, subject to the call of the president, or to the time of the annual meeting, which, by the by-laws, was fixed to be held sometime during August of each year at such day and place as the executive committee may determine.

The committee charged with the work of codifying rules were instructed to secure as many different sets of codes as may be at present in force by any of the State or local Boards throughout the country, and by such light and power companies as may have given careful thought to this matter. It is proposed that these shall be, if possible, harmonized and condensed, and that a draft embodying whatever may be desirable from all, be sent by the committee to the organizations from which the different codes emanated for criticism and suggestion. Also, that on return of such criticisms a final arrangement may be made, and an improved code, thus prepared, submitted to a future meeting of the Bureau for adoption.

It will at once be seen that from the fact that the large majority of the members of this Bureau are executive insurance officers, and that as they represent one hundred and fifty or more of the leading insurance companies doing business throughout the United States, the adoption of any code of rules by such a body will mean the immediate enforcement throughout the territory over which they have control. Copies will be at once sent to the representatives of these numerous companies, including agents and local boards, and the inspectors will be provided with the code as a method of instruction, simply forming an addition to their previous duty, for the general inspection of buildings, and thus a most effective plan of determining whether or not proper methods have been pursued will at once be adopted by the underwriters. Hence, by the operation of a logical and mandatory plan, a rigid surveillance will be exercised over all constructing firms, and a great advantage immediately gained by the application of a uniform standard throughout the country.

The significance of the action taken and the probable results may be better understood when it is remembered that this is the first systematic effort made to secure the adoption of a uniform code of rules by the executive managers of a large number of the different insurance organizations, represented by the several associations of the United States.

PHILADELPHIA TO NEW YORK IN 36 MINUTES.

Prof. Wm. D. Marks, engineer of the Edison Electric Light Company, of Philadelphia, an electrical expert, says he is willing to stake his reputation as an electrical engineer on his ability to construct an electric motor that could take a train of cars from Philadelphia to New York in thirty-six minutes. One hundred and fifty miles an hour is the speed Prof. Marks' motor would have to make.

SOME SPECIAL LAMPS MADE AT THE EDISON LAMP WORKS.[1]

BY F. E. JACKSON.

It is desired to call the attention of the managers of the Illuminating Companies and others, to a few lamps provided by the Lamp Works, which are designed for special uses; with the exception of the "small battery lamps" the lamps to be described have not long been on the market, and are but little known. The small low-volt lamps, which are made for use with primary batteries, have been manufactured for several years, and are more or less known to all, although comparatively few have been used in central stations; until recently comparatively few have been made, but now the demand is increasing rapidly.

The one purpose for which these lamps were made was, as their names indicates, for use with batteries, and particularly with primary batteries. The E. M. F. of the lamps is very low, varying from 10 to 12 v., in the 6 c. p. lamps to as low as 2½ v. in the small ½ c. p. lamp made for the use of surgeons and dentists; the E. M. F. is purposely made low so that the lamps can be used with the least number of cells of batteries. It should be noted that not less than two cells can be used with any of the lamps.

The lamps vary in candle power from ½ to 6 candles; they are also made of ½ candle power in the special forms of "dental," "surgical" and "pea" lamps. The efficiencies are high, as they should be where current is as costly as it is where primary batteries are the generators. The efficiencies average not more than 2 volts per candle.

It was stated that not many of these lamps had been used until within a short time; the reason, no doubt, is that they were not advertised in a way that would bring them to the notice of possible purchasers.

A small pamphlet descriptive of the lamps and of cheap batteries that can be used with them is now issued by the Lamp Works, and the lamps have lately been advertised more extensively in other ways; the results are easily seen in the number of lamps ordered. Also, there have been so many orders received for material for making the batteries described in the catalogue that it was decided to make up complete outfits, and these are now made and kept in stock. By securing a few samples and advertising them, the Illuminating Companies would find a sale for a good many lamps.

About a year ago there was a demand for small lamps suited for burning in series on the regular 110 volt lighting circuit. Before the time mentioned there had been no special demand for lamps to be burned in series, and no lamps had been made for that purpose. The "battery" lamps were used in this way in a number of cases, but they did not always give satisfaction; it was found that, to give the best results when used in this way, the carbon in the lamps should be made of different proportions and different dimensions.

The lamps then made for burning in series on the dynamo circuit have given very satisfactory results. They are the lamps which were used in the electrical exhibition at the Lenox Lyceum, New York, during last winter, and which are used here at Minneapolis Exposition, where they speak for themselves.

The "small series burning lamps" are made higher in voltage and of lower efficiency than the battery lamps. They are made in candle powers of 1 to 4 candles. The voltage of all lamps is about 14 v., so eight lamps of any one candle power can be burned in series on the 112 volt circuit.

The lamps are made of efficiencies varying in different lamps from 3 to 5 watts per candle. The lamps are tested and marked for the current takes when burning at normal candle power, and those taking the same amount of current are selected for burning in series together. The "series burning lamps" are made of lower efficiency than the battery lamps. When a dynamo is used as the generator the cost of producing current is low as compared with the cost of the current from a primary battery; therefore, high efficiency is not so great an object; also as the lamps are burned in series, the breaking of one lamp stops the flow of current in several others, making it appear as though the lamps broke more frequently than they actually do; the comparatively low efficiency of the "series" lamp is an advantage as the increased lamp life which comes with a decrease in efficiency reduces the number of renewals proportionally, and also presents the annoyance which would be the result if the lamps broke more frequently.

Some tests in order to determine the best efficiency to give these "series burning lamps" are now being made at the lamp factory. So far the results are very satisfactory. At the time of this writing only one lamp has broken. It broke at the end of 320 hours; the number of lamps burned in the test was twenty-two. Another set of thirty-three lamps have been burning for 250 hours and no lamps have been broken.

The lamp which it is believed will become the most popular one for decorative purposes and for producing scenic effects has not

1. A paper read before the Edison Association, Minneapolis, Sept. 16 and 17, 1890.

yet been used outside of the factory, the lamps having been made only during the past few weeks. The lamp referred to is the 1 c. p. 14 v. or "8 in series" lamp.

For use in fancy designs and in producing effects where it is the effect only, and not illumination, that is wanted, the result obtained with the 1 c. p. lamps are quite as good as those obtained with the lamps of higher power. The decided advantages in using the 1 c. p. lamps are, that less current is required than for the 3 and 4 c. p. lamps, and the heating effects are less also.

In the exhibition we have an illustration of some of the uses to which these small lamps can be put, but there are many ways in which they can be used with profit on a smaller scale by the Illuminating Companies. A profit can be derived from the sale of current to light them.

At the Lamp Works several different fancy designs have been gotten up when called for, in which the small lamps are arranged in the form of letters spelling words and names: the lamps have also been arranged in other forms, such as stars. With suitable switches, the lamps forming letters, words, or different parts of designs can be lighted or turned off at will, attracting the eye and producing pleasing effects. We think that there is a sale for a large number of such signs and figures for use in stores, large and small, and in hotels, etc.

The lamps are made of different colors. The colors in which they are now made are red, blue, violet, green and amber. These colored lamps have been made only during the past few weeks, and they have been used only to a limited extent as yet. It is hardly necessary to say that with the colored lamps the number of combinations and effects that can be produced is greatly multiplied.

The handling of these small lamps is a branch of the electric lighting business which has not yet been taken hold of and developed by the illuminating companies. It is believed that when the lamps are better known, they will find a large demand.

Another lamp to which it is desired to call attention, is the lamp specially designed for use on power circuits where lamps are burned in series, and particularly for use on the 500 volt street railway circuit; in fact, the lamp is called the "electric railway lamp," and it is so labeled. When the electric railway business was first started it was intended, of course, to use incandescent lamps, but the question of the proper lamp to use was of small importance in comparison with others, and it was neglected in consequence. The lamp generally used on the Sprague roads when they first started was the regular 100 v., 16 c. p. lamp, the lamp of highest resistance and highest efficiency.

The importance of selecting lamps taking the same current, when they are to be burned in series, was not considered, and very often, I think I may say that on almost every road, lamps of different sizes and of different manufacturers have been placed in the same series, with results not always explained or accounted for, but apparently unfavorable, by comparison, to the lamp taking the least current under normal conditions.

If a lamp of higher candle-power, or if any lamp of equal voltage and taking a greater current is burned in series with a high efficiency 16 c. p. lamp, the result is that the 16 c. p. lamp receives the greater pressure; and, if the pressure is normal for burning two similar lamps in series, the above 16 c. p. lamp would be forced above normal candle-power and would soon be broken, if not broken immediately.

The Edison lamp has been the lamp of highest resistance on the market, and therefore it has been the one to suffer most for the above reason. As before stated, the Sprague roads have generally used these lamps at starting. No special lamp was made for the use of the railway companies, and no particular lamp has, in most cases, been recommended, consequently all lamps have been considered as being alike and suited for burning in series, particularly if they had the same marks for voltage. The natural result has been that dissimilar lamps have been placed in the same series, and the 16 c. p. Edison lamps have often given a very short life when, if they had been used alone, they would have given the best results. For the reason that the causes mentioned have not been understood, a large part of the lamp renewal business has been lost to the Lamp Works and to the Illuminating Companies.

The difficulty has been recognized by the Lamp Works, and we believe that it has been effectually provided against in the "electric railway lamp" which has but lately been put on the market. These "electric railway lamps" are designed particularly for the use of railways, but they are equally well suited for use on other power circuits, or in all other cases where lamps are burned in series on circuits of 200 to 500 or 600 volts. The lamps are made to give 18 c. p. The voltage ranges from 95 to 100 v.; and they take currents varying in different lamps from .60 to .75 ampere. The lamps have a special label, and the normal currents, the fractions of an ampere required to bring the lamps to 16 c. p., are marked on the labels.

The lamps are selected for voltages ranging from 95 to 100 v., but the voltage is not marked on the lamps; the marks for voltage have been found to produce confusion; customers, in some cases at least, have supposed that all lamps having the same marks for voltage were suited for burning in series as well as for burning in parallel circuit, whether the lamps were of the same resistance or not. For this reason the marks for the voltage of the lamps are omitted altogether.

As the regular 16 c. p. lamp has a very fine and delicate carbon, it was thought best, in designing the "railway" lamp, to give it a stouter carbon such as would not be so easily injured by the mechanical strain to which the carbon of the lamps are subjected. Also, very high efficiency is not to be desired in these lamps on account of the constant variation in the E. M. F. on the circuit. The efficiency of the lamp as determined on is about four watts per candle. Lamps of this efficiency will give the best results. The voltage on the circuit can fall considerably below the 500 v. limit, as it is constantly doing on the railway circuits, without bringing the lamps to a very low incandesence; also an increase in pressure of 10 per cent. will not cause the lamps to break at an abnormal rate.

Although the lamps in the regular stock will vary so as to take currents varying in different lamps from .60 to .75 ampere, it is not supposed that the lamps taking this whole range shall be sent to any one place. For any one plant the range of currents taken by the lamps will be limited to about 3–100 ampere, or all lamps sent to any one plant will be practically identical.

At the Lamp Works, and at other places where the "railway" lamps will be kept in stock, records of the amperage or the currents taken by the lamps sent to the different plants will be kept so that it will always be known just what lamps are wanted when lamps are called for by the railway company's renewal orders, and lamps of the same resistance will always be sent for use on the same circuits. Therefore it will be necessary to specify only the "electric railway lamp" when ordering lamps, and the proper lamps will be selected at the Lamp Works or at the other store houses where the lamps are kept.

Electric railways are being introduced very generally now, and such a large number of lamps are being consumed by them that it is well worth the while of those interested to look after the lamp renewals and see that the best lamp is used.

Where there are different roads in the same town, or where there are several different branches of the same system, it would be an advantage to have signal lamps of different colors on the different cars to distinguish those on one branch from those of another. Such colored lamps will be provided by the Lamp Works at small additional cost; we can now provide them of five different colors. When colored lamps are ordered by the railway companies, the lamps will be selected for the currents taken in the same way that the plain lamps are selected, so that all will be suited for burning in the same series.

On the street cars colored lamps can be placed on the front and rear platforms and in conspicuous positions to serve as signal lamps, while the remaining three lamps in the series are used to illuminate the interiors of the cars.

It may be added that the lamps will be made with bases other than the Edison bases, but, unless some other base or plug is specified, all lamps will be made to fit the regular Edison socket.

MEETING OF THE NEW YORK STATE STREET RAILWAY ASSOCIATION.

THE eighth annual meeting of the Street Railway Association of the State of New York, was held at the Powers Hotel, Rochester, N. Y., Tuesday, September 16th, 1890.

The following members were in attendance:—

ALBANY, N. Y.—Samuel Cowdry, Pres't Watervliet T. & Ry. Co.; John W. McNamara, Pres't Albany Railway.

BROOKLYN, N. Y.—E. W. Bliss, Director Brooklyn City Railroad Co.; Daniel F. Lewis, Pres't Brooklyn City Railroad Co.; John N. Partridge, Pres't Brooklyn City and Newtown Railroad Co.; William Richardson, Pres't Atlantic Avenue Railroad Co.; William J. Richardson, Sec'y Atlantic Avenue Railroad Co.

BUFFALO, N. Y.—Porter Norton, Director East Side Railway Co.; Henry M. Watson, Pres't Buffalo Street Railway Co.

NEW YORK CITY.—Charles P. Emmons, Sec'y Forty-second Street and Grand Street Ferry R. R. Co.; George Green, Pres't Forty-second Street and Grand Street Ferry R. R. Co.; Daniel B Hasbrouck, Sec'y Houston, West Street and Pavonia Ferry R. R. Co.; C. Densmore Wyman, V. P., Central Park N. & E. River R. R. Co.

PELHAM, N. Y.—W. R. Lambertson, Pres't Pelham Park Railroad Co.; Sherman T. Pell, Director Pelham Park Railroad Co.

ROCHESTER, N. Y.—John N. Beckley, Sec'y Rochester Railway Co.; Norman McD. Crawford, Asst. Mgr., Rochester Railway Co.; Arthur Luetchford, Treas., Rochester Railway Co.; Arthur G. Yates, Pres't Rochester Railway Co.

TROY, N. Y.—Charles Cleminshaw, Pres't Troy and Lansingburgh R. R. Co.; Charles H. Smith, Supt. Troy and Lansingburgh R. R. Co.

The meeting was called to order by President John N. Partridge, who in the course of his opening address spoke as follows:

Marked progress has been made since our last meeting in the

substitution of mechanical and electrical devices for the propulsion of street cars in the place of horses.

In many of our cities and towns where the electric car was unknown a year ago, it is to-day a familiar sight. Its coming has been opposed by a few alarmists, who predicted that it would bring with it death and destruction. Similar predictions were made of the locomotive, and even of the horse cars, in their early days. But public convenience was served by both, and their use has been marvelously extended. Wherever the electric car has been introduced, it seems to have met with general favor. Its noiselessness, its cleanliness, and its capacity for attaining a high speed wherever a high speed is safe, commend it to the riding public as a welcome substitute for the horse car, with the clatter of the hoofs and the slow jogs of the horses and their offensive droppings.

Some of the brightest minds in this and other countries are actively working to develop improvements in the various systems known as the "conduit," the "storage battery" and the "overhead wire." Who will dare to say what they will accomplish, in view of the great progress made during the last decade in the telephone and in electric lighting?

What we, as street railroad men, want, is a system which is simple and economical in its construction, in its adapation to our existing equipment and in its operation. The introduction of the electric car, with its greater weight, creates a demand for a heavier rail and a more substantially constructed road. Inventors are looking after our needs in this direction, and new patterns of rails and new methods of laying them are constantly brought to our notice.

THE REPORT OF THE EXECUTIVE COMMITTEE contained the following in relation to electricity:—

As the subject of the propulsion of street cars by electricity has become so prominent a question in the consideration of municipal authorities, as well as on the part of street railway managers, your Committee deemed it advisable to give unusual prominence at this meeting to the subject of electricity as a motive power. To this end, a report on the subject of "An Electric Street Railway Motor," prepared by the president of a company that is using a system of electric power, will be followed by the presentation of facts concerning electrical propulsion by the representatives of the several overhead systems, all of whom have been invited to attend the meeting for this purpose. It is confidently believed that the facts elicited will materially aid companies that for some time past have had the subject under consideration, in bringing about the desired change.

MR. JOHN W. MCNAMARA then read a paper entitled "Electric Street Railway Motors."[1]

The companies manufacturing electric railway apparatus having been invited to describe their various systems before the Convention were then called upon to address the members.

MR. FRANK A. ROGERS, representing the Short Electric Railway Co., described the system of the company, and laid stress upon the fact of the employment of very large pinions (6½ in. in diameter) made of the best machine steel. The large gears are made of cast-steel, and have wooden webs between the rim and the hub, which are put there for the purpose of deadening the noise, and also to serve as an insulation, insulating the motor itself from the ground; the ground connection being made directly from the motor to the car axle by flexible cable connectors. The axle part of the motor is insulated by heavy wooden beams, connecting the motor itself with the axle portion. This was done in order to deaden the noise and to get perfect insulation from the ground to the armature. The field-magnets employed on the motor are four in number, are "series" wound in one coil on each magnet, and the coils on the armature are entirely separate from each other. If one of the coils should happen to burn out, it does not touch any other coil on the armature and is very easily repaired.

In reply to an inquiry, Mr. Rogers said that the "series" system, while it operated satisfactorily on small roads having but few cars, as, for instance, at Huntington, W. Va., or Columbus, O., had been abandoned for the parallel system by his company. One of the chief reasons which dictated this change was the difficulty experienced in constructing large series generators which would regulate quickly enough.

Mr. Rogers also referred to the fact that in the Short system no solder is employed where there is a strain on the line. The connections are all mechanical and made by a special device.

MR. E. E. HIGGINS, representing the Edison General Electric Co., followed with a description of the Sprague system, in which he remarked that the cost of coal and water required to operate a car for one day was seventy-five cents, while to feed 11 horses, necessary for the same service, cost over two dollars. He dwelt upon the use of the commutated field for varying the power of the motor, by which the use of a rheostat was avoided, and which caused a saving in fuel and in engine capacity required.

Mr. Higgins also drew attention to the fact that Mr. Edison had lately been devoting his entire attention to some changes in the motor, mostly mechanical. The fields of the motor are now spread slightly so as to allow a little more wire on the field coils, and to vary somewhat the amount of metal in the machine. This makes a somewhat more powerful machine, and in some respects improves the design. The gears have been widened. But the most important advance which had recently been made in electrical railway work was the adoption of the new style of winding the armatures, in which each coil of wire was entirely separate from the next, and could be put together, and taken off, independently, without disturbing its neighbor. The new winding left no awkward protuberance at the end of the armature and made repairs a simple matter.

Mr. Higgins also mentioned the fact that, in order to avoid all shock on starting, the new cars on the system of his company would have a slow starting device. This is put in the very instant the car starts, but is cut out immediately, and is not in the circuit at any time during the operation of the car.

Referring to the safety of their overhead system, Mr. Higgins said that at every two or three thousand feet the trolley wire is divided into sections entirely distinct from one another. Each section is fed from the conductors on the side through fusible cut outs, which, when the current in that line exceeds a given amount, will melt and cut off the entire section of the trolley wire from the source of electricity. In case of accident or fire, a rope can be thrown over the line, and the instant it touches the ground it is dead. It can then be taken up and put out of the way.

MR. NORMAN MCCARTY, who represented the Thomson-Houston Electric Company, in describing their system, said that his company had long recognized the fact that electrical railway apparatus involved not so much an electric, as a mechanical, problem. They had aimed to get it as simple as possible, and used no commuted fields. They had made up their minds that it was a good deal better to spend a little more money for coal, and avoid wear and tear.

They used a trolley wire which had about four or five times the sectional area of the silicon bronze wire, consequently they get rid of feed wires along the sides of the street. There was more objection to the wires on the side of the street than through the centre. They feed their lines, but do not break the circuit, except on extended and complicated circuits. They used the trolley wire as a conductor, and only fed where it is necessary on account of special grades or excessive work.

MR. RICHARDSON called attention to the fact that the Boston *Daily Advertiser*, one of the most conservative papers in this country, had sent out a letter asking information from all cities, from Portland, Me., to Galveston, Tex., in which electric railways are operated, inquiring what systems they used, whether there had been any loss of life in connection with the wires, whether there was any objection to the overhead system on the part of the public, and what had been the effect on the street railway service of the particular locality. They published these answers, so far as they have received them, from 64 different places. All but four of them were favorable to electricity. Nashville, Tenn., was the only place where there was any loss of life reported. The answer from that city was rather amusing. There had been a wire broken in that city, causing the death of a horse, and a negro woman caught up the wire and threw it over, and it gave her a shock that was very amusing in its effects, but it did her no injury. It killed the horse, but did not hurt the woman, going to show that it is easier to kill a horse than it was to kill a human being. Another objection came from Newport, R. I., where the upper ten were objecting to anything which should popularize riding. The Mayor of Rochester responded favorably, as also did the Mayors of Troy, Buffalo and Albany.

MR. F. R. CHINNOCK, of the Edison Company, said that he had been connected with the Bell Telephone Company, of New York, the Bell Telephone Company, of Boston, and the New York and New Jersey Telephone Company. The telephone companies could do away with induction, if they would only go to expense. The method was well known. They should provide a return metallic circuit.

MR. CLEMINSHAW, of Troy, said they were threatened with injunction suits by the telephone companies. They kept them off until the accidental discovery was made in Albany of a method of overcoming this interference. They put down two supplemental wires, connected them, and ran them through to the station. The thing had worked very effectively, and was an inexpensive method of overcoming the trouble referred to.

Officers for the ensuing year were then elected as follows: President, Daniel F. Lewis, Brooklyn; first vice-president, John N. Beckley, Rochester; second vice-president, John S. Foster, New York; secretary and treasurer, William J. Richardson, New York; executive committee, John N. Partridge, Brooklyn; Charles Cleminshaw, Troy; C. Densmore Wyman, New York.

At one o'clock an adjournment was taken, after which the members had luncheon at the Rochester Club House. A trip to Charlotte over the electric road followed. In the evening the members were entertained at the Genesee Valley Club House. The entertainment of the members while in the city was conducted by Secretary Beckley, of the Rochester Railway Company.

The next meeting of the Association will be held at the Hotel Metropole, New York, the third Tuesday in September, 1891.

1. See page 334.

MEETING OF THE ASSOCIATION OF EDISON ILLUMINATING COMPANIES, AT MINNEAPOLIS.

THE session was opened by President John I. Beggs, at 11.30 A. M., Tuesday, September 16. The members present at the opening session were as follows:

Edison General Electric Company: —Samuel Insull, Second V. President; H. Ward Leonard, Gen. Mgr. Light and Power Department; John Muir, Gen. Mgr. Railway Department; Francis R. Upton, Gen. Mgr. Lamp Mfg. Department; F. E. Jackson, Inspector Lamp Mfg. Department; Wilson S. Howell, Inspector Lamp Mfg. Department; W. J. Jenks, Legal Department; M. J. Sullivan, Official Stenographer; L. Stieringer.

Illuminating Companies:—John I. Beggs, Director, Harrisburgh, E. L. Co., Harrisburgh, Pa.; G. H. Finn, Sec. & Treas. E. Co., St. Paul, Minn.; C. H. Maxcy, Sec. Edison L. & P. Co., Minneapolis, Minn.; Oscar Ericksson, Supt. The Cascade Milling Co., Sioux Falls S. Dak.; Edwin R. Weeks, Gen. Mgr. E. E. L. & P. Co. Kansas City, Mo.; Frederick Nicholl, Mgr. & Sec. Toronto Incandescent E. L. Co., Toronto, Canada; F. G. Kurz, Supt. Appleton E. L. Co., Appleton, Wis.; B. L. Smith, Asst. Sec. & Supt. Laramie E. Gas Light & Fuel Co. Laramie, Wyoming; Wm. D. Kurz, Supt. E. L. & P. Co., La Crosse, Wis.; Wm. L. Church, Supt. The Chicago Edison Co., Chicago, Ill.; John R. Markle, Director E. L. & Fuel Gas Co., Grand Rapids, Mich.; M. A. Seal, Sec. & Treas. Forest City E. L. & P. Co.; W. H. Van Sickel, Mgr. Edison Sault L. & P. Co., Sault Ste. Marie; W. F. Wollen, Supt. E. E. L. Co., York, Pa.; Leigh Carroll, Pres. E. E. L. Co., Birmingham Ala.; C. L. Edgar, Gen. Mgr. E. E. L. Co., of Boston, Mass.; J. A. Colby, Sec. & Mgr. Des Moines Edison Light Co.; W. S. Barstow, Asst. Supt. E. E. L. Co., Brooklyn, N. Y.; H. J. Smith, Gen. Oper. Supt. The E. E. L. Co., New York; Chr. Wuestenfeld, Mgr. Elgin City Railway Co., Elgin, Ills.; A. L. Smith, Pres. Appleton Edison L. Co., Appleton, Wis.; C. P. Gilbert, Sec. & Mgr. E. L. Co., Detroit, Mich.; Hoyt Post, Director and Attorney E. L. Co., Detroit, Mich. The choice of officers for the ensuing year resulted as follows:—President, John I. Beggs; V. President, C. L. Edgar; Secretary, W. J. Jenks; Treasurer, Wilson S. Howell; Executive Committee, John I. Beggs, ex-officio; A. L. Smith, Appleton, Wis.; Thos. P. Merritt, Reading, Pa.; E. R. Weeks, Kansas City, Mo.; C. P. Gilbert, Detroit, Mich.; Leigh Carroll, Birmingham, Ala.

In addition to the representatives of Edison interests, the following gentlemen were in attendance: Robert Coleman, Indurated Fibre Co., New York; Fred. W. Cushing, Central Electric Co., Chicago; B. L. Ames, Ames-Wright Co. (Western Electric Co. agents), St. Paul; John Roberts, *Street Railway Gazette*, Chicago; M. E. Baird, A. D. Newton, vice-president, Eddy Electric Motor Co., New York; Senator Washburn, of Minnesota; H. T. Greenfield, Interior Conduit and Ins. Co., New York; D. B. Dean, *Electrical Review*, Chicago; Fred. DeLand, *Electrical World*, Chicago; A. C. Durburow, J. B. O'Hara, *Western Electrician*, Chicago; E. L. Powers, *Electrical Industries*, Chicago; W. Forman Collins, ELECTRICAL ENGINEER, Chicago; Thos. R. Taltavall, *Electric Age*, New York; William Hubbard, Elgin Telephone Co., Elgin, Ill.; Foree Bain, Chicago; H. L. Lufkin, C. & C. Elec. Mot. Co., N.Y.

The following gentlemen represented Edison interests at the Exposition: E. W. Hammer, A. Theo. E. Wangeman, Edison Phonograph Co.

An interesting discussion arose upon the results of the burning of arc lamps on Edison circuits, during which it appeared that the trial of this method during the past few months has resulted very satisfactorily to the companies whose experience was quoted.

At the afternoon session, Mr. Insull, second vice-president of the Edison General Electric Co., made interesting and important explanations of the status of the patent suits now being pressed by the parent organization, and the recent consolidation of all the licensed manufactories with the General Company. By this statement it appears that the effort will be to furnish electric light and power apparatus of any variety of the most approved character and at low prices in competition with any other venturing to come in the market. It is also the purpose of the company to furnish an Edison motor, and thus by the keeping of a stock of armatures and other supplies at each of the district centres, render it more easy for the companies to secure more promptly anything of this kind than heretofore. Also that Mr. Edison, who was unavoidably detained at the laboratory, is, and will in the future be, actively engaged in perfecting the present and developing new apparatus in the field of electric light and power.

A discussion of the effects of crosses from high pressure circuits with Edison three-wire conductors developed great interest, and a report from Mr. Wilson S. Howell, who has for some months been gathering statistics, showed that in no case thus far noted, had a cross with a high pressure direct or alternating circuit proved damaging to the Edison wires or apparatus. A committee was appointed to further investigate this subject with special reference to the possible future interference of electric power systems, such as railways. The committee was appointed by the president, as follows:—C. P. Gilbert, Detroit; Wilson S. Howell, New Brunswick, N. J.; C. L. Edgar, Boston; H. Ward Leonard and J. H. Vail, N. Y.

The recent improvements in the Edison electric meter and the development of a new mechanical (registering) meter formed the subject of two papers, one by Mr. A. E. Kennelly,[1] of the Edison laboratory, and another by Mr. R. S. White,[2] of the Edison E. I. Co., of Brooklyn, N. Y.

A report by the secretary on the "Grounding of the Neutral Wire in Three-wire Systems" was read and assigned for discussion on Wednesday.

Special assignment of the questions of central station insurance and the proposed National Code of insurance rules for electric light and power work was also made to Wednesday at 10 a.m.

A paper on "Comparative Statistics on Electric Lighting in the United States" was read by Mr. F. R. Upton, of the lamp department of the Edison General Electric Company, and brought out an interesting discussion.

Adjournment was then made till Wednesday morning.

WEDNESDAY SESSION, SEPTEMBER 17TH.

The session was opened by the Report of the Special Committee on Insurance of Central Stations, after which Mr. S. E. Barton, president of the Electric Mutual Insurance Co., was introduced.

MR. BARTON, after explaining the plan of the Electric Mutual Company, stated that his company had already nearly $2,000,000 worth of insurance, $1,700,000 of which was written on electric stations, and $300,000 on first-class manufacturing property. He explained that the premiums charged were about five times what experience has ever shown losses and expenses to require and the company therefore returned the other four-fifths in the way of dividends, so that the chances for assessment were very remote. The premium charged for a station of the best construction, built of brick or stone, not over two stories high, and with electrical apparatus arranged in strict accordance with the requirements, was nine-tenths of one per cent.

MR. MARKLE, of Detroit, Chairman of the Committee on Fuel Gas, made a brief report as to the progress made since the Niagara Falls Convention in the experimental work of adapting this fuel to uses akin to that of electric light and power stations.

MR. F. E. JACKSON, of the Lamp Department of the Edison General Electric Company, presented a paper "On the Use of Miniature Incandescent Lamps in Decorative Work".[3]

MR. L. STIERINGER, the well known expert in the distribution of light, being called on to make some further explanations of the possibilities in the application of small lamps, gave an interesting and valuable talk upon the general subject, referring among other things to the effects produced on the Tower of Light at the Minneapolis Industrial Exposition.

MR. E. R. WEEKS, of Kansas City, introduced the subject of the "Heating of Buildings from Central Stations by Exhaust Steam," and a discussion which followed was participated in by Messrs. Edgar, Beggs, Markle and Vail.

As pertinent to the subject of insurance, the secretary read a paper "On the Formation of a Code of Insurance Rules,"[4] which it is proposed shall be adopted by the underwriters throughout the country.

MR. VAN SICKEL, of Sault Ste. Marie, inquired as to the proper construction of submarine cables for electric light and power works, and remarks were made by Messrs. Stieringer, Edgar, Beggs, Nichols, and the secretary was instructed to request Mr. Kennelly, of the Edison Laboratory, to prepare a paper on the subject to be incorporated in the minutes of this meeting.

The Association then adjourned, to meet on the Atlantic seaboard 12 months hence, the exact date and place to be designated by the executive committee.

AMERICAN ELECTRICAL UNITS.

THE first meeting of the American Institute of Electrical Engineers for the season 1890–91, was held at the handsome headquarters, 12 West Thirty-first street, this city, on September 16. Prof. Anthony, president, was in the chair. The committee on wiring tables presented their report, in which they came to the conclusion that, "Matthiessen's standard" is: "A hard drawn copper wire, one metre long, weighing one gramme, has a resistance of .1469 B. A. ohms, at 0° centigrade." The report was discussed and referred back to the committee for slight revision. Constants for converting the above to metre, millimetre and foot-mil dimensions, and to legal ohms at an assumed specific gravity, will be given.

The meeting then took up the proposition of Prof. F. B. Crocker that the unit of self-induction be hereafter known as the "henry," after Prof. Joseph Henry, instead of as the "quadrant," the term adopted at the last Electrical Congress in Paris. After a very interesting and animated discussion, the name was unanimously adopted amid applause. A committee was appointed to consider what would be the proper size of the unit, and to report at the next meeting. The unit will then be submitted for approval to the next International Electrical Congress, which will probably be that of 1892 in this city or Chicago.

A committee was appointed to co-operate with that of the National Electric Light Association on determining the true values and ratings of incandescent lamps.

ON ANTI-EFFECTIVE COPPER IN PARALLEL CONDUCTORS OR IN COILED CONDUCTORS FOR ALTERNATE CURRENTS.[1]

BY SIR WM. THOMSON.

It is known that by making the conductors of a circuit too thick, we do not get the advantage of the whole conductivity of the metal—copper, let us say—for alternate currents. When the conductor is too thick, we have in part of it comparatively ineffective copper present; but, so far as I know, it has generally been supposed that, the thicker the conductor, the greater will be its whole effective conductance, and that thickening it too much can never do worse than add comparatively ineffective copper to that

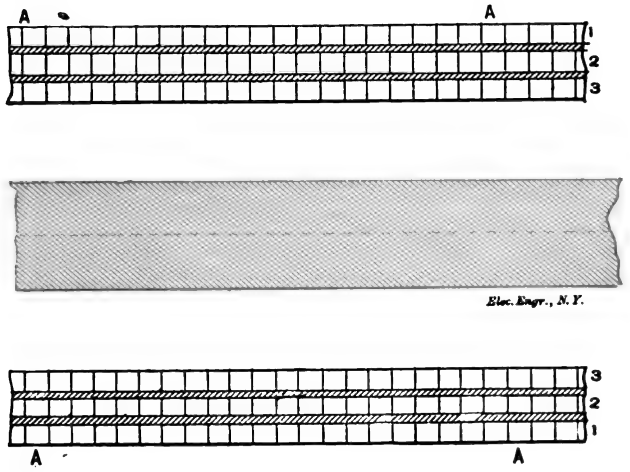

Fig. 1.

which is most effective in conveying the current. It might, however, be expected that we could get a positive augmentation of the effective ohmic resistance, because we know that the presence of copper in the neighborhood of a circuit carrying alternate currents, causes a virtual increase of the apparent ohmic resistance of the circuit, in virtue of the heat generated by the currents induced in it. May it not be that, anti-effective influence, such as is thus produced by copper not forming part of the circuit, can be produced by copper actually in the circuit if the conductor be too thick? Examining the question mathematically, I find that it must be answered in the affirmative, and that great augmentation of the effective ohmic resistance is actually produced if the conductor be too thick, especially in coils consisting of several layers of wire laid over one another in series around a cylindric or flat core (as in various forms of transformers).

Fig. 1 may be imagined to represent the secondary coil of a transformer, consisting of solid square copper wire in three layers. For simplicity, we suppose the axial length to be infinitely great, and straight; but the uniformity which this involves, and a close practical application to its simplicity is realized in that excellent form of transformer which consists of a toroidal iron core completely covered by primary and secondary wires laid on toroidal surfaces. To simplify the mathematical work, I suppose the whole thickness of the three layers to be small in comparison with the greatest radius of curvature of the circular or flat cylindric surface on which the wire is wound, but if it is not so the solution is easily obtained, for the case of circular cylinders, in terms of the Fourier-Bessel functions. It is of no consequence for our present question what there be inside of coil No. 3, and if we please we may imagine there to be nothing but air; the drawing, however, indicates an iron core and space which might be occupied by the primary coil, if a transformer is the subject; or our coil, A, A, A, A, may be the primary coil of a transformer with secondary coil and core inside it, and the alternate current maintained in it by an external electromotive agent acting in an arc between its ends outside. Our present results are applicable to all these varieties of cases indifferently, all that is essential being that the total quantity of current be given at each instant, and be uniform throughout the whole length of the coiled conductor.

The full mathematical work which I hope to communicate to the *Philosophical Magazine* for publication in an early number, includes an investigation of the self-induction of the coil, with, or without, anything in its interior (such as the core, or primary wire of a transformer), but at present, I merely give results so far as effective ohmic resistance, or generation of heat in the interior of the wire of the coil, A, A, A, A, itself is concerned; which, as said above, is independent of everything in the interior, and of the mode in which the alternating current is produced, provided only that the total amount of electricity crossing the section of the wire per unit of time be given at each instant.

I have found an expression for the intensity of the current at any point in the metal of any one of the layers of a coil of one, two, three, or more layers; and have deduced from it an expression for the quantity of heat generated per unit of time, at any instant, per unit breadth in any one of the layers. I need not at present quote the former expression; the latter is as follows, with q to denote the dynamical value of in time average of the heat generated, per unit of time at different instants of the period, per unit breadth and unit length in layer No. i from the outside of the coil, c, the time average of the square of the total current per unit breadth at the time of its maximum, and a the thickness of the layer.

$$q = \frac{2\pi}{\lambda} \rho \, \Theta \, c^2,$$

$$\text{where } \Theta = \frac{\varepsilon^{2\theta} + 2\sin 2\theta - \varepsilon^{-2\theta}}{\varepsilon^{2\theta} - 2\cos 2\theta + \varepsilon^{-2\theta}} + 2i(i-1)\frac{\varepsilon^{\theta} - 2\sin\theta - \varepsilon^{-\theta}}{\varepsilon^{\theta} + 2\cos\theta + \varepsilon^{-\theta}}$$

and $$\theta = \frac{2\pi a}{\lambda}.$$

The numerical results shown in the table have been calculated, and the accompanying graphic representation (Fig. 2), drawn for me by Mr. Magnus Maclean.

Table of Values of θ.

$\frac{16\,\theta}{\pi}$	$i = 1$	$i = 2$	$i = 3$	$i = 4$
1	5.113	5.118	5.127	5.141
2	2.553	2.592	2.669	2.786
4	1.316	1.634	2.270	3.224
6	.9854	1.997	4.019	7.053
8	.9173	2.993	7.143	13.37
10	.9452	4.062	10.30	19.65
12	.9822	4.899	12.73	24.48
14	1.000	5.276	13.83	26.66
16	1.002	5.362	14.08	27.16
∞	——	5.00	13.00	25.00

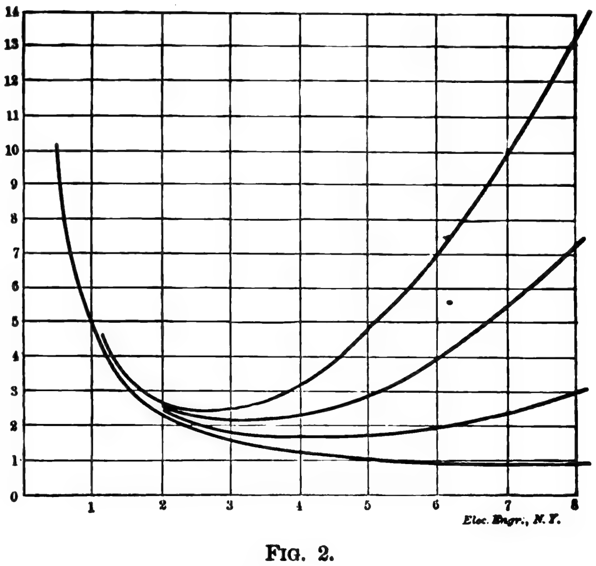

Fig. 2.

We see from the table and curves that each curve has a minimum distance from the line of abscissas, and that each comes to a horizontal asymptote, parallel to the line of abscissas, for $\theta = \infty$. By looking at the formula, we see that there is, in fact, an infinite succession of minimums and maximums in the expression for Θ, but it is only the first minimum, and the following maximum, that come within the range of variation of Θ, which we regard as sensible. In the case of $i = 1$, the formula gives $\theta = \frac{1}{2}\pi$ for the first minimum. The curves show for the case of $i = 2, 3, 4$, respectively, the first minimum at $\frac{16\,\theta}{\pi} = 4\frac{1}{2}$, 3, and 2.6, respectively. The thickness which corresponds to $\theta = \pi$ is the half wave length of the electric disturbance, which, is for copper 2.244 centimetres, when the frequency of the alternations

1. Abstract of a paper presented at the British Association Meeting, Leeds, September, 1890.

is 80 periods per second; and for this case, therefore, the thicknesses that give minimum generation of heat in the first, second, third, and fourth layers are, respectively, 11.22, 6.31, 4.21, and 3.65 millimetres. Anything more of continuous copper than these thicknesses in any of the layers would be not merely ineffective or comparatively ineffective, but would be positively anti-effective. Even with so small a thickness as 2.8 millimetres, for copper and frequency 80, line 2 of the table (corresponding to a sixteenth of the wave-length) shows, in the first, second, third, and fourth layers, losses of 0.3 per cent., 2 per cent., 5 per cent., and 10 per cent. in excess of that due to the true ohmic resistance of the copper, were it all effective. When the size chosen for the transformer and the amount of output required of it are such that a thickness of 2½ millimetres in the direction perpendicular to the layers is insufficient, a remedy is to be had by using braided wire, or twisted strand, with slight insulation of varnish or whitewash, crushed or rolled into rectangular or square form of the desired thickness and breadth. A very slight resistance between the different wires thus crushed together would suffice to cause the current to run nearly enough full bore to do away with any sensible loss from the cause which forms the subject of this communication.

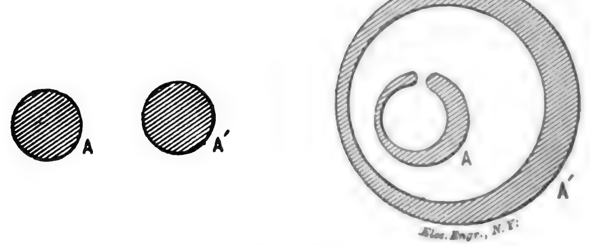
ON ALTERNATE CURRENTS IN PARALLEL CONDUCTORS OF HOMOGENEOUS OR HETEROGENEOUS SUBSTANCE.[1]

BY SIR WILLIAM THOMSON.

THIS paper consists of a description of some of the results of a full mathematical investigation of the subject which I hope to communicate to the *Philosophical Magazine* for an early number.

Two or more straight parallel conductors, supposed, for simplicity, to be infinitely long, have alternating currents maintained in them by an alternate current dynamo, or other electromotive agent applied to one set of their ends at so great a distance from the portion investigated, that in it the currents are not sensibly deviated from parallel straight lines. The other set of ends may, indifferently in respect to our present problem, be either all connected together without resistance, or through resistances, or through electromotive agents. All that we are concerned with at present is, that the conductors we consider form closed circuits, or one closed circuit; and that, therefore, the total quantities of electricity per unit of time at any instant traversing the normal sections in opposite directions are equal.

We suppose the period of the alternation to be very great in comparison with the time taken by light to traverse a distance equal to the greatest diameter of cross-section of our whole group of conductors. This supposition is implied in the previous assumptions of parallel rectilinearity of the electric stream-lines, and of equality of the quantities of electricity traversing, in opposite directions, the several areas of a normal section.



FIGS. 1 AND 2.

We further suppose that the length of our conductors and their effective ohmic resistances, are so moderate that the quantities of electricity deposited on, and removed from, their boundaries to supply the electrostatic forces along the conductors required for producing the alternations of the currents, are negligible in comparison with the total quantity flowing in either direction in the half-period. This supposition excludes important practical problems of telegraphy and telephony, the problem of long submarine cables, for instance, but it includes the problem of electric lighting by alternating currents transmitted at high tension through considerable distances, as, for example, from Deptford to London.

The general investigation includes as readily any number of separate circuits of parallel conductors, as a single circuit, but for simplicity in describing results, I suppose our system of conductors to be so joined at their ends as to constitute a single simple circuit of two parallel conductors. It may be either two conductors or one conductor, one of which may, or may not, surround the other, as shown in Figs. 1 and 2, representing cross-sections. Each conductor may be single, as in Figs. 1 and 2; or either may be multiple parallels.

We suppose each conductor to be homogeneous in substance and in cross-section from end to end, but not necessarily homogeneous in different parts of the cross-section. Thus, the different conductors, or the different parts of either, may be of different metals, or either conductor, or any part of either conductor, may consist of two metals (as iron and copper or iron and lead) laid parallel and soldered together.

We shall call A and A′ the cross sectional areas, or groups of areas of the two conductors, respectively, of the other. All the different portions of A are connected metallically at their two ends, and are thus all of them at one potential at one end and another potential at the other end, and similarly for A′. The homogeneousness of the material and of the cross-sections along the length of the conductors, and the uniformity of the total currents assumed above, implies that all the different parts of A in one cross sectional plane are at one potential, even though A consist of mutually isolated parts, or A′ consist of mere isolated parts. If, as in Figs. 1 and 2, all the parts of A are in mutual

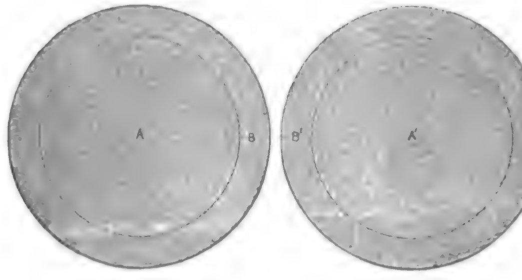


FIG. 3.

metallic connection, and all the parts of A′ are in mutual metallic connection, this would entail uniformity of potential through A, and uniformity of potential through A′, even without the limitation of our subject laid down above.

The following are among some of the most noteworthy results of the full mathematical treatment of the subject:—

I. When the period of alternation is large in comparison with 400 times the square of the greatest thickness or diameter of any of the conductors, multiplied by its magnetic permeability, and divided by its electric resistivity, the current intensity is distributed through each conductor inversely as the electric resistivity; the phase of alternation of the current is the same as the phase of the electromotive force; and the current across every infinitesimal area of the cross-section is calculated, according to the electromotive force at each instant, by simple application of Ohm's law.

II. When the period is very small in comparison with 400 times the square of the smallest thickness or diameter of any of the conductors, multiplied by its magnetic permeability, and divided by its electric resistivity, the current is confined to an exceedingly thin surface stratum of the conductors. The thickness of this stratum is directly as the square root of the quotient of resistivity, divided by the magnetic permeability of the substance in different parts of the surface, but the total quantity of the current per unit breadth of the surface is independent of the material, and, except in such cases as those referred to at the end of II. below, varies in each cross-section in simple proportion to the electric-surface density of the static electrification induced by the electromotive force applied between the extremities for maintaining the current. The distribution of this electric density is similar in all cross-sections, but its absolute magnitude at corresponding points of the cross-section varies along the length of the conductor in simple proportion to the difference of electric potentials between A and A′, and is zero at one end in the particular case in which the conductors are connected through zero resistance at one end while the electromotive force is applied by an alternate current dynamo at the other end. On the other hand, the surface-distribution of electric current is uniform throughout the whole length of the conductors, and it is only its distribution in different parts of the cross-section that varies as the electric density.

The proportionality of surface intensity of the current to electric density, asserted above, fails clearly in any case in which the circumstances are such that the distance we must travel along the surface to find a sensible difference in electric density is not very great in comparison with the thickness of the current-stratum. Such a case is represented in Fig. 3, which is reduced to scale, for alternate currents of period $\frac{1}{80}$th of a second in round rods of copper of 6 cms. diameter. The spaces between the outer circular boundaries and the inner fine circles, indicate what I have called the mhoic thickness being[1], .714 of a centimetre for copper of resistivity 1611 square centimetres per second. The full solution for such

1. Abstract of a paper presented at the British Assoc. Meeting, Leeds, 1890.

1. Collected Papers Vol. III., Art. CII., § 35.

a case as that represented in Fig. 3, belongs to the large class of cases intermediate between I. and II., and could only be arrived at by a kind of transcendent mathematics not hitherto worked. But without working it out, it is easy to see how the time-maximum intensity of the current will diminish inwards from the surface, and will be, at any point of either of the inner fine circles, about $\frac{1}{2}$ or $\frac{1}{3}$ of what it is at the nearest point of the boundary surface: and that at points in the surface, distant from B B′ by one-half, or one, or two times the mhoic thickness, the current intensity will be much smaller than it is at B B′.

III. In case I. the heat generated per unit of time, per unit of volume, in different parts of the conductors, is inversely as the electric resistivity of the substance, and directly as the square of the total strength of current at any instant. In case II. the time-average of the heat generated per unit of time, per unit of area of the current stratum, is as the time-average of the square of the quantity of current per unit breadth, multiplied by the square root of the product of the electric resistivity into the magnetic permeability.

Examples of cases I. and II.:—Let A consist of three circular wires, C, L and I, of copper, lead, and iron, respectively. In case I., the quantities of the whole current they will carry, and the quantities of heat generated per unit of time in them, will be inversely as their resistivities. In case II. if the centres of the three circular cross-sections form an equilateral triangle, the quantities of heat generated in them will be directly as the square roots of the resistivities for C and L; and for I would be as the square root of the product of the resistivity into the magnetic permeability, if the magnetic permeability were constant and the viscous or frictional resistance to change of magnetism nothing for the iron in the actual circumstances. This last supposition is probably true, approximately, with a permeability of $\frac{1}{80}$th for iron or steel, according to Lord Rayleigh, if the current is so small that the greatest magnetizing force acting on the iron is less than 0.1 C. G. S.

The dependence of the total quantity carried, on extent of surface, and on the solution of the electrostatic problem described in II, justifies Snow Harris, and proves that those who condemned him out of Ohm's law were wrong, in respect to his advising tubes or broad plates for lightning conductors, but does not justify him in bringing them down in the interior of a ship (even through the powder magazine), instead of across the deck and down its sides, or from the masts along the rigging and down the sides to the water. The non-dependence of the total quantities of current on the material, whether iron or non-magnetic metals, seems quite in accordance with Dr. Oliver Lodge's experiments and doctrine regarding "Alternative Path" and lightning conductors.

TELEPHONING THROUGH SUBMARINE CABLES.[1]

BY W. H. PREECE, F. R. S.

At the Newcastle meeting last year I gave the reasons and experiments which led to the conclusion that telephoning between London and Paris was practical. New and distinct overground lines of four copper wires are now being erected by the respective governments from each capital to the coast, and a new cable, the joint property of the two governments, will be laid during this year, between the Kent coast and San Gatte, to connect these two lines. There will thus be two metallic circuits between the two capitals. The K R, that is, the product of the capacity, K, and the resistance, R, of each circuit, upon which the clearness of articulation depends, will be 5,900, indicating that speech should be excellent.

A somewhat similar circuit has been established, since October last, between Buenos Ayres and Monte Video, under my advice. The cables across the La Plata are each 28 miles long, for there are two separate single wire cables, and the total distance between the two cities is 180 miles. Subscribers who have metallic circuits in each city have no difficulty whatever in speaking to each other from their respective offices, although the K R is as high as 10,400.

The cable across the channel will be a four-wire cable, and the specification for its construction has been based on the following mathematical considerations by Mr. H. R. Kempe.

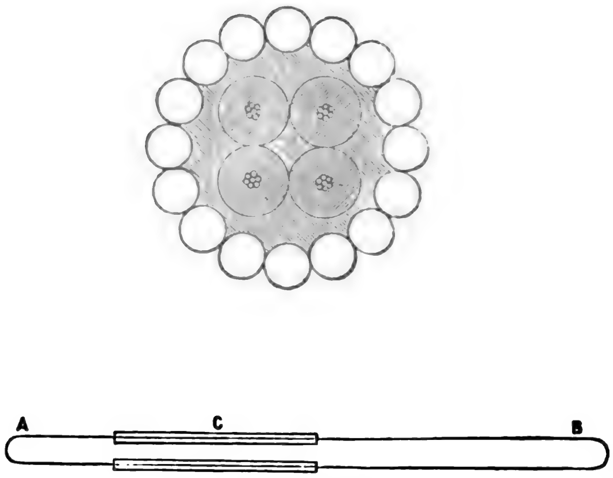
Let there be a looped telephonic line between A and B, Fig. 1, with a cable C, at an intermediate point on the route.

The working capacity of the whole line is dependent upon the product of the total resistance, R, and the total capacity, K. Therefore, if we take the resistance of the aerial portion of the line to be a fixed quantity, there will be a particular size of cable conductor which will give the smallest possible size of dielectric sufficient to enable a particular value of K R not to be exceeded. For, if we make the conductor larger than this size, and thereby diminish its resistance, we can, it is true, do with an increased capacity, but the diminution in the thickness of the dielectric which could thereby be allowed, is more than compensated for by the fact that the surface of the conductor is larger; in other words, we increase the capacity in a greater proportion than we diminish the resistance. If, on the other hand, we diminish the size of the conductor, we increase the resistance in a greater proportion than we diminish the capacity. Strictly speaking, the requirements of the problem are to determine the size of cable core which shall *cost least*; but, inasmuch as the costs of gutta-percha and copper, *bulk for bulk*, do not differ greatly, the problem resolves itself into the determination of the smallest outer diameter which can be employed.

The values obtained correspond very closely to a core, the weight of whose conductor is 160 lbs., and the weight of whose gutta-percha covering is 300 lbs., and it has, therefore, been decided to adopt those dimensions.

Although the calculation has been made on the assumption that the land lines on both sides of the cable are to be of 400 lbs. wire, the French government have decided that the wires to be erected by them shall be of 600 lbs. weight; the result of this will be to reduce the value of K R to 5,900, as stated at the commencement of the paper.

The specification of the cable states that: (1) Each conductor shall be formed of a strand of seven copper wires, all of equal diameter, shall weigh 160 lbs. per nautical mile, and shall at a temperature of 75° Fahrenheit have a resistance not higher than 7.632 ohms or lower than 7.478 ohms per nautical mile.



FIGS. 1 AND 2.

(2) Each conductor shall be insulated by being covered with three alternate layers of Chatterton's compound and gutta-percha, beginning with a layer of the said compound, and no more compound shall be used than may be necessary to secure adhesion between the conductor and the layers of gutta-percha. The dielectric on each conductor shall weigh 300 lbs. per nautical mile, making the total weight of each conductor when covered with the dielectric 460 pounds per nautical mile.

(3) The inductive capacity of such insulated conductor shall not exceed .3045 microfarad per nautical mile.

(4) The insulation resistance of each coil of core shall be not less than 500 megohms per nautical mile after such coil shall have been kept in water maintained at a temperature of 75° Fahrenheit for not less than 24 consecutive hours immediately preceding the test, and after electrification during one minute.

The cores (four in number) are to be served with the best wet fully tarred yarn, and with a sheathing of 16—280 mil. wires, each having a minimum breaking strain of 8,500 lbs., and a minimum of 10 twists in 6 inches. The section of the cable is shown in the accompanying engraving, Fig. 2.

1. Abstract of a paper read at the British Association meeting, Leeds, 1890.

THE WESTERN UNION ANNEX BUILDING.

Plans for a fourteen-story building to be built at 8 Dey street, this city, adjoining the Western Union Building, have been filed with the Building Bureau. The structure will be 25 by 67 feet and will cost $100,000. The architect is H. J. Hardenburgh and the builder, James B. Smith.

WORK OF THE YOUNG MEN'S INSTITUTE.

The Young Men's Institute of the Young Men's Christian Association, at 222 Bowery, will this year have classes in arithmetic, free-hand and mechanical drawing, carriage drafting, steam engineering, grammar and composition, vocal music, physiology, and first aid to the injured. The cost of membership is extremely moderate.

SECONDARY CELLS.[1]

BY W. J. S. BARBER STARKEY.

I SHALL only try to give a few of my personal experiences with secondary cells without attempting to go into their theory or construction, and I do this more in the hope that it may lead to some interesting discussion than for any value which may be attached to my experiences. Soon after the introduction of M. Faure's cells into this country I was fortunate enough to become possessed of one, which for a time gave excellent results, but it so happened I had to go away from home for six months, and on my return I found the cell would no longer work satisfactorily, and had become very inefficient.

To find out the cause of this I removed the plates from their felt envelopes, and found that they were partially covered with a white hard sulphate of lead, which I was unable to again reduce; I also found that it had eaten into the supporting plates, and that there was a thin film of white sulphate between these plates and the active material, which practically acted as a non-conductor. This seemed to me such a serious defect that I determined, if possible, to find out a remedy, and, after numberless ineffectual attempts, I at last found out that if a small quantity of carbonate of soda was added to the dilute acid, it not only allowed the existing sulphate to be again reduced, but it also prevented the formation in future of the hard white intractable sulphate, even if the cells were allowed to stand idle for any length of time. I have allowed plates to remain idle in this solution for more than 18 months, without the slightest trace of white sulphate appearing. I was so much impressed with the use of carbonate of soda to prevent sulphating of the plates that I brought the matter before Mr. Preece, and he very kindly came to look at the cells, and afterwards carried out a most careful series of experiments to determine the value, or otherwise, of using sulphate of soda in secondary cells. The results of these experiments are, I believe, well known, and have been published, and the exact amount of carbonate of soda which it is desirable to use has been determined; it is only necessary to use a very small quantity to effect the desired purpose. If much is used it is of no advantage, and may tend to cause scaling of the plates. Now that it is no longer necessary to pass a heavy current through cells, to prevent sulphating, it appears to me that it would be much more satisfactory to use larger cells for stationary work, and both charge and discharge them at a considerably lower rate than at present recommended, thereby enormously increasing the life and efficiency of the cells, and leaving a large surplus of energy in case of emergency. My own cells have been treated in this way, and I cannot see that they have in any way deteriorated after nearly five years' use. If the plates are kept free from sulphate they may be bent to a considerable extent without suffering any damage, and if the grids are made of pure soft lead they may be readily straightened again. Certainly my experience leads me to recommend the use of soft lead grids in preference to those of a hard and brittle alloy. I consider that burning the lugs together is the most satisfactory way of connecting up the cells, but if brass screws and nuts are used they can be greatly protected by pressing some lead foil over and around them; this will keep off any acid spray which might reach them while the cells are being charged, and should any of the brass connections become corroded, I have found that they can be effectually cleaned without trouble by immersing them for a time in a solution of carbonate of soda, and then washing them thoroughly in pure water. If it is desired to use separators between the plates, a very simple and cheap way to make them is to use perforated porous paper which has been saturated in melted paraffin wax; this stands well in dilute acid, and I have some which have been in use for several years.

Although secondary batteries are now undoubtedly very efficient when carefully used for stationary purposes, it appears to me that as at present constructed they will not stand for any long period the wear and tear, shaking and washing of the liquid against the active material to which they must be subjected when used for traction purposes; at least such is the impression left on my mind after inspecting cells which have been used for even a short time; some of the plates generally soon show signs of buckling, and the bottoms of the cells became covered with disintegrated particles of the active material, which forms a sort of mud. I have endeavored to overcome these defects by packing the plates in a solid, though porous, mass of plaster of Paris mixed with sawdust, and for three months a battery of 96 cells thus prepared was successfully running a tramcar at Canning Town and doing the same work as the other cars; however, at the end of this time the management passed into other hands, and I hear that the cells have been taken to pieces, as they were not giving satisfaction; so for the present this experiment has come to an end, and is apparently a failure, but I have not given up hopes that some modification of this plan may be successful, as for a time the working was very satisfactory. The proportion of plaster of Paris used in this experiment was two of plaster of Paris to one of sawdust, but I think the plaster of Paris was not pure, and its proportion was too great. I am now using a set of 22 Elwell-Parker cells, in which the proportion is 2½ of sawdust to 1 of plaster of Paris. The way I prepare the cells is to mix the plaster of Paris and sawdust intimately together in a dry state, and fill in the spaces between the plates with this mixture. I then pour in gently some dilute sulphuric acid to which a little carbonate of soda has been added, when the whole sets into a compact porous mass. After a time I pour in the electrolyte till it stands above the level of the tops of the plates, and it will be found that the cells will contain nearly as much liquid as if no porous material were used.

Last autumn I used a set of these cells in conjunction with a turbine and dynamo, and although they were last charged in November, I found on my return this year in June that they still retain the charge well after seven months' rest, and burnt the lamps brightly, the E. M. F. of each cell being just under 2 volts. Although in my experiments I have used plaster of Paris to insulate the particles of sawdust from each other, and to give stability of the porous mass, I have tried many other substances, both soluble and insoluble, mixed with it, but sawdust appears to act as well as anything which I have yet tried, and it has the advantage of being cheap, and can be easily procurable. This method of treating the cells would appear to be of no advantage in stationary work for electric lighting purposes, and would, indeed, be a distinct disadvantage, as, owing to the want of free circulation of the liquid, the E. M. F. falls more rapidly under a long-continued heavy discharge, but it immediately recovers with a short interval of rest, and, in practice, these intervals are constantly occurring in electric traction, when the car stops to take up and set down passengers; and with cells treated in this way the vibration and shaking of the car is a positive advantage, as it facilitates the circulation of the electrolyte, and tends to liberate any occluded gases. The defect of this arrangement would appear to be that it must hinder the free circulation of the liquid, and also add to the internal resistance of the cell, whilst, on the other hand, it prevents the plates from buckling, retains the active material firmly in its place, preserves the plates from injury, and makes the cell very portable. I have ventured to mention this crude experiment in the hope that it may induce some one to produce a thoroughly practical cell for traction purposes which will stand rough usage—be free from the defects which at present exist.

1. Abstract of a paper read before the British Association Meeting, Leeds, September, 1890.

RENTALS IN THE NEW YORK SUBWAYS.

The meeting of the Board of Electrical Control, on September 19, was devoted to a long discussion of subway rentals. Engineer Kearney reported on the subject. The report gives the present schedule of rentals charged by the subway company as follows: For 4-inch ducts, $1,250 per mile per annum. For 3-inch ducts, $1,000 per mile per annum. For 2½-inch ducts, $850 per mile per annum. For 2-inch ducts, $700 per mile per annum. For 1½-inch ducts, $550 per mile per annum. For 1¼-inch ducts, $500 per mile per annum. For distribution ducts, 1 to 4 inches, $1,000 per annum.

The telegraph and telephone companies have made no complaint in reference to the rentals. The high-tension electric light companies have appealed from the schedule. They generally occupy ducts of three inches diameter, and are charged rentals of $1,000 per mile per annum.

The subway company filed a statement with Mr. Kearney, showing that up to Jan. 1, 1890, 501 miles of telegraph and telephone ducts and 515 miles of electric light and power ducts had been constructed, making a total of 1,016 miles of ducts, the cost of maintaining and constructing which was $4,827,647.97 from 1886 to 1890. Only 404 miles of subways was occupied, producing at present rates an annual rental of $388,771. The yearly expenses of the subway company are placed at $826,382, and an annual deficit of $437,611 is figured out.

Some of the local companies want an investigation of the subway company's books, but Mr. Lauterbach claims that as the company is not making 10 per cent, such investigation is not in order. It is now proposed that pending a settlement of the question, the companies shall pay $500 per mile of duct.

THE NEW OHM.

At the recent meeting of the British Association it was recommended that the ohm be defined by the resistance of a mercury column of one square millimetre section, 106.3 centimetres long and at 0° C. Profs. Rowland and Barker undertook to refer this recommendation to the United States Government, while M. Mascart and Mr. Preece, respectively, will present it to the French and English authorities.

THE SMITHSONIAN INSTITUTION has been benefited by two donations to its funds. One is a legacy of $5,000, and the other a personal gift of $5,000 from Prof. A. Graham Bell to the Superintendent. The latter gentleman has handed over the sum to the Institution.

CORRESPONDENCE.

PITTSBURGH.

An Electric Process for Making "Wrought" Iron—Regulating the Wires.

A PROCESS of making wrought iron from pig metal without puddling is one of the discoveries made by Dr. Emmens, of Greensburg, near this city. The doctor accomplishes his object with the aid of electricity. He takes a vat which is filled with a chemical solution and a number of thin sheet iron plates. Then, the pig iron is also placed in the vat, after which the pig iron and the sheet iron are connected with a dynamo. The current generated by the dynamo is said to have the effect of causing the pure iron to be separated from the impurities in the pig iron and form a deposit on the sheet iron plates.

The quality of this wrought iron is stated to be superior to that of the best Swedish metal. It can be bent, rolled or twisted into any shape, while cold. Dr. Emmens says that he can take a horse shoe nail of this iron, fasten the head in a vice and twist it into an almost perfect screw without breaking.

An ordinance providing for the regulation of electric wires in the streets will be acted upon by councils within the next few days. All the electric wires must be placed at least twenty feet above the side walks, and where there are street railway wires on the same street, the former wires must be a sufficient distance above the others so as not to interfere. Underground wires, cables, tubes, conduits and subways shall be placed at least two feet under the ground and as near the street curb as practicable.

PITTSBURGH, Sept. 18, 1890.

ST. LOUIS.

Electric Railway News.—Resignations and Appointments.—The Turner Unicycle Road.

DURING the summer months the work of changing the motive power on the Lindell Railway has progressed steadily, but with some delay at times on account of scarcity of material of all kinds. The policy of the company is to construct a first-class electric railway regardless of cost and time. The new power house is finished and the machinery is being placed in position. Six boilers are set and ready for steam. Eight dynamos are on hand and being set up, and the first of the four 400 h. p. Armington & Sims engines is expected to arrive about the 20th.

The Vandeventer Avenue Street Railway will be operated as a part of the Lindell Railway. The construction of this road is being pushed to completion with the same thoroughness as the main line of the Lindell, the intention being to have it in operation by October 1 so as to accommodate visitors to the St. Louis Agricultural Fair. The Vandeventer avenue line will extend from Chouteau avenue to the fair grounds, and will thus form a direct line from Union Depot to the fair grounds. The acquisition of the Vandeventer line gives the Lindell Railway Company a total of 18 miles of double track.

Mr. E. J. Bagnall has resigned his position as superintendent of the St. Louis Illuminating Company and has accepted the position of engineer of the Lindell Railway Company, and will have complete charge of everything pertaining to mechanical and electrical engineering.

The St. Louis Unicycle Railway Company has been incorporated under the laws of the State of Missouri, with a capital stock of $200,000, with the following officers: President, L. A. Brown; vice-presidents, John H. French and J. W. Tremayne; treasurer, W. A. Adams; secretary, Chas. H. Wengler; directors, Chas. H. Gleason, Chas. H. Blake and David Strawbridge. The Unicycle railway is the invention of E. M. Turner, of Texas, and is an elevated electric railway having only one rail. A motor car propelled by a one h. p. Sprague electric motor is now in operation at the exposition.

The McKee street railway syndicate have closed a contract with the Short Electric Railway Company for 1,000 motors. This syndicate has been formed lately for the purpose of purchasing, constructing and operating electric railways, and this order is given so as to have the motors ready for use as fast as they may be required.

Mr. C. L. Abbott has resigned his position as superintendent of the Short Electric Railway, on the south end of the St. Louis railroad, and has accepted the position of superintendent of the Glenwood and Greenlawn Street Railway, Sprague system, Columbus, O., and will leave shortly for his new field of labor.

The Board of Public Improvements have appointed Andrew J. O'Reilly supervisor of city lighting in place of E. V. Matlack. No specific charges were brought against Mr. Matlack by the board, the change being made merely to quiet a general dissatisfaction which has existed since Mr. Matlack's appointment over a year ago, he at that time not being legally a citizen of St. Louis.

ST. LOUIS, September 15, 1890.

LETTERS TO THE EDITOR.

Notice to Correspondents.

Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, *150 Broadway, New York city.*

TESLA'S NEW ALTERNATING MOTORS.

[189.]—I hope you will allow me the privilege to say in the columns of your esteemed journal a few words in regard to an article which appeared in *Industries* of August 22, to which my attention has been called. In this article an attempt is made to criticise some of my inventions, notably those which you have described in your issue of August 6, 1890.

The writer begins by stating: "The motor depends on a shifting of the poles under certain conditions, a principle which has been *already*[1] employed by Mr. A. Wright in his alternating current meter." This is no surprise to me. It would rather have surprised me to learn that Mr. Wright has *not yet* employed the principle in his meter, considering what, before its appearance, was known of my work on motors, and more particularly of that of Schallenberger on meters. It has cost me years of thought to arrive at certain results, by many believed to be unattainable, for which there are now numerous claimants, and the number of these is rapidly increasing, like that of the colonels in the South after the war.

The writer then good-naturedly explains the theory of action of the motive device in Wright's meter, which has greatly benefited me, for it is so long since I have arrived at this, and similar theories, that I had almost forgotten it. He then says: "Mr. Tesla has worked out some more or less complicated motors on this principle, but the curious point is that he has completely misunderstood the theory of the phenomena, and has got hold of the old fallacy of screening." This may be *curious*, but how much *more curious* it is to find that the writer in *Industries* has *completely misunderstood* everything himself. I like nothing better than just criticism of my work, even if it be severe, but when the critic assumes a certain "l'état c'est moi" air of unquestioned competency I want him to know what he is writing about. How little the writer in *Industries* seems to know about the matter is painfully apparent when he connects the phenomenon in Wright's meter with the subject he has under consideration. His further remark, "He (Mr. Tesla) winds his secondary of iron instead of copper and thinks the effect is produced magnetically," is illustrative of the care with which he has perused the description of the devices contained in the issue of THE ELECTRICAL ENGINEER above referred to.

I take a motor having, say eight poles, and wrap the exciting coils of four alternate cores with fine insulated iron wire. When the current is started in these coils it encounters the effect of the closed magnetic circuit and is retarded. The magnetic lines set up at the start close to the iron wire around the coils and no free poles appear at first at the ends of the four cores. As the current rises in the coils more lines are set up, which crowd more and more in the fine iron wire until finally the same becomes saturated, or nearly so, when the shielding action of the iron wire ceases and free poles appear at the ends of the four protected cores. The effect of the iron wire, as will be seen, is two-fold. First, it retards the energizing current; and second, it delays the appearance of the free poles. To produce a still greater difference of phase in the magnetization of the protected and unprotected cores, I connect the iron wire surrounding the coils of the former in series with the coils of the latter, in which case, of course, the iron wire is preferably wound or connected differentially, after the fashion of the resistance coils in a bridge, so as to have no appreciable self-induction. In other cases I obtain the desired retardation in the appearance of the free poles on one set of cores by a magnetic shunt, which produces a greater retardation of the current and takes up at the start a certain number of the lines set up, but becomes saturated when the current in the exciting coils reaches a predetermined strength.

In the transformer the same principle of shielding is utilized. A primary conductor is surrounded with a fine layer of laminated iron, consisting of fine iron wire or plates properly insulated and interrupted. As long as the current in the primary conductor is so small that the iron enclosure can carry all the lines of force set up by the current, there is very little action exerted upon a secondary conductor placed in vicinity to the first; but just as soon as the iron enclosure becomes saturated, or nearly so, it loses the virtue of protecting the secondary and the inducing action of the primary practically begins. What, may I ask, has all this to do with the "old fallacy of screening?"

With certain objects in view—the enumeration of which would

1. All italics are mine.—N. T.

lead me too far—an arrangement was shown in THE ELECTRICAL ENGINEER, about which the writer in *Industries* says: "A ring of laminated iron is wound with a secondary. It is then encased in iron laminated in the *wrong direction* and the primary is wound outside of this. The layer of iron between the primary and secondary is supposed to screen the coil. Of course it cannot do so, such a thing is unthinkable." This reminds me of the man who had committed some offense and engaged the services of an attorney. "They cannot commit you to prison for that," said the attorney. Finally the man *was* imprisoned. He sent for the attorney. "Sir," said the latter, "I tell you they *cannot* imprison you for that." "But, sir," retorted the prisoner, "they *have* imprisoned me." It *may not* screen, in the opinion of the writer in *Industries*, but just the same it *does*. According to the arrangement the *principal* effect of the screen may be either a retardation of the action of the primary current upon the secondary circuit or a deformation of the secondary current wave with similar results for the purposes intended. In the arrangement referred to by the writer in *Industries* he seems to be certain that the iron layer acts like a choking coil; there again he is mistaken; it does not act like a choking coil, for then its capacity for maintaining constant current would be very limited. But it acts more like a magnetic shunt in constant current transformers and dynamos, as, in my opinion, it ought to act.

There are a good many more things to be said about the remarks contained in *Industries*. In regard to the magnetic time lag the writer says: "If a bar of iron has a coil at one end, and if the core is perfectly laminated, on starting a current in the coil the induction *all along the iron* corresponds to the excitation at that instant, unless there is a microscopic time lag, *of which there is no evidence*." Yet a motor was described, the very operation of which is dependent on the time lag of magnetization of the different parts of a core. It is true the writer uses the term "perfectly laminated" (which, by the way, I would like him to explain), but if he intends to make such a "perfectly laminated" core I venture to say there is trouble in store for him. From his remarks I see that the writer completely overlooks the importance of the size of the core and of the number of the alternations pointed out; he fails to see the stress laid on the saturation of the screen, or shunt, in some of the cases described; he does not seem to recognize the fact that in the cases considered the formation of current is reduced as far as practicable in the screen, and that the same, therefore, so far as its quality of screening is concerned, has no role to perform as *a conductor*. I also see that he would want considerable information about the time lag in the magnetization of the different parts of a core, and an explanation why, in the transformer he refers to, the screen is laminated in the *wrong direction*, etc.—but the elucidation of all these points would require more time than I am able to devote to the subject. It is distressing to find all this in the columns of a leading technical journal.

In conclusion, the writer shows his true colors by making the following withering remarks: "It is questionable whether the Tesla motor will ever be a success. Such motors will go round, of course, and will give outputs, but their efficiency is doubtful; and if they need three-wire circuits and special generators there is no object in using them, as a direct current motor can be run instead with advantage."

No man of broad views will feel certain of the success of any invention, however good and original, in this period of feverish activity, when every day may bring new and unforseen developments. At the pace we are progressing the permanence of all our apparatus it its present forms becomes more and more problematical. It is impossible to foretell what type of motor will crystalize out of the united efforts of many able men; but it is my conviction that at no distant time a motor having commutator and brushes will be looked upon as an antiquated piece of mechanism. Just how much the last quoted remarks of the writer of *Industries*—considering the present state of the art—are justified, I will endeavor to show in a few lines.

First, take the transmission of power in isolated places. A case frequently occurring in practice and attracting more and more the attention of engineers is the transmission of large powers at considerable distances. In such a case the power is very likely to be cheap, and the cardinal requirements are then the reduction of the cost of the leads, cheapness of construction and maintenance of machinery and constant speed of the motors. Suppose a loss of only 25 per cent. in the leads, at full load, be allowed. If a direct current motor be used, there will be, besides other difficulties, considerable variation in the speed of the motor—even if the current is supplied from a series dynamo—so much so that the motor may not be well adapted for many purposes, for instance, in cases where direct current transformation is contemplated with the object of running lights or other devices at constant potential. It is true that the condition may be bettered by employing proper regulating devices, but these will only further complicate the already complex system, and in all probability fail to secure such perfection as will be desired. In using an ordinary single-circuit alternate current motor the disadvantage is that the motor has no starting torque and that, for equal weight, its output and efficiency are more or less below that of a direct current motor. If, on the contrary, the armature of any alternator or direct current machine—large, low-speed, two-pole machines will give the best results—is wound with two circuits, a motor is at once obtained which possesses sufficient torque to start under considerable load; it runs in absolute synchronism with the generator—an advantage much desired and hardly ever to be attained with regulating devices; it takes current in proportion to the load, and its plant efficiency within a few per cent. is equal to that of a direct current motor of the same size. It will be able, however, to perform more work than a direct current motor of the same size, first, because there will be no change of speed, even if the load be doubled or tripled, within the limits of available generator power; and, second, because it can be run at a higher electromotive force, the commutator and the complication and difficulties it involves in the construction and operation of the generators and motors being eliminated from the system. Such a system will, of course, require three leads, but since the plant efficiency is practically equal to that of the direct current system, it will require the same amount of copper which would be required in the latter system, and the disadvantage of the third lead will be comparatively small, if any, for three leads of smaller size may perhaps be more convenient to place than two larger leads. When more machines have to be used there may be no disadvantage whatever connected with the third wire; however, since the simplicity of the generators and motors allows the use of higher electromotive forces, the cost of the leads may be reduced below the figure practicable with the direct current system.

Considering all the practical advantages offered by such an alternating system, I am of an opinion quite contrary to that of the author of the article in *Industries*, and think that it can quite successfully stand the competition of any direct current system, and this the more, the larger the machines built and the greater the distances.

Another case frequently occurring in practice is the transmission of small powers in numerous isolated places, such as mines, etc. In many of these cases simplicity and reliability of the apparatus are the principal objects. I believe that in many places of this kind my motor has so far proved a perfect success. In such cases a type of motor is used possessing great starting torque, requiring for its operation only alternating current and having no sliding contacts whatever on the armature, this advantage over other types of motors being highly valued in such places. The plant efficiency of this form of motor is, in the present state of perfection, inferior to that of the former form, but I am confident that improvements will be made in that direction. Besides, plant efficiency is in these cases of secondary importance, and in cases of transmission at considerable distances, it is no drawback, since the electromotive force may be raised as high as practicable on converters. I can not lay enough stress on this advantageous feature of my motors, and should think that it ought to be fully appreciated by engineers, for to high electromotive forces we are surely coming, and if they must be used, then the fittest apparatus will be employed. I believe that in the transmission of power with such commutatorless machines, 10,000 volts, and even more, may be used, and I would be glad to see Mr. Ferranti's enterprise succeed. His work is in the right direction, and, in my opinion, it will be of great value for the advancement of the art.

As regards the supply of power from large central stations in cities or centres of manufacture, the above arguments are applicable, and I see no reason why the three-wire motor system should not be successful. In putting up such a station, the third wire would be but a very slight drawback, and the system possesses enough advantages to over-balance this and any other disadvantage. But this question will be settled in the future, for as yet comparatively little has been done in that direction, even with the direct current system. The plant efficiency of such a three-wire system would be increased by using, in connection with the ordinary type of my motor, other types which act more like inert resistances. The plant efficiency of the whole system would, in all cases, be greater than that of each individual motor—if like motors are used—owing to the fact that they would possess different self-induction, according to the load.

The supply of power from lighting mains is, I believe, in the opinion of most engineers, limited to comparatively small powers, for obvious reasons. As the present systems are built on the two-wire plan, an efficient two-wire motor without commutator is required for this purpose, and also for traction purposes. A large number of these motors, embodying new principles, have been devised by me and are being constantly perfected. On lighting stations, however, my three-wire system may be advantageously carried out. A third wire may be run for motors and the old connections left undisturbed. The armatures of the generators may be rewound, whereby the output of the machines will be increased about 35 per cent., or even more in machines with cast iron field magnets. If the machines are worked at the same capacity, this means an increased efficiency. If power is available at the station, the gain in current may be used in motors. Those who object to the third wire, may remember that the old two-wire direct system is almost entirely superseded by the three-wire system, yet my

three-wire system offers to the alternating system relatively greater advantages, than the three-wire direct possesses over the two-wire. Perhaps, if the writer in *Industries* would have taken all this in consideration, he would have been less hasty in his conclusions.

NIKOLA TESLA.

NEW YORK, Sept. 17, 1890.

REPORTS OF COMPANIES.

WESTINGHOUSE AND PULLMAN INTERESTS.

With regard to various reports current on the subject, it now transpires that arrangements have been made between George Westinghouse, Jr., of Pittsburgh, and George M. Pullman, of Chicago, by which the Westinghouse Electric Mfg. Company will erect works conveniently close to the Pullman Palace Car Works, at Pullman, Ill., and the agreement reached, it is understood, is that the Pullman company will purchase all of their electric railway motors from the Westinghouse concern. The works to be erected are to cost between $400,000 and $500,000, and Mr. Westinghouse says 2000 men will be employed at the new shops. Work on the structures will probably begin next spring. That the immense works of Pullman's Palace Car Company and the big plant of the Westinghouse Company, at Pittsburgh, are to be consolidated both Messrs. Pullman and Westinghouse deny. Mr. Westinghouse further says that the erection of works at Pullman does not mean that the Pittsburgh business of the company is to be removed to Chicago. It will be merely an extension of their business. The works at Newark, N. J., Pittsburgh, New York City, etc., will also be continued as before.

DIVIDENDS.

THE EDISON GENERAL ELECTRIC CO. has declared its fourth quarterly dividend of 2 per cent.

STOCKS AND BONDS.

ROYAL ELECTRIC CO.—Application will be made to the Legislature of the Province of Quebec to change the value of the shares of the Royal Electric Co. from ten to one hundred dollars each.

FINANCIAL MARKET.

QUOTATIONS ON ELECTRICAL STOCKS.

Mr. F. Z. Maguire, Electrical Securities of 18 Wall street, this city, reports the following quotations of September 19th from New York, Boston and Washington :—

LEGAL NOTES.

BRUSH ELECTRIC CO. VS. SPRAGUE ELEC. R'Y & MOTOR CO.

The Brush Electric Co. has brought an action in the U. S. circuit court against the Sprague Electric Railway and Motor Co. of New York, to restrain them from selling or using a certain dynamo electric machine on the ground of infringement. The complainants set forth in their bill that C. F. Brush was the original and first inventor of a new and useful improvement in dynamo electric machines, which was secured by letters patent. About Jan. 1, 1887, Mr. Brush assigned all his right, title and interest in said machines to complainants in this action, such assignment being duly recorded in the U. S. patent office.

The suit in question is based on the patent issued to Charles F. Brush, No. 260,652, dated July 4th, 1882, entitled Dynamo-Electric Machine. The claims cover the application of a copper sleeve surrounding the field magnets of a dynamo-electric machine, whereby the insulation of the magnets is preserved from the high potential of self-induction created by fluctuations in the exciting current. The device is no longer used on the street car motors of the defendants, who now claim that its employment makes the magnets sluggish and causes burning out of the armature by retarding the generation of counter-electromotive force in it.

A PRIZE SCHEME OF LIGHTING.

Mr. F. H. Whipple has been awarded a prize of $100 at Davenport, Ia., for the best plan of lighting that city. Mr. Whipple, with native modesty, writes us from St. Louis that there was nothing special about the plans. Owing to the many hills and hollows in the town, it was difficult to light it economically. "There was nothing technical about it; but it was more the use of common sense in the location of lights."

TELEGRAPHY DURING THE COMMUNE.

One of the first things to be done after the recent disastrous fire at the New York offices of the Western Union Company was to re-establish the identity of each of the maze of wires running into the premises. Experienced electricians being on the spot, the task was not a very difficult one, and in a single day 300 circuits were restored. The ease with which this work was carried out at New York recalls to our mind, says *La Lumière Electrique*, a very instructive historic incident which occurred during the Commune. When the Republican Government quitted Paris, the operators at the central office in the Rue Grenelle managed to mix up all the wires before leaving. The Communists were so ignorant of everything connected with telegraphy, that it was beyond their powers to unravel the wires; and during the whole time that they were in possession of the building, namely, from the end of March to the end of May, they were only able to use the military lines. M. Fabre de Lagrange, who was forced to accept the appointment of chief electrician to the Commune, took good care to keep the wires in confusion; and among other services to the State, he sent misleading telegrams, and thus saved many public and private buildings which the rebels wished to blow up by using an explosive mixture of air and coal-gas. These facts were clearly authenticated by the court-martial which tried M. Lagrange, and he was honorably aquitted.

THE TROUVE ELECTRIC ERYGMATOSCOPE.

At a recent meeting of the Académie des Sciences, M. G. Trouvé described an electrical appliance devised by him to facilitate the inspection of the geological strata pierced by the boring tool. The apparatus consists of a powerful incandescent lamp enclosed in a cylinder. One of the hemicylindrical surfaces of this cylinder constitutes the reflector; whilst the other, which is of thick glass, allows the luminous rays to pass through it, and light up the successive strata through which the lamp descends. At the base of the instrument there is an elliptical mirror, while the top is open, so as to enable an observer placed at the head of the boring and armed with suitable glasses to see on the mirror the reflected image of the stratum illuminated by the lamp, which is arranged so that its upward rays are intercepted. The whole apparatus is suspended from a cable formed by the two conducting wires. This cable is wound on a drum, the trunnions of which are insulated from one another and connected to the leads, current being obtained by two rubbing contacts attached to the poles of a portable battery. This arrangement enables the instrument to be raised and lowered without difficulty and without interrupting the observations. The erygmatoscope as at present arranged gives excellent results down to a depth of over 600 feet, and with a more powerful lamp it could be used at still greater depths. An expedition which has been sent out to the Mozambique coast by the Portuguese government, to search for coal beds and other mineral deposits, has been supplied with erygmatoscopes.

SOCIETY AND CLUB NOTES.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

AT the meeting of the Council, on September 16, at the rooms of the Institute, 12 West Thirty-first street, the following gentlemen, being properly endorsed and qualified, were admitted to associate membership :—

Braddell, Alfred E., Electrical Inspector, Underwriters' Association, Middle Department, 308 Walnut Street, Philadelphia, Pa.
Knight, Wm. B., Civil Engineer (Specialty, Cable and Electric Railways), 200 West 6th Street, Kansas City, Mo.
Keen, William B., Electrician, The Clark Electric Co., 478 Pearl Street, New York City.
Taber, Robert B., Secretary and Electrical Engineer, New Bedford Gas Light Co., New Bedford, Mass.
McCay, H. K., Electrician, Edison Electric Light Co., Box 439, Birmingham, Ala.
Nesmith, S. D., Ohio Agent, United Edison Manufacturing Co., 822, Society for Savings Building, Cleveland, O.
Hewitt, Charles, Engineering Department, The Sprague Electric Railway and Motor Co., 278 Hicks Street, Brooklyn, N. Y.
Rodman, Samuel, Jr., Lieutenant 1st Artillery, U. S. A., Fort Columbus, N. Y. Harbor.
Forbes, Francis, Lawyer, 137 Broadway, New York City.
Tobey, William Boardman, Department Electrical Engineering, Cornell University, Student, Class of 1890.
Loomis, Osborn P., Electrician, Eureka Electric Co., 530 Nostrand Avenue, Brooklyn, N. Y.
Woolf, Alfred E., Electrician and Inventor, Woolf Electrical Co., 864 Lexington Avenue, New York City.
Atwood, George F., Edison Laboratory, Orange, N. J.
Binney, Harold, Assistant in the Practice of Patent Law, with Gilbert M. Plympton, 245 Broadway, New York City.
Putnam, H. St. Clair, Treasurer and Electrician, Thomson-Houston Carbon Co., Fremont, O.
Perrine, Frederic A. C., Superintendent Insulated Wire Department, John A. Roebling's Sons Co., 137 E. State Street, Trenton, N. J.
Merritt, Ernest, Instructor in Physics, Cornell University, Ithica, N. Y.
Hall, William P., President, The Hall Signal Co., 50 Broadway, New York City.

INVENTORS' RECORD.

Patents issued Sept. 16, 1890.

Alarms and Signals:—*Electro-Magnetic Bell*, John Geary, 436,410. *Electro Mechanical Gong*, G. Doyle, 436,560. *Electrical Automatic Fire Alarm System*, W. F. Singer, 436,640. *Municipal Signaling Apparatus*, J. W. Stover, 436,747.

Conductors, Conduits and Insulators:—*Electric Conductor*, W. E. Oehrle, 436,432. *Insulating Material*, J. W. Easton, 436,733.

Dynamos and Motors:—*Dynamo-Electric Machine*, S. D. Field, 436,408.

Galvanic and Thermo-Electric Batteries:—*Galvanic Battery*, J. F. Wollensak and W. E. Gill, 436,516.

Lamps and Appurtenances:—*Socket for Incandescent Electric Lamps*, H. E. Swift, 436,387. *Arc Lamp*, C. A. Tucker, 436,465. *Electrical Head-Light*, J. Thorne and E. B. Burr, 436,677.

Metal Working:—*Method of Electrically Heating Bars*, etc., M. W. Dewey, 436,519.

Miscellaneous:—*Electric Cigar Lighter*, M. M. Hayden, 436,354. *Electrical Switch*, F. De A. Goold, 436,412.

Railways and Appliances:—*Railway Signal*, P. C. Morse, 436,371. *Electric Railway*, H. W. Libley, 436,425. *Electric-Motor Car*, W. Robinson, 436,439 and 436,440. *Trolley for Electrical Railways*, D. A. Ainslie, 436,571. *Motor-Armature Car-Wheel*, E. Wagemann, 436,728. *Electric-Motor Car*, W. Robinson, 436,742.

Secondary Batteries:—*Storage Battery*, W. B. Hollingshead, 436,602.

Telegraphs:—*Printing Telegraph*, J. B. Odell, 436,740.

Telephones and Apparatus:—*Telephone*, W. Burnley, 436,334 and 436,335. *Telephone*, S. L. Wiegand, 436,512 and 436,513. *Telephone-Relay*, S. L. Wiegand, 436,514. *Graphophone*, J. Daniels, 436,576.

CLOSING UP THE VAN GESTEL CO.

Deputy Sheriff Carraher has sold out all the right, title, and interest of the Van Gestel Electric Street Car Company in the machinery, fixtures, etc., at 542 West Thirty-fourth street, this city, realizing about $250. Judgment for $1,688 was recently entered against the company in favor of R. R. Weiler. The company was incorporated in July, 1889, under West Virginia laws, with an authorized capital stock of $5,000,000, which was issued for patents on a street-car motor and storage battery, Henry M. Munsell being the president.

TRADE NOTES AND NOVELTIES AND MECHANICAL DEPARTMENT.

THE STANDARD ELECTRIC SUPPLY CO., OF BOSTON.

The above company has been formed in Boston with a capital stock of $100,000, buying out the partnership formerly carried on under the same name. The officers of the company are:—Mr. W. P. Fairbanks, president; Mr. W. C. Woodward, for many years connected with the Standard Electric Company, of Vermont, treasurer, and the directors will consist of these two along with Mr. T. B. A. Price. The purpose of the company is to handle all electric railway, light and power supplies, and their strong specialties will be the Kerite wires, cables and tapes, and the Solar carbons, manufactured by the Solar Carbon Manufacturing Company, of Pittsburgh, Pa. These carbons are made from the product of natural gas, being different from all other carbons in this respect. They will also carry a full line of the goods of the National Electric Manufacturing Company, of New York, and will sell the flexible brackets, controlled by the Hunt Engineering Company, of Brooklyn, N. Y., and the well known Hill switches and fuse devices. The Standard Company are already doing a large business in Kerite tapes and wires, the tapes especially being in great demand. Mr. Woodward has a host of friends, is deservedly popular, and is sure to make a success. Mr. E. O. Johnson has been connected with them for some time as salesman, and this week Mr. W. E. Sto.v, well known throughout New England, and who requires no introduction, has also accepted a position to represent them in the vicinity. Handsome offices and store room have been taken in the New England building, 180 Summer Street, Boston.

ACCUMULATORS AT THE RESIDENCE OF VICE PRESIDENT MORTON.

Some time ago a plant of the Sawyer-Man incandescent system was installed at the country residence of Vice President Levi P. Morton, Ellerslie, Rhinecliff-on-Hudson. Mr. B. W. Philbrick, engineer in charge, now reports as follows to Mr. D. H. Bates, of the Electrical Accumulator Co., 44 Broadway :—

"In reply to your inquiry respecting the electric lighting on Mr. Morton's place, I beg to say that the plant has been in operation for over two years and is in as good condition to-day, apparently, as when first installed. It has given no trouble whatever outside of ordinary care and has cost practically nothing for repairs. The lights have given entire satisfaction and the accumulators have never failed to furnish the required energy. This system of lighting compares very favorably with gas in point of economy and has the advantage of being free from smoke and heat, besides affording a most agreeable light. There is a large saving as compared with the cost of running the engine all the time, in labor, fuel and wear and tear on the machinery. In other words, Mr. Morton has found the system very satisfactory in every way."

THE CONNECTICUT MOTOR CO.

The new catalogue and price list issued by the Connecticut Motor Co., of Plantsville, Conn., is much more than its name implies, a large portion of its contents being devoted to a discussion of motor work and an excellent technical discription of the motor itself. Numerous illustrations are given of the motor and details, and these are accompanied by figures of the amount of power required for various classes of work, including H. B. Prindle's article on "Electric Power for Small Plants"; A. T. Snell's "Nominal Outputs of Two-Pole Dynamos and Motors"; and the same gentleman's "Electric Traction Calculations." At the end are cited a large number of testimonials from users of Connecticut motors as to good results obtained with them.

THE CROSBY ELECTRIC CO.

Mr. Louis Walsh, who was formerly connected with the Daft Electric Light Co. during a period of four years, has now joined the forces of the Crosby Electric Co., and will be their representative among the trade in handling their well-known dry battery and other specialties. Mr. Walsh has a high reputation for energy and ability, which he proposes to enhance in his new sphere of labor.

THE BAKER COMMON SENSE OIL FILTER.

Mr. Walter E. Crane, of 421 Thirteenth avenue, S. E., Minneapolis, reports excellent success with his Baker common sense oil filter among electric light people, and he has been enjoying a brisk run of orders. This filter, which is shown in our advertis-

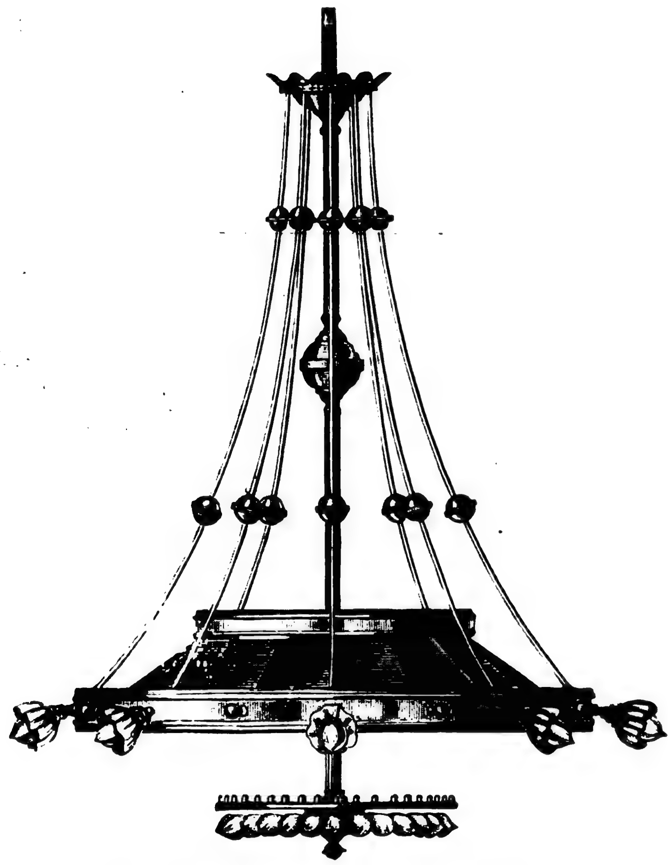
ing columns, and has been fully described in these pages, is one in which the whole process of filtration can be watched. The oil thus treated can be used over and over again indefinitely, and as the apparatus is cheap, it pays for itself many times over in a single year.

A. G. DAY CABLE WORKS EXCURSION.

W. R. Brixey, superintendent of the A. G. Day Cable Works, at Seymour, Conn., gave the employés, to the number of sixty or more, an excursion to Seaside Park, Bridgeport, and a first-class shore dinner Saturday, Sept. 13. The day was passed most pleasantly by all and will be an occasion long to be remembered by the participants. They returned by the evening train.

A NEW "FRINK" ELECTRIC LIGHT REFLECTOR.

Mr. I. P. Frink, 551 Pearl street, this city, whose reflectors are so well-known, has lately been devoting attention to electric lighting as well as gas. Now that the electric light has been so generally introduced, it has been found necessary to use his system of reflectors with the incandescent electric light; he has, therefore,



NEW FRINK ELECTRIC LIGHT REFLECTOR.

issued a catalogue containing a variety of reflectors to be used with incandescent lamps, one of which, 1152 E., we illustrate. This represents a fixture containing one of his double cone reflectors, lined with silver-plated corrugated glass, with a cluster of gas lights and one of incandescent lamps underneath, to thoroughly illuminate and evenly diffuse the light in any large audience room. It also has attached electric lamps on the outer rim, giving it the appearance of an electrolier.

Mr. Frink is now executing orders for the finer class of reflectors to be used with electric light for churches in Wilmington, N. C.; Goldsboro, N. C.; Spokane Falls, Wash.; Montesano, Wash.; Columbus, Ga.; Newburgh, N. Y.; Middletown, N. Y., and Hackettstown, N. J.

FIRE IN THE W. U. OFFICE AT LYNCHBURG, VA.

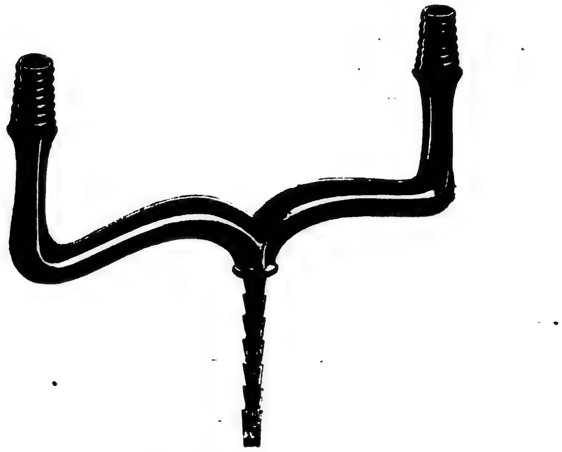
A very destructive fire occurred at Lynchburg, Va., on Sept. 14. Fire was first discovered in the battery room of the Western Union Telegraph office, and spread so rapidly that nothing was saved belonging to the office. The flames quickly spread to the adjoining buildings, and half a block was destroyed. The estimated total loss on buildings and stock will amount to $150,000. No estimate of insurance can be made.

T. McCOUBRAY.

The above named gentleman, who is so well known in electrical circles, has severed his connection with the Crocker-Wheeler Motor Co., with whom he has been associated for some time past as secretary and general sales agent. He has joined the forces of the Okonite Co., and will enter upon active service with that concern at the beginning of October. Mr. McCoubray's new duties will be largely those of a special agent in looking after the interests of the company in all parts of the country, and his wide acquaintance ensures for him a welcome everywhere.

A NOVEL BREAK ARM.

In the varied electrical industries, as in other mechanical lines, the old and heavy cast iron appliances are being supplanted by lighter and neater ones of wrought or malleable iron. Quite recently we described a malleable iron wall-bracket, made by the Great Western Electric Supply Co., which marks another step in this direction. The same firm is now putting out the Chubbuck break arm, which is also made of malleable iron, and is claimed to be stronger, lighter and tougher than the forms now in use. Our illustration shows the rather neat design, with the strengthening rib and taper screw as in the Chubbuck (Springfield) bracket. The star shaped section of the arm gives great strength, while the hollow split screws have a slight spring and grip the insulator firmly. Another new feature is the small barbed pin used. As



A NOVEL BREAK ARM.

this is made for a ⅝ inch hole, the cross arm is weakened much less than by the 1⅛ inch holes needed for other break arms. Moreover, when once driven in, the barbs catch in the wood, holding the arm firmly in its place.

THE JEROME KIDDER MEDICAL BATTERIES.

The Jerome Kidder Mfg. Co., of 820 Broadway, are in receipt of the following letter, dated August 8, 1890, from Henry Gerard, the publisher and proprietor of the *Manufacturer & Builder*, of this city: "I was taken in October last with a severe nervous disorder characterized by my physician as a depression of the sensory nerves. I tried medicine, the application of iodine to the spine as a counter-irritant, and rubbing. These benefited me only partially. My physician advised me to get a medical electric battery, and I ordered one of your $27 machines. It effected wonders, and I improved rapidly under its use until I am now in perfect physical health. My observation, however, leads me to say that the battery should be used daily (I used it 5 minutes each day just before retiring) until a cure is effected, otherwise it cannot be fully effective. I found the best application to be to the hands; and at the base of the brain or back of the neck. In the latter case the positive pole at the neck and the negative at the feet; running the sponge down the spine was not necessary."

BUILDING THE SIOUX CITY CORN PALACE.

The convenience of the electric motor is being shown to the crowds which watch the Sioux City, Ia., Corn Palace, now in course of construction.

About fifteen thousand bushels of corn are used to decorate the building. Last year, the saws to split the corn were run by four horses, and the irregular speed caused much annoyance to those feeding. This year a three-horse power Hawkeye motor, belted direct to a saw, does all the work much more satisfactorily. One man saws about sixty bushels an hour to supply over two hundred men and about the same number of women, who are decorating the building.

For working at night, the immense structure is illuminated by fifty arc and over one thousand incandescent lights.

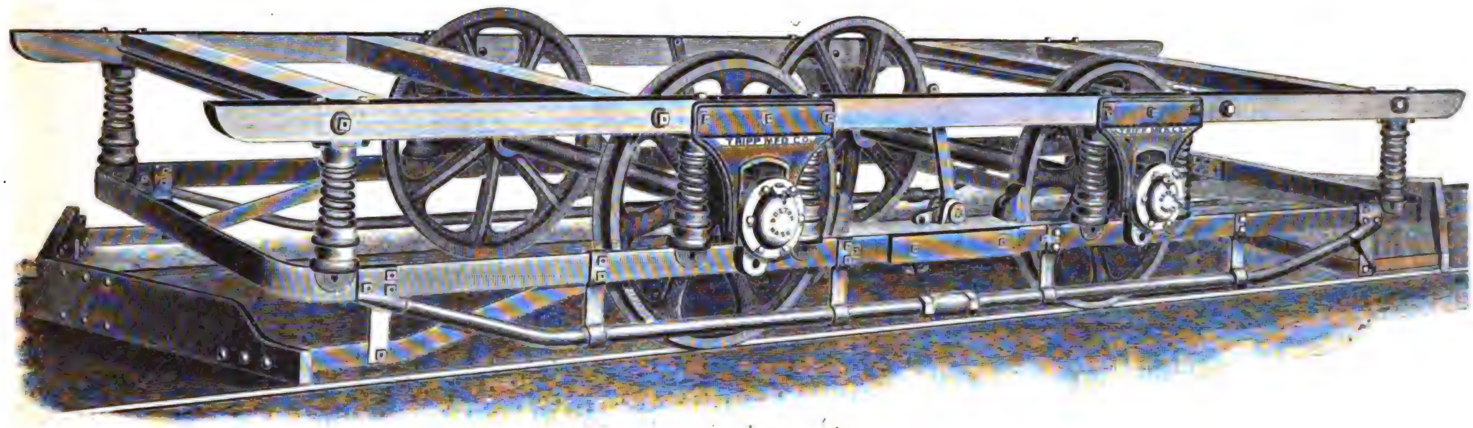
THE TRIPP ELECTRIC TRUCK FOR 18-FOOT CARS.

We illustrate this week another form of truck manufactured by the Tripp Manufacturing Co., of Boston, designed specially for long 18-foot cars. It differs from the truck described in our issue of August 20, in that it has a strong bottom truss, and top rail, so as to support the extra length. In all other respects it is the same, and has all the good points of the other, being fitted with the Tripp patent anti-friction roller-bearings.

The Tripp Manufacturing Co., of Boston, the extensive manufacturers of electric car trucks, to accomodate their rapidly increasing business, are about to increase their plant, by doubling their capacity. This plan will be immediately carried into effect, and their force largely increased, which will enable them to fill all orders with dispatch. This company manufacture every variety of trucks for electric cable and steam cars, which are equipped with Tripp's anti-friction journal bearings, which are noteworthy for saving in power effected, as well as being absolutely dust proof. The leading railways of the country indorse these trucks.

The city of Boston recently contracted with the Tripp Manufacturing Co. for their celebrated anti-friction journal bearings for the equipment of the large Federal street draw bridge, which is being re-built at great expense. Undoubtedly the same bearings will be placed under the various street bridges of that city at an early date.

The Tripp Company are now represented in the West by Samuel A. Randall, Sup't., who is on a business trip to Chicago and other Western cities, and Martin J. Deviney, salesman, who is on the Pacific Coast, where many large orders are being secured.



The Tripp Electric Truck for 18-Foot Cars.

It is worthy of mention also that the Tripp Manufacturing Co., of Boston, who are the sole manufacturers of the "Tripp Metallic Packing," which has been adopted by leading corporations of New England and the Middle States, are now shipping to customers in Canada and Great Britain, where a large business is assured. The company is now represented by agencies in all the principal cities of the United States and Canada; also in London and Liverpool, England, and Glasgow, Scotland.

WORK OF THE CONSOLIDATED ELECTRIC STORAGE COMPANY.

The Consolidated Electric Storage Company has appointed the following agents: Mr. Henry C. Eddy, 170 La Salle street, Chicago, Ill.; Messrs. Bemis & Perry, 21 Old Sentinel Building, Indianapolis, Ind.; Mr. H. P. Broughton, 401 Mermod-Jaccard Building, St. Louis, Mo. These agents are going actively into the work of storage battery installation for lighting and power.

We have seen recently the detailed record of the work the storage battery cars are now doing on Fourth and Madison avenues. It brings out remarkably few accidents and stoppages. There are nine cars now in service. Beginning with the 1st of October the cars running between midnight and the morning service will be exclusively electric cars. They will then have an opportunity of showing how much they can shorten the horse-car schedule between Eighty-sixth street and the post office, as they will have a free track.

A letter from Mr. Pritchard, the engineer in charge at Birmingham, England, states that the twelve Julien cars now in regular service there are doing good work. Storage battery traction is being rapidly pushed in New Orleans; eight (8) cars have just been received there from Brill & Co., to be followed by twenty-two (22) more. Thirty cars in all are to be installed within the next few months. Thirty trucks are already mounted with motors and prepared to receive the car bodies.

The Consolidated Electric Storage Company has got up a very handsome accumulator for phonograph work. The accumulator is placed in a hardwood box so as to accord in style with the phonograph box. The box is water tight, so that the accumulator may be shipped charged without fear of spilling the solution. It is carried by a leather strap, somewhat similar to a shawl strap. The capacity of the accumulator is from 260 to 300 ampere hours, and weighs, including the box, about forty-two (42) pounds.

SOME NEW WESTINGHOUSE WORK.

The Westinghouse Electric and Manufacturing Company has just obtained the contract from the Citizens' Electric Light and Power Company, of Blairsville, Pa., to light up that town. The contract was secured under the severest kind of competition; it is said there is not a company in the country which did not bid upon it, and the fact that the contract was given to the Westinghouse Company speaks volumes for their alternate current system, especially because the Westinghouse people entered the contest with the second highest figure. In order to assure themselves that the company would get the best system of electric lighting, a committee of seven was appointed with a view of making a personal investigation in several towns and cities where electric lights are now in use. This committee traveled to Altoona, Elizabeth, Tarentum, Allegheny and Pittsburgh, Pa. What they saw evidently convinced them that the Westinghouse system suited their purpose, and the contract was made. The plant will start with a capacity of 750 incandescent and 40 arc lights, but the company expects to increase this almost immediately.

The Newark, N. J., Electric Light and Power Company has been operating the Westinghouse alternating system for more than a year. In all this time the service of the company has been of such a character as to constantly grow in public favor. As a natural result of this fact, the company is now obliged to make extensive additions to its plant. When the plant was first operated 2,250 incandescent lamps seemed to be sufficient to supply all demands. However, the superiority of electric lighting over any other illuminant has since been demonstrated so largely that to-day the plant has to be more than doubled. The contract for 3,000 lights was awarded the Westinghouse Electric and Manufacturing Company a few days ago, and the apparatus is to be installed immediately.

The central station plant of alternate current incandescent lighting at Windsor Locks, Conn., is being enlarged, and the capacity of the plant will be increased 750 lights, making the total capacity 1,250 lights. The company is operating the Westinghouse alternate system, and the Westinghouse Company is now engaged in installing the additional apparatus.

The new Westinghouse motor, which has been in operation on the Pleasant Valley electric railway, Allegheny, Pa., for a week, has been the subject of daily conversation among parties interested in the electric motor business. The patrons of the road are perfectly delighted with it. They have named it the "Noiseless," and it is not an unusual thing for people to let several cars go by and wait for No. 130, the car fitted up with the Westinghouse motor. One of the officials of the Pleasant Valley Company, who has made the electric motor a study, and who has had experience with all of them, in answer to a series of questions as to the distinctive points of the Pittsburgh street car motor, said:—

"There is above all the wonderful ease and quietness of operation, which causes the cars to run along with a wonderful smoothness and silence. This noiselessness makes the car at once conspicuous on our line, and there is hardly a passenger on the route to-day who does not know the 'Noiseless.' People are enabled to converse even in an ordinary tone of voice on the car, and the residents along the line are in great praise of it. The car has been running 167 miles each day since the first day of its operation,

which is 47 miles a day more than any other car runs. That is, of course, because we run the car all night, and thus are able to accommodate the traveling public without having our cars become a nuisance to the people who are desirous of having a night's rest undisturbed by the rattling and grating of the street car motor. I also think the Westinghouse motor superior in its construction. All the details are far stronger than any other, especially the fields and the armature. Another noticeable feature is that the 'Noiseless' starts with the greatest ease while the other cars start with a sudden jerk, which is very objectionable to the passengers. I agree with Mr. Henry, the president of our road, who says that the Westinghouse street car motor is the best to-day. Noise has been the great objection to all motors and we have introduced the rawhide pinions on our ordinary cars; even then they are not nearly so noiseless as the Westinghouse motor."

The business of the Westinghouse Electric Manufacturing Company has received, it is stated, an extraordinary boom during the last month. The shops are now running at their full capacity day and night, and the company has still orders ahead to keep it busy the entire winter. This large increase in the work is especially caused by the wonderful success of the street car motor lately brought out. Several roads have been equipped already and their operation has proved to give more than ordinary satisfaction.

The manufacture of alternating current apparatus has also gained considerably, and the new Westinghouse system of alternating current arc lighting is rapidly becoming the popular method of illumination. Among the contracts the company has recently obtained are St. Paul, Minn., for an increase of apparatus to the extent of three thousand incandescent lights' capacity; Arlington Heights, Texas, five hundred lights; Rochester, Pa , an increase of five hundred lights, and Colorado Springs, Colorado, an increase of fifteen hundred lights.

ST. LOUIS TRADE NOTES.

THE COLUMBIA INCANDESCENT LAMP CO., who began here in a quiet and unpretentious way a year ago, have built up a substantial business, and have lately moved into commodious quarters at 1912-1914 Olive street. They manufacture lamps of any voltage and for all systems, the vacuum being very complete, a mercury test showing an air bubble the size of a pin point. Seventeen hundred of their lamps are in use at the Exposition Building. The company will shortly increase their capital stock from $16,000 to $50,000 and will increase their manufacturing facilities. Mr. J. H. Rhotehamel is president and general manager of the company.

MR. GUIDO PANTALEONI, Western representative of the Westinghouse Electric Co., has closed contracts for the complete installation of 20 motor cars for the Waco Texas Street Railway, 10 cars for the Ogden, Utah, Street Railway, 750 lights for Joplin, Mo., 750 lights for Carthage, Mo., and an increase of 750 lights for Sedalia, Mo.

THE SOUTHWESTERN ELECTRIC ENGINEERING CO. are doing a large business in wiring and installations. The Exposition building has been wired by them for 1000 additional lights and a new switch board erected. They are now engaged in wiring the Boatman's Bank for 1200 incandescent lights and 60 arcs, also an elaborate system of call bells for bank purposes. Hard rubber tubing will be used throughout. The Thompson building is being wired for 500 incandescent lights. They are also laying all the underground wires for the St. Louis Automatic Refrigerator Co., and three floors of Odd Fellows Hall are being wired for 500 lights. Outside the city they are installing 500 incandescent lights at Hiawatha, Kan.

WESTERN TRADE NOTES.

THE CHICAGO EXPOSITION.—Among the electrical attractions of the Chicago Exhibition is the varied display of fixtures, telegraph instruments and house goods by the Great Western Electric Supply Co. A sign made of cleats, and another made of colored shades are novel, and like the elk-head electrolier, which lights this exhibit, are much admired. The assortment of linemen's tools shown, also seems to catch the eye of the electrical people who visit the exposition. The same firm also has a display of its specialties at the St. Louis exhibition, in charge of Mr. G. T. Hewes.

THE FLEMING BUILDING, Washington & Montague streets, Jersey City, was struck by lightning on the morning of the 17th inst. The New York and New Jersey Telephone Co. occupied the top floor, and on the first alarm the 18 girls employed made a hasty escape. The arresters were destroyed and wires much tangled. Loss, $2,000.

STEALING TELEGRAPH WIRE.

Six employés of the city fire-alarm service have been held in the Criminal Court, Chicago, to answer to the charge of larceny. They are charged with stealing between 3,000 and 4 000 pounds of copper wire from the American Telephone and Telegraph Company, which operates the service of long-distance telephony. The thefts were accomplished by removing the poles of the company.

NEW ENGLAND TRADE NOTES.

THE UNION ELECTRIC CAR CO., of Boston, are building three more cars for immediate service on the Beverly and Danvers street railway. The two cars which have been running on that road for nearly a year have given great satisfaction, and they are now running on the Naumkeag tracks, a short distance in Beverly, and also from Danversport to Danvers Plains. The Union Electric Car Company are also building six of their cars to run on a new road in a Massachusetts town, which will be fitted in the same way with storage batteries and the Stevens patent gearing.

MR. CHARLES E. ROWE, for many years connected with the electric supply business, has opened an office on his own account at room 412, Shoe and Leather Exchange Building, Bedford and Kingston streets, Boston. His specialties at present will be the Sanford electric protector and lighting arrester and the Pumpelly storage battery, and he will also do general electric construction work.

THE JOHN BECKER MANUFACTURING CO., of 157 Pearl street, Boston, are making a specialty of furnishing electrical manufacturers with neatly designed name plates for dynamos, motors, and all kinds of electrical apparatus, and are reaping a rich harvest in this specialty. This firm produces the best work in this line to be had, and they can refer to nearly every electric manufacturing company, and most of the largest machinery manufacturing concerns in the United States. They manufacture every style and design of name plate in either nickel or bronze. Their factory is particularly well adapted for this class of work, Mr. Becker having a wide reputation for fine light castings, and having a particularly fine lot of machinery for executing tasteful designs. The beauty of all machines is much enhanced by a suitable name plate, and a large variety of designs can always be seen at their office.

THE EASTERN ELECTRIC LIGHT AND STORAGE BATTERY CO., at Lowell, has supplied the Sorley storage battery for lighting the Lawrence Mills, White Bros. & Co., Lowell Bleachery, Traders' and Mechanics' Insurance Co., Lowell; J. M. Sears' private residence, Southbridge; F. L. Ames' residence, North Easton; and has several orders on hand, including orders for installing batteries in Abbot Academy, Andover; Howland Mills Manufacturing Co., New Bedford, etc.

J. A. GRANT & COMPANY, Boston, are filling an order for a complete steam plant for electrical purposes at Zacatecas, Mexico, consisting of boilers, McIntosh and Seymour engines, pumps, feed-water heaters, etc.

THE WRIGHT ELECTRICAL ENGINEERING COMPANY, Boston, have made a contract with the Clinton Gas Light Company, Clinton, Mass., for the line work to accomodate 120 series 25 c. p. lamps, and 30 1,200 c. p. arc lamps. About 550 poles will be used, and 27 miles of wire furnished by the American Circular Loom Company, of Boston. The Wright Company will also wire the station and furnish the slate switchboard, the arc and the alternating incandescent lights.

THE STANDARD ELECTRIC COMPANY, of Vermont, have received through the Hunt Engineering Company, of Brooklyn, N. Y., their New York agents, the contract for furnishing two 500-light dynamos for the Broadway Theatre, at Norwich, Conn. The wiring will be done by the Hunt Engineering Company.

THE PETTINGELL-ANDREWS COMPANY are having quite a run on their new socket to fit Thomson-Houston lamps. It is extremely simple in its action. They have sold in the past few weeks no fewer than 50,000 of these sockets, which are giving great satisfaction. They are also selling in large quantities the tested fuse wires of the Massachusetts Engineering Company, and are enjoying a large sale of the new Bryant switches. Okonite is also in large demand, and the Pettingell-Andrews Company have now one of the largest stocks of insulated wire ready for immediate shipment in the country.

THE ROBINSON ELECTRIC TRUCK AND SUPPLY COMPANY has been formed as a sub-company of the Robinson Radial Car Company, to operate under license for the construction of the Robinson radial car trucks for street railway work. The company are making arrangements for the necessary works and will most probably erect a factory in Lynn.

THE

Electrical Engineer.

VOL. X. OCTOBER 1, 1890. No. 126.

LIEUT. FISKE'S NEW RANGE FINDER.

THE importance of being able to determine the exact position and range of an object to be fired at, whether from a fort or war vessel, is too obvious to need further exemplification, and hence a ready means of determining this point is evidently of the utmost practical importance in gunnery. As our readers may be aware, Lieut. Bradley A. Fiske, U. S. Navy, has devoted considerable attention to this subject, and has designed a variety of forms of these instruments. His most recent work in this branch is a range finder which embodies a decidedly novel application of the Wheatstone

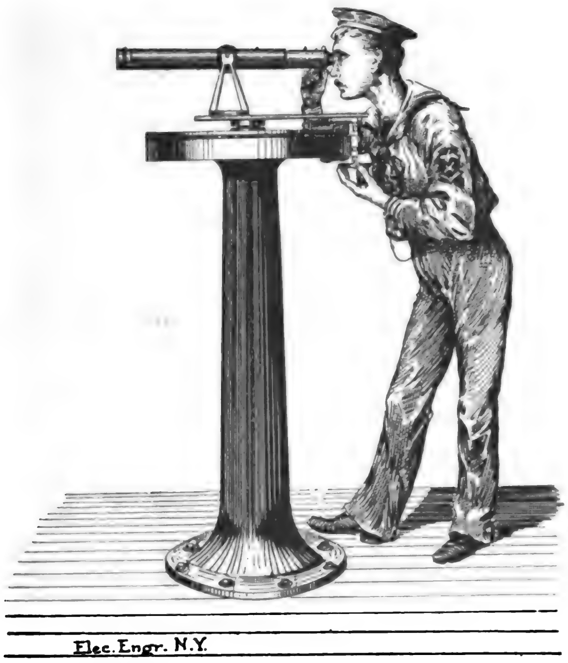


FIG. 1.—LIEUT. FISKE'S RANGE FINDER IN POSITION.

bridge as a means of measuring the angles, and by means of which ranges or distances can be read directly from a scale.

Broadly considered, Lieut. Fiske's latest method consists in determining a fractional portion of a conductor bearing in length a ratio to the angle included between two lines of sight directed upon a distant object, and simultaneously causing a disturbance in an electrical balance, including the conductor in its circuit, proportional to the resistance of the fractional portion, and observing the difference in potential due to the disturbance.

The accompanying diagram, Fig. 2, illustrates the simple and ingenious manner in which this is carried out. We will suppose AB to be a base line, and T the position of a distant object, the range of which AT is to be determined. By trigonometry, in the triangle ATB,

$$A\,T = \frac{AB}{\sin ATB} \times \sin ABT.$$

Let C and D represent two telescopes pivoted at the points A and B and sweeping over arcs E and F of conducting material, the arcs having their extremities upon the base line AB. Let the telescope C be directed upon the point T, assuming the position represented by C', in dotted lines. Then obviously, the angle $C'A\,C$ is equal to the angle $A\,TB$ and the portion of the arc E included between the positions C and C' of the telescope, will measure the angle at $A\,TB$.

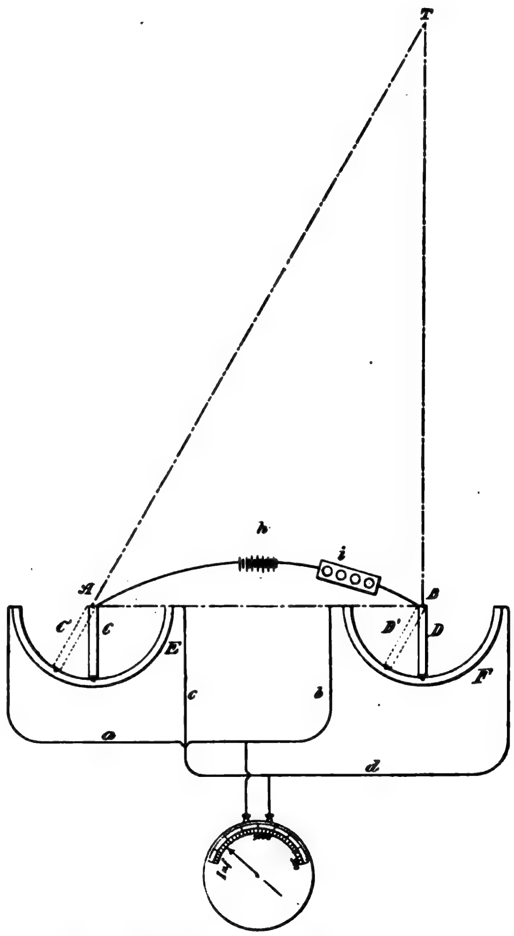

FIG. 2.—METHOD OF USING THE FISKE RANGE FINDER.

In the foregoing formula, the base line $A\,B$ is known by measurement, and the angle $A\,B\,T$ may be observed; and if the angle $A\,B\,T$ is, as shown in Fig. 2, a right angle, then the sin $A\,B\,T$ becomes unity. It remains, therefore, to find the angle $A\,TB$ in order to determine the distance $A\,T$; so that it becomes necessary to provide a simple and rapid means of at once determining what the angle $A\,TB$ is. To this end, the conducting arcs E, F, are connected in the manner of a Wheatstone bridge, the four members of which are shown respectively at a, b, c, d. In this bridge is connected a galvanometer in the usual way, and also the battery h; the terminals of the battery wire being connected to the telescopes at their pivot points A, B, so that

the circuit proceeds through the telescopes to the arcs, and then at the arc F divides through the wires b, d, and at the arc E divides through the wires a, c.

It will be plain that when the two telescopes C and D stand at right angles to the base line, and hence parallel to each other, the bridge will balance, and the galvanometer will show no deflection. The lines of sight of the two telescopes then being parallel, the galvanometer will then indicate infinite range; and of course, this will be true no matter where the telescopes may be on their respective arcs, so long as their lines of sight are relatively parallel. But if one telescope be moved out of parallelism with the other, as for example, the telescope C moved to the position C', then clearly the bridge will be thrown out of balance, and the galvanometer will be deflected. It will also be clear that the extent of deflection of the galvanometer will depend upon the length of arc included between the two positions of the telescope, C, C', and will be greater as that arc increases; so that with a battery of constant electromotive force, it becomes possible to determine the extent of movement of the telescope C by simply observing the indication of the galvanometer.

It will of course be obvious, that as the angle between the positions C and C' of the telescope increases, the length of the line $A\ T$ will constantly decrease, while the deflection of the galvanometer will constantly increase; so that the galvanometer indicates ranges starting from infinity when the galvanometer shows no deflection, small ranges being indicated by large deflections of the galvanometer, and *vice versa*. As a matter of convenience, Lieut. Fiske employs for this purpose a galvanometer so constructed that the deflections of the index will be proportional to the differences of potential at the terminals.

It will be clear that by the method just described the operation of finding the range is reduced to a very easy and rapid process, and at the same time, greatly simplified as regards apparatus.

Observers stationed at the two telescopes C and D align them with the distant object, when a third observer instantly reads the range from the galvanometer, which is provided with a scale suitably marked in linear units, such as yards.

If, however, the angle $A\ B\ T$ is not a right angle, then the factor, sin $A\ B\ T$, must be taken into consideration in solving the formula, $A\ T = \dfrac{A\ B}{\sin A\ T B} \times \sin A\ B\ T.$

Or, in other words, the observer at the galvanometer may simply multiply the range indication by the sin $A\ B\ T$ numerically expressed, in order to reduce the indicated range to the true range. The angle, $A\ B\ T$, is observed directly on the arc F.

In the foregoing demonstration, it is assumed that the resistance in the circuit remains constant, that is, remains the same as it is when the two telescopes are parallel to each other, and stand in the positions, $C\ D$, touching the middle parts of their arcs. But, as a matter of fact, this resistance does not remain the same when the telescopes move to positions nearer the extremities of the arcs. To illustrate, if the resistance of the circuit is a certain amount with the telescopes in the position $C\ D$, it will be less when the telescopes are turned in the position, $C'\ D'$. Now, the variation of resistance due to this change of position will affect the total resistance in circuit to an extent depending upon its ratio to the resistance of the whole circuit. And, consequently, if that ratio be made very small, as it easily may be by simply introducing a high resistance in the battery loop at i between the points A and B, then, inasmuch as the variation in resistance due to change in position of the telescopes may thus be rendered inappreciable, the total resistance of the circuit may be taken as constant; so that, despite the fact that the angle, $A\ B\ T$, differs from a right angle, the deflection of the galvanometer, as before, will remain practically constant for any given angle, $A\ T B$.

It is evident that if the high resistance before mentioned be not put in the battery loop, then the decrease in resistance due to change in position of the telescopes from the middle point of their arcs toward the extremities of the arcs may bear a considerable ratio to the resistance of the whole circuit. And as this decrease in resistance will be attended by corresponding increase in current strength, it follows that proportionately greater deflections of the galvanometer will follow for any given angle, $A\ T\ B$; so that, consequently, the ranges indicated by the galvanometer will be less than those which would have been shown had the high resistance been put in the battery loop. Again, if the resistance of the battery loop between A and B is extremely small with relation to the rest of the circuit, the decreasing resistance of the whole circuit, due to change in position of the telescopes, may become very large; and this result may be intensified if the members a, b, c, d, connecting the arcs, are connected to those arcs at points less than 90 degrees from the middle points of those arcs. If, for instance, these wires were connected to the arcs at points 81 degrees removed from the middle points, and if the resistance in the battery loop were one-tenth of the arc of 81 degrees, then when both telescopes were moved to positions 60 degrees from the middle points, the resistance of the whole circuit would then be only about half of what it was when the telescopes were at the middle parts or the positions $C\ D$. Consequently, for any given relative angular displacement of the telescopes occurring 60 degrees away from the middle points of the arcs, the corresponding deflection of the galvanometer would be about twice as great as if the same relative angular displacement occurred when the telescopes were near the middle points of the arc; so that the range indicated in the latter case would be about half as great as in the former.

But it will be observed that if the telescope, D, for instance, were 60 degrees removed from the central position, the angle $A\ B\ T$ would be 30 degrees, or 150 degrees, and then its sine would be one-half; so that the range indication for any given angle $A\ TB$, would be only one-half of what it would be with the same angle $A\ TB$ when the telescope at D' is in its middle position. In other words, the fact of the decreased resistance caused in the circuit as the telescopes move away from the middle position, tends to automatically make the very correction for the sine of $A\ B\ T$ which ought to be introduced, because the telescope no longer stands at 90 degrees to the base line; and this is found to be the actual occurrence in practice.

In what has been said above, the resistance of the galvanometer has been neglected, and it has been assumed that the E. M. F. and internal resistance of the battery, and the resistance of the various contacts, remain constant. While this is not theoretically true, Lieut. Fiske finds that by using storage batteries and by making the contacts carefully, no appreciable error is introduced. Careful experiments with this range finder at sea, show that the errors of the instrument are insignificant and the indications absolutely instantaneous.

Fig. 1 shows the range finder as actually used on shipboard. The instruments are made of aluminum, bronze and iron, and are left exposed on deck without any protection whatever, except that a cover is placed over the telescope when not in use. The instruments require no care except an occasional cleaning.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

At the meeting of Council, held September 16th, Messrs. E. M. Barton, A. H. Bauer and E. M. Izard, of Chicago, were appointed as a committee of three to represent the Institute at a meeting of various engineering societies, to be held in Chicago, October 14th, under the auspices of the Western Society of Engineers. The object of this meeting is to organize an International Engineering Conference, to be held in conjunction with the Columbian Exposition in 1893.

NEW STREET RAILWAY MOTOR OF THE UNITED ELECTRIC TRACTION COMPANY.

WE illustrate herewith, in Figs. 1 and 2, the new 30 h. p. railway type motor of the United Electric Traction Co., of this city, with its gearing in position, mounted on one axle of the car. The other extremity of the motor, attached to which is seen an iron ring, is adapted to be suspended on a bearing on the other axle, not shown. This other bearing is about 8 inches long and has an end play on its axle regulated by means of two collars, which is sufficient to give the suspension flexibility when the motor is going around curves or in other difficult places. Figs. 3 and 4, page 355, give an upper and lower view of the end casting, which attaches the motor to the driven axle. This casting is made of gun steel and is provided with oil reservoirs and chain pumps, keeping the bearings flooded in oil while the motor is running. The I beam shown in Fig. 3 and also in Figs. 1 and 2, is of forged steel bolted to the casting at the back and reaching around the motor, supporting the front end of it. The motor fields, as may be seen from the illustrations, are built up of bars of Swedish wrought iron, securing a very high degree of efficiency, both from the quality of the metal and the lamination resulting from this form of structure. The armature is of the Gramme type, wound in a large number of sections. It is built up of a core of iron wire. The winding is so arranged that considerable ventilating space is left, and so that one or more sections can be very easily and cheaply removed and replaced. The regulation of the motor is secured by the use of a cumulative winding on the fields. For starting, a small rheostat is used to prevent the shock to the gearing which follows a sudden starting of the motor. The gearing consists of two gears of gun steel, cast and carefully tested before cutting. The two pinions are cut from blanks of forged steel of very high quality. This work of gear cutting is done with great accuracy by special cutting machines in the company's shops. It will be noticed that the armature can be removed by simply unkeying the armature pinion and removing four bolts from the bronze spider at the other end of the armature shaft. This is a matter of considerable importance where repairs to the armature are necessary.

The starting mechanism furnished in connection with these motors is of very simple character, and is operated from either platform of the car by means of a simple mechanical connection. The space occupied on the platforms is reduced to a minimum by this arrangement. The field coils of the motor are wound upon spools of peculiarly rigid construction, are covered with heavy canvas and are thoroughly waterproofed. Every part of the motor as described above, except the steel castings, is made in the United Electric Traction Co.'s shops, at Jersey City, and all parts are made interchangeable upon United States government standards to 1-1000 of an inch. The capacity of the Works has been recently enlarged and they are now turning out car motors of this type at the rate of about one a day. The standard type of 20 h. p. motor is similar to the above, only smaller. A new standard for storage battery work where two motors are required on a car is shortly to appear.

It may be mentioned in connection with the foregoing that it has been found that suspending the motor directly from the two axles by a more or less elastic suspension almost entirely does away with the noise which is heard when the motor is attached to the truck frame or to any part of the car body or truck above the springs, the car body being in this case a resonator to magnify the noise.

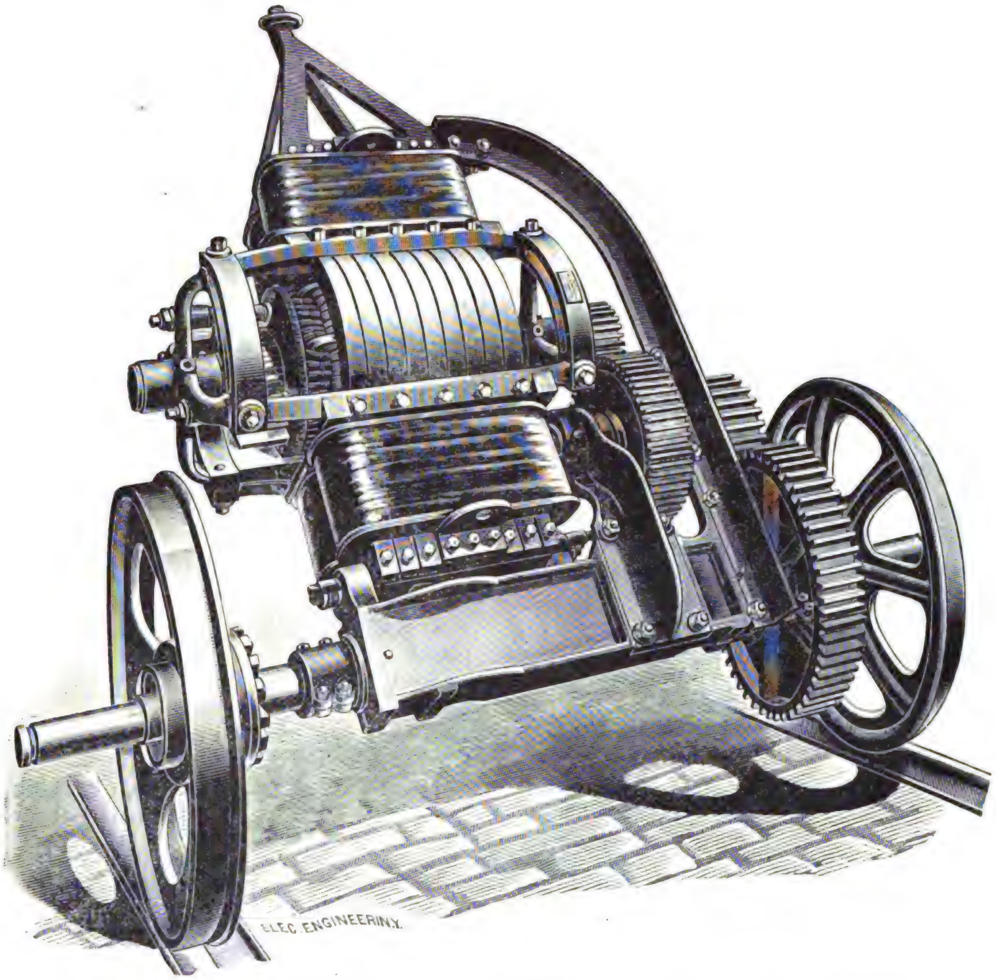

FIG. 1.—NEW STREET RAILWAY MOTOR OF THE UNITED ELECTRIC TRACTION CO.

The bronze spider at one end of the armature shaft, with the two brush holders in position, is shown in Fig. 5. It will be noticed that these brush holders are adjustable in three different directions and that their mechanical action is exceedingly simple and certain. The brushes used are of carbon, a special variety of carbon composition having been found, after a long course of experiment, to best suit the requirements of railway motors. This compound has been patented by the United Electric Traction Co. The brush holders are made of rich brass and are very strongly and securely attached to the spider.

POLARIZING CONDITIONS IN A GALVANIC BATTERY.

PROF. A. E. DOLBEAR.

When hydrogen accumulates upon one of the plates of a galvanic battery so as to reduce the current, the cell is said to be polarized, and various methods have been devised to prevent this, some chemical, as in two fluid cells, and some physical, as when the plate is rotated, and these are called depolarizers; the idea being that the polarization itself consists simply in the accumulation of gas upon the plate. I do not know that any attempt has been made to explain the underlying conditions present where chemical action is present or latent in a battery, which bring about such a result, for it is plain that such a result must have some antecedent physical conditions that determine it.

The following explanation has seemed to me to be probable, and the commendations of a number of my electrical friends induce me to publish it, not as proved, but as a step towards a clearer understanding of the mechanical conditions present in a galvanic battery.

When a piece of zinc is immersed in water it is found to be electrified, and its potential may be measured by a suitable electrometer.

Now, we know from purely chemical sources that there is chemism, or chemical attraction, existing between zinc and oxygen, and that under favorable conditions zinc will be oxidized. This so-called affinity of zinc and oxygen is not suddenly created by their juxtaposition under certain circumstances, but exists all the time, only waiting for an opportunity to show itself.

What then are the real conditions present when a piece of zinc is immersed in water? The zinc is a solid, the molecules cohere, and there is a certain degree of rigidity to the molecules. With the water it is different. As a fluid, the molecules are free to move about among each other with but little internal friction. As the molecule of water is made up of both oxygen and hydrogen, it may have an oxygen side and a hydrogen side, in which case, if there be any selective agency acting more upon the oxygen part of the molecule than upon its hydrogen part, and if the molecule as a whole is capable of shifting its position easily by a simple rotation upon any axis, as is true in this case, then all the molecules of the water that come in contact with the zinc must be oriented by the zinc so that the oxygen side of the molecule faces the zinc at every point, and consequently the hydrogen side is away from it. This would be a true polarization of the molecules of water, and the distance to which it would extend would depend upon the strength of the chemism between the two acting elements. Such a chemical field might extend indefinitely.

When a piece of carbon or copper or other element is placed in water, it exhibits similar electrical property, but different in degree from that of zinc; so similar polarization of molecules would be set up about it. The difference in the degree of chemism between the two elements and the oxygen of the water would determine the rate of oxidation under given conditions, and this difference we call the electromotive force of the cell. Also, the mere fact that there was a difference in this particular between the two immersed elements would tend to produce between them a similar condition of arranged or polarized molecules.

All this might be expected to occur, whether there was a chemical reaction or not, that is to say, whether or not the zinc was dissolved and water decomposed. Whether this happens, or not, depends upon the degree of tension represented by the difference in the so-called chemism between the two elements, which difference we measure in volts, and needs to be about 1.5 for water.

If other solutions than water be used, the same mechanical conditions and arrangements would be present, differing from it only in degree.

The substance of the idea is this, that the chemism existing between the zinc and the element oxygen in the water *compels* the molecules of the water to turn so as to present their oxygen side to the zinc, which they are able to do freely, because such movements are not subject to appreciable friction in the liquid.

When the other battery element cannot combine with oxygen in any degree under the existing conditions, as when carbon or platinum is used, then only hydrogen will be set free, as there is a greater stress for the oxygen at the other element and there must be an exchange of partners among the molecules along the whole line between the elements, according to Grotthüs' hypothesis; so that, underlying the accummulation of hydrogen called polarization, is a real polarization in which all the molecules are facing one way from the mechanical necessities present.

It seems not unlikely that this condition of things in a heating liquid might be observed by noting the effect produced by it upon a beam of light transmitted through the liquid, especially upon reversal of electrical condition.

THE HISTORY OF ELECTRIC TANNING.

In a recent article in *La Lumière Electrique*, M. Rigaut says: "Like all other discoveries and inventions, that of using electricity in tanning is not a new one. About 1850, a currier named Crosse, invented an apparatus to utilize what he called the 'effects of electricity or galvanism for tanning purposes.' Two electrodes were placed in a tan-pit, one made of lead, the other of zinc. The pit was then filled with water and skins, and, after an interval of three days, tan was added in small proportions, in order to concentrate the liquor. Ten years later, an Englishman named Ward, of Lancashire, made a series of experiments. Instead of electrolyzing the skins in water before adding the tan, he used electricity in the tanning baths. At Paris, in 1861, a M. Rebu invented a system of electric tannage. This is said to have been very complicated. The skins were treated with carbonic acid and hydraulic pressure, and then submitted to the action of salts of lime, of magnesia, and of iron. Currents of electricity were passed through the skins while they were immersed in the above mixtures and the usual tanning solutions. In 1874, M. de Mertens tried another system. At the bottom of a large vat was placed a layer of carbon, connected with the positive pole of a dynamo. On this skins covered with tan were placed. On the top of this heap a plate of zinc was placed, connected to the negative pole. The vat being filled with tanning liquid, the current was passed through. M. Mertens' system has been employed in nearly 600 pits for some years past at a tanyard in the environs of St. Petersburg, and by it about thirty-five days is required to tan the skins. In 1876, Gaulard and Kresser brought out another process, and in 1883, skins tanned by Gaulard's process were exhibited in England. In 1887, in Sweden, Messrs. Abom and Landin brought out a method for the use of electricity, and this has been in operation for two years at Noorköping, in Sweden, with good results, forty-five days being required for tanning. Some months before this Messrs. Worms and Balé, at Paris, had worked a process for the rapid tanning of skins by the aid of the electric current.

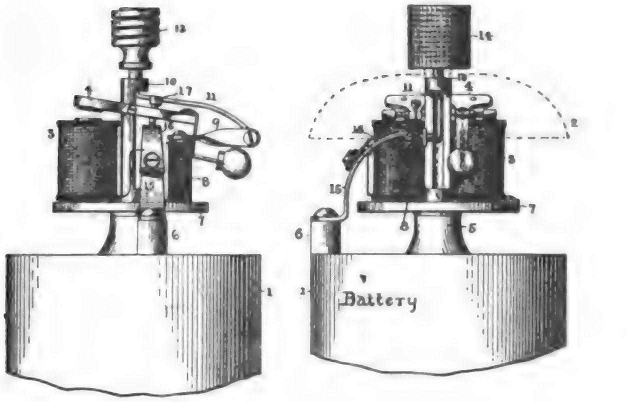
A NOVEL PORTABLE ELECTRIC FIRE ALARM.

There are many instances where it is desirable to provide means for giving a local fire-alarm in buildings which are not wired and connected to the engine-stations or fire-department of a city, as when a building is used temporarily for storage or like purposes, or in buildings outside of the fire-department limits. In addition to this the manufacture of many articles involves the application of heat, as, for instance, in drying rooms where a certain temperature must not be exceeded. For these and similar purposes a portable electric alarm can be most conveniently applied, and with that object in view, Messrs. F. R. Upton and F. J. Dibble have recently devised and patented a compact arrangement. The apparatus consists broadly of a battery with a bell or buzzer, normally on open circuit, and a thermostat for closing the circuit when the temperature exceeds a given limit.

The accompanying engravings show the arrangement of the combined bell, thermostat and battery. As will be seen, the bell-dome is supported on the dry battery which is here employed. The insulating post 8 carries an arm which terminates in an adjustable contact. Through the upper part of the post 10 extends an angle-rod terminating in a contact 12. The upper end of this angle-rod is rigidly connected to one end of a thermostatic coil 13, which is composed of two metals of unequal expansibility. The other end of the coil is connected to a stationary part of the apparatus. Around this thermostatic coil there is placed a shield composed of perforated sheet metal or wire fabric for protecting the coil from mechanical injury. From the other electrode of the battery rises an arm 15, the end of which carries an electrical contact, which in the normal condition of the apparatus is in contact with a terminal carried by spring 16, insulated from the arm as shown. This spring is weaker than the retracting-spring of the armature and is held compressed by means of the retracting-spring through an adjustable screw which terminates



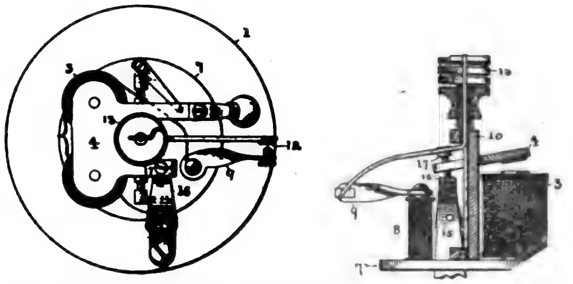
Figs. 1 and 2.—Portable Thermostatic Alarm.

in an insulating-point. Spring 16 is connected by a wire through the magnet to arm 9.

In using the alarm, the contact in arm 9 is adjusted to a certain distance from contact 12, the distance depending upon the degree of heat at which it is desired to sound the alarm. This adjustment can be made when the bell dome is in position. The apparatus having been adjusted, is placed in the room to be protected. As the temperature rises the thermostatic coil will be affected in such manner as to throw the angle-lever and its contact 12 toward the contact on arm 9, and when the limit of temperature is reached for which the apparatus is adjusted the contacts will come together and will close the circuit. This closure of the circuit energizes the magnet and attracts its armature, bringing the bell-hammer against the bell-dome. At the same time it raises the screw 17 from spring 16, allowing the spring to rise and break the circuit. As soon as this occurs the retracting-spring draws the armature back to its original position, thus again closing the circuit between 15 and 16, which again energizes the magnet. It will be seen that the contacts on 15 and 16 cause the bell to act as a vibrating bell in the well-known manner. With this arrangement the alarm continues to sound as long as the temperature remains high enough to keep the circuit closed between arms 9 and 11.

An ordinary dry battery is found to furnish sufficient current, to require practically no attention and to last for a long period of time. Moreover, with this form of battery, all danger of leakage of liquid or spilling the same by breakage of the jar is obviated; but evidently other forms of battery would serve the purpose.

By the construction described several important advantages are gained. In the first place, the thermostatic coil



Figs. 3 and 4.—Portable Thermostatic Alarm.

or device is raised away from the mass of the battery and other apparatus. It will therefore be much more sensitive to the influence of heat in the room where it is placed, since it will be affected at once and will not be dependent on the temperature of the supporting mass. By placing the bell-dome as shown, the circuit contacts and springs are protected from mechanical injury and to a very large degree from dust, which otherwise would settle upon them.

THE ROBINSON RADIAL CAR SYSTEM.

One of the features that was early brought out in the application of electricity to street railway work was the enormous amount of power that the cars with the ordinary trucks and four-wheel base consumed in going around curves. The present writer has witnessed scores of runs when the needle of the ammeter would jump forward in "blocks of five," ten and twenty amperes at a time, showing how great was the draft at such periods on the source of current. Where storage cells have been used, the frequent inability of the cells to last has been due to the drain and strain on them necessitated by the effort of the motors to overcome the sudden and tremendous increase of friction. Evidently something had to be done to bring the jogging and jolting horse car up to a point of efficiency at which there could be some realization of the hopes and convictions entertained as to the superior economy of electricity. So long as the abnormal, terrific strain fell upon the horse, nobody seemed to care much; but when the wringing of withers and the exhaustion of vitals was transferred from animals to mechanism, the shameful cruelty and barbarism of the whole thing became apparent. The result is that within the last year or two cynical indifference on a very important subject has been succeeded by the most lively interest, and no questions to-day are more closely studied than those which relate to smoothness of running and economical operation of the car gear.

Among the first to attack the problems involved in the condition of affairs thus exposed was Mr. Robinson, of Boston, well known in electrical and railroad circles as the inventor of the system of electrical signals for railways now owned by the Union Switch and Signal Co. It was natural that this gentleman should be attracted to the

subject. His earlier work had required the use of the rails of the tracks as conductors for the current; and we believe that the method now in universal use on electric railways of connecting the rails together by means of wires was his invention. In the department of work now under consideration, Mr. Robinson went straight for a correction of the troubles and losses due to getting around curves. Fig. 1 represents a truck or street car of ordinary construction with rigidly parallel axles, showing how it gets around a curve in the direction of the arrow. When the wheel, A, strikes the curved rail, the rail resists the shock and causes the wheel to rebound or glance; at the same instant the propelling power gives a forward impetus to the truck or car, when the wheel again strikes the rail with great force and again rebounds. The course which the wheel travels is indicated by the saw-tooth line, H, in the accompanying cut. Thus the truck or street car finally gets around the curve, if at all—not by rolling, in accordance with mechanical principles—but by a succession of blows or jerks, commonly called "grinding;" it is skidded around by main force.

When the "horse car" is propelled by electricity the grinding on curves is exaggerated; the wheels, which strike the rails at an angle, tend to mount them at every instant, and frequently do so; the motor car often gets stalled on sharp curves, especially in towing another car, and in order that it may get around street corners at all, the curved rails are kept liberally daubed with grease. The horse car has its two axles placed near together and near to the centre of the car, otherwise it could not get around the street corners at all. These axles act as fulcrums on which the car body has an end tilting and rocking motion extremely disagreeable to passengers, and which frequently throws the car off the track. This construction furthermore makes a high rate of speed, with safety, impossible—even on a straight track.

In order to remedy this, Mr. Robinson has devised and adopted a six-wheel radial truck. Fig. 2 illustrates the position which the axles and wheels of such a truck assume in running over the curve track, B. The axles automatically assume an exactly radial position on any curve upon which the car runs, and the power required to propel this car around curves is little, if any, more than that required to propel it on a straight line. The radiation of the axles diminishes the power required to propel cars around street corners from fifty to seventy-five per cent., it is said, and often more than this, and also makes it possible to roll cars around street corners easily which, without the radial axles, could not, by any possibility, be got around such curves, on the rails, however much power might be applied.

The "grinding" on curves, inseparable from all car trucks with rigidly parallel axles, that is, all now in use, is obviated in the electric "Radial" car. In this car each axle is always at right angles to the line of travel, whether on a straight line or on a curve; that is, the axles automatically, but positively, adjust themselves to the changes in the direction of the line of travel; they are always parallel on a straight track and radial on curves.

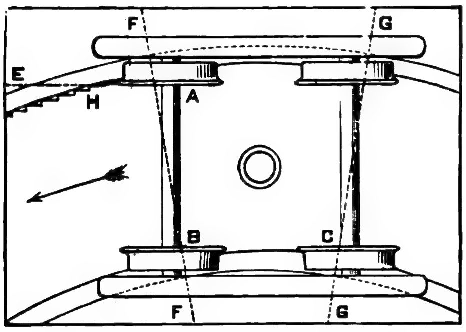


FIG. 1.—RIGID TRUCK ON CURVE.

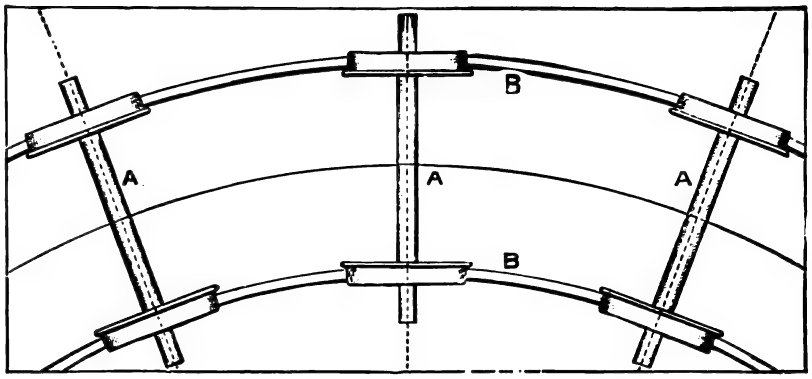

FIG. 2. RADIAL TRUCK ON CURVE.

In Fig. 3 we show clearly the construction and appearance of one of the Robinson "Radial" steel trucks for electric roads. As will be seen, there are three axles and six wheels, two of the axles carrying motors and four of the wheels being drivers. The truck here shown has been running under a closed car in the regular electric service of the West End road since June 1, 1890. Each axle carries a 15 h. p. Thomson-Houston Motor. The dimensions of the car are as follows: Length over all, 36 feet, 4 inches; length of body, 28 feet; wheel base, 15 feet; seating capacity, 42 passengers; carrying capacity, including standing room, 150. Fig. 4 shows another closed car of the same type, but of slightly smaller dimensions, which has been running since last December. Fig. 5 is an engraving of the Robinson "Radial" open car. It has twelve benches and seats 60 passengers. It is 34 feet, 3 inches long over all; has a 14 feet wheel base, and its steel truck is provided with two 15 h. p. Thomson-Houston motors. It has been running on the West End road in regular service between Arlington and Bowdoin Square since July 12. Fourteen

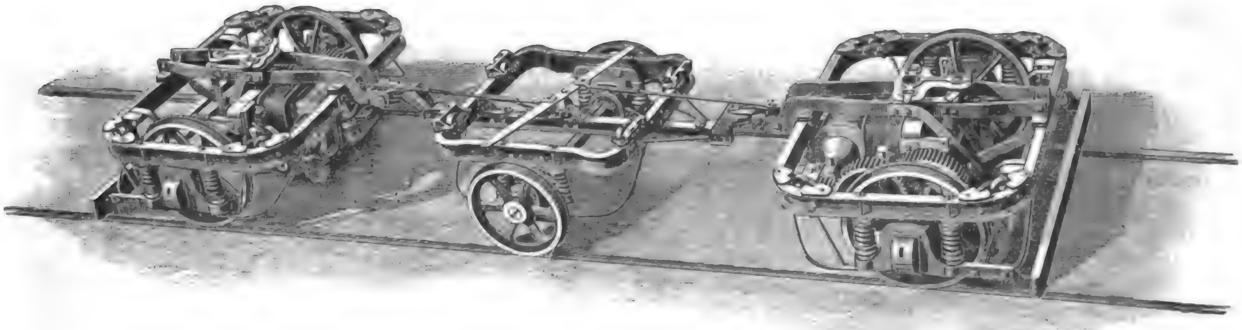

FIG. 3.—THE ROBINSON RADIAL ELECTRIC CAR TRUCK.

other closed cars are now being built for the West End road and are nearly ready. A new Robinson car of magnificent proportions has recently been supplied to the Eckington & Soldiers' Home Railway Co., at Washington. It exemplifies strikingly the luxury that is to prevail under the new regime of electric power. It is a closed car and seats 40 passengers. The interior is furnished in rich mahogany with gold panels. On the inside it has a sweeping arch roof similar to the design of the latest steam cars. Above this is a monitor top not seen from the inside. A number of ventilators in the ceiling communicate with the monitor top and through it with the exterior air, giving excellent ventilation without any draught.

In conclusion it should be stated that it has lately been shown by special tests made under competent authorities that, in addition to better running on curves and grades, these trucks have been found to take less power in straight-away running than do eight wheeled cars of the same weight and load. We have seen the figures of the report, which bear out this assertion, but as they are "confidential" and the private property of the company for whom the tests were made, we are not at liberty to publish them. The patents on the truck, etc., are owned by the Robinson Radial Car Truck Co., of Boston, which is the parent organization; and the active work of supply and construction is carried on by the Robinson Electric Truck and Supply Co., of Boston.

EICKEMEYER WINDING FOR ELECTRIC RAILWAY MOTOR ARMATURES.

A NEW departure has recently been made by the Edison General Electric Co. in its electric railway work by the introduction upon its motors of the Eickemeyer method of armature winding, whose use it controls in that class of work. As our readers are aware, the armatures of electric railway motors have generally been wound upon the Siemens system, the main objection to which is that the irregular mass of wire at the end has a tendency to move, abrading the insulation and leading to a short circuit. As the burn-out most frequently occurs in the under or inner coils, repairs are unduly expensive.

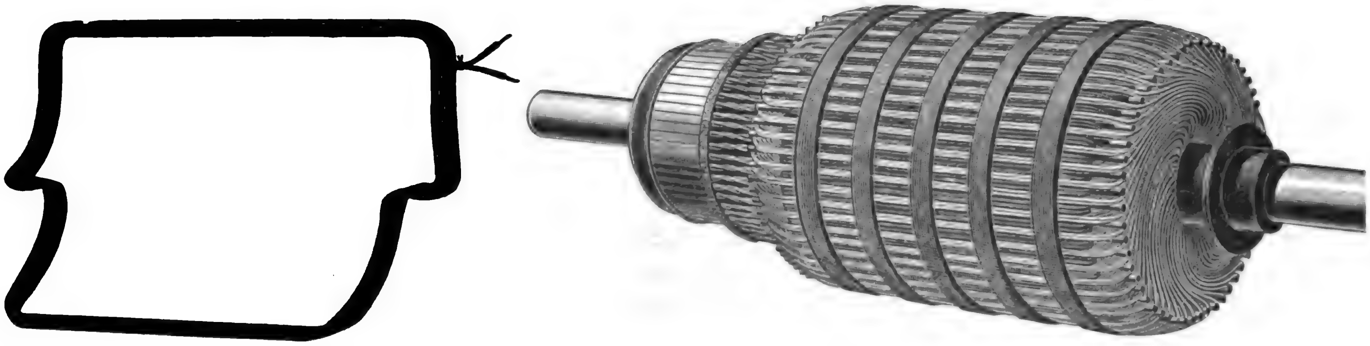
In the Eickemeyer system of winding, each armature coil, Fig. 1, is wound upon a form of peculiar construction, and comes out standard and interchangeable in every respect. In building an armature originally, the laminated iron core is first prepared as in the Siemens armature, and upon this are loosely placed the necessary number of standard coils, which are locked in place around the armature by means of the wooden pegs, shown in Fig. 2. The result is, a square end both front and rear, instead of the cone-shaped end of the Siemens armature. The coils are held firmly in place, with absolutely no chance for motion, and there is no mechanical pressure from coil to coil which would tend to cause short circuit. The armatures are necessarily of standard diameter and interchangeable, and it is claimed

that the Eickemeyer armature will never burn out except from dead over-load causing melting of the wire, from accidental mechanical injuries, or from short circuit due to outside causes. If, however, an armature coil should burn out from any of the causes mentioned, it could be replaced without difficulty by any ordinary mechanic and without return to the factory, the whole operation consuming about a day's time and a small amount of material. The local railway company would be provided with a sufficient number of standard coils held in reserve.

The temperature is regulated by the arrangement shown, which constitutes a governor, set in operation and acting through the expansion of the oil, and the action of which is to automatically shunt the heating current around the resistance within the heater.

C. & C. MOTOR COMBINED WITH VENTILATING FAN.

We illustrate on this page a combination of the C. & C. motor with the Blackman ventilating fan. The plant from which the engraving is made was installed not long



Figs. 1 and 2.—New Edison Electric Railway Armature and Coil.

since in the Union Trust Company's building on Broadway. It is made up of a 30-inch disc exhaust fan and electric motor mounted directly on the shaft and supported by the fan brackets. It revolves at a speed of 600 revolutions and delivers 20,000 cubic feet of air per minute. A large demand has arisen for machines of this character as being preferable to the equipment in which the motor is belted to a pulley on the fan, causing a certain amount of

C. & C. Motor and Ventilator Combined.

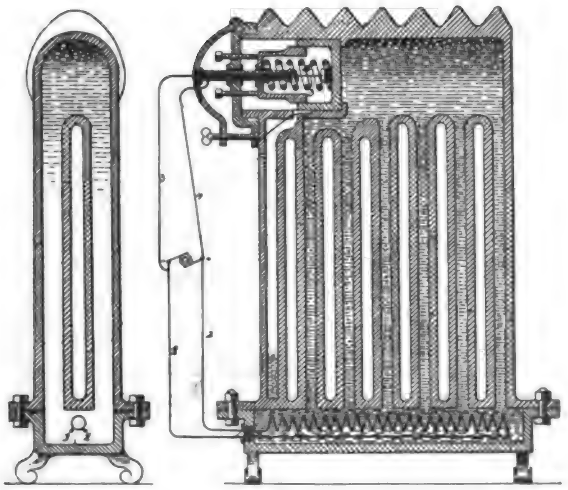
noise and dirt. The arrangement is very easily installed, and may be placed in any position without regard to belting or shafting. The combination is also superior in the qualities of compactness of form, and it in no wise obstructs the draught of air set up. In view of the numerous places of public resort and gathering where ventilation is bad, it is eminently to be desired that arrangements of this kind should be more generally installed. Their utility will be apparent at once.

Fig. 2 shows the peculiar curvature of the coils at the rear. The same curvature is found at the front end. The whole armature is perfectly ventilated, particularly at the front, where difficulty has frequently occurred. It is the strong belief of the Edison Company that one of the most serious difficulties that has been met with in electric railway work is entirely overcome by this new type of armature they are now manufacturing and using.

ABSHAGEN'S ELECTRIC HEATER.

Now that the possibilities of electric heating are becoming more and more apparent, a variety of apparatus is being designed to carry out the method. Among the more recent of these is that due to Mr. Ernest Abshagen, of Chicago, which is illustrated in the accompanying engraving.

Mr. Abshagen employs, as the material to be heated, a



Abshagen's Electric Heater.

non-conducting fluid, such as whale, linseed, or cotton oil. The oil evidently is brought into immediate contact with the heated wire, whether hot or cold. The use of oil also allows a high temperature to be employed. Whale oil, for instance, boils at a temperature of 650 degrees Fahrenheit. As no steam or vapor is generated below that point, no precautions against internal pressure are necessary.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, *150 Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

VOL. X. NEW YORK, OCTOBER 1, 1890. No. 126

The discoveries of physical science are a part of the nation's strength and glory. The inventions of mechanical skill are, or ought to be, the poor man's boon and blessing.—Professor Sedgwick.

ELECTRICAL ENGINEERING AT THE WORLD'S FAIR.

AT the Philadelphia Centennial Exposition of 1876, there were 9,857,625 visitors; at the Chicago Columbian Fair, if recent European precedent is to be accepted, there should be three or four times as many. Let us say that 25,000,000 entrances will be registered at the turnstiles. What is to be the leading impression carried away by that vast aggregate of people? What fact do electrical engineers wish most to be imprinted in their memories and to influence them in daily life?

Fourteen years ago, the part played by electricity at Philadelphia was insignificant. It was not even mentioned among the dramatis personæ of that great and stirring spectacle. General Walker in his masterly review of the subject does not touch on electricity. There was, in truth, little material to work up, and he could not make bricks without straw. American skill in the invention and production of agricultural implements, small arms, sewing machines, scales, locks, wood working machinery, carriages, cars, engines, and the like, was amply displayed; but the exhibit of electrical handicraft created no sensation, and the electricians were but a handful. Still, as if to show how great and incalculable were the latent possibilities of electricity, it was there that the world first listened to the faint tremulous whisper of the telephone.

Now, in what way are we to distinguish at Chicago the coming into activity since that time of a group of industries that, together with the older one of telegraphy, employ more than 250,000 souls and count up an investment of $600,000,000, of which by far the larger part has been massed together during the last ten years? The answer to this, in our opinion, is that the single attempt should be to enforce the truth by ocular demonstration that electricity is the one supremely successful modern agency for distributing light and power. The opportunity is the grandest that electrical engineering has yet had, and it must be utilized to the fullest extent. No doubt there will be other important new electrical inventions before the Fair opens, but the triumphs of electric light and power, with their allies in electric heating and electric metal working, must be brought forward so thoroughly that never after can there be popular ignorance or a lack of popular appreciation.

The late Centennial at Paris exemplified what could be done with the aid of the electric light in opening Expositions by night. The attempt was brilliantly successful and settled the question for the Fair in this country, whereever held. When the extent of the buildings and grounds at Chicago is definitely known, some estimate may be formed of the lamps required. It is not unlikely that anywhere from 50,000 to 100,000 incandescents can be used to advantage in interiors, with a countless number for "structural" and decorative effects. For the grounds and larger spaces perhaps 2,500 arcs would suffice.

But this only represents a steam and electrical plant of from 7,500 to 10,000 h. p., an everyday matter in modern work on light and power stations of the new class. The more marked display of electrical engineering will evidently occur in connection with the electric power service. The public is still quite unfamiliar with the versatility of the electric motor and the economic efficiency of electric power distribution. Instead of grouping all the moving apparatus, therefore, in a heterogeneous, confused collection under one big roof, dependent on a few long, heavy lines of shafting, every exhibit to be driven can be located just where it belongs geographically, industrially, or in any division that State or politico-economic considerations may require. The advantages of this in an educational sense it is needless to dwell upon. The World's Fair will thus come nearer what theory supposes it to be, as a kindergarten of the nations.

Other suggestions involving the use of electric power naturally arise. One might look for concrete examples of long distance power transmission, illustrative of what can be done in utilizing a little more than the present one per cent. of our 200,000,000 h. p. running away in our falls and streams. Then the question reasonably comes up whether electricity shall be used not only in transporting people about the grounds, but in the heavy service between the two sections miles apart.

In other words, taking it generally and broadly, the proposition we have made is that electricity shall be the active motive power of the whole Columbian World's Fair. The plan has possibly been hinted at before, but we have now taken the trouble to point out some of the conditions it involves and to open up the glorious opportunities for the very best electrical engineering skill and inventive genius of the country. We wish to point out further that the plan looks necessarily to the concentration of the steam plant and current generating apparatus in one grand station, probably by the side of the Lake, where the most advanced types of American engines and boilers can be put most perfectly in operation. Evidently the steam equip-

ment for such service as we have outlined would be of a colossal nature, but it would all be bunched, and would be easy to handle as well as cheap to run. From the dynamos, of a magnitude corresponding to that of the engines, current would be carried in a variety of ways to motors of every shape, class and size, and every motor inventor and builder could take, or be allotted, the work best suited to his machine.

We venture to offer these suggestions the more readily because Mr. Gardiner C. Sims is the chairman of the World's Fair Commission Committee on Electricity and Electrical Appliances. As a distinguished and representative engine builder and steam engineer, he may safely be trusted to look to the welfare of his own profession. As one of the warmest friends and advocates of electrical development, he may equally be relied upon to see, with quick intuition, how much is to be gained by the two great industries that so strikingly in this country have gone on to perfection hand in hand together, and that have every interest in common. He may also be depended upon to gather around him the ripest skill, ability and experience that can be secured for the undertaking.

DOLBEAR ON POLARIZATION THEORIES.

The action going on in electrolysis was one which early attracted the attention of electrical scientists, and numberless theories have in the past been promulgated to explain the phenomena involved. Even now the subject still attracts attention, and deservedly so, as a clear comprehension of this particular action cannot fail to aid in the comprehension of others closely allied to it. Prof. Dolbear, whose ability as an instructor and teacher of electrical science is recognized, gives elsewhere an interesting explanation of the phenomena of polarization, in which he embraces not merely the action of the gas generated, but also takes into account a peculiar condition of the electrodes. He bases his arguments upon observed phenomena, and his ideas cannot fail to assist in clearing up a subject of much importance.

ELECTRICITY IN WARFARE.

The introduction of the electric light on board ships and especially on war vessels, with a full equipment of generators, has naturally afforded an opportunity for the introduction of other electrical devices, notable among which are electric motors for ventilation, for the training of guns, for the hoisting of shot, etc. But a new departure has recently been taken in the application of electricity to warlike purposes in the introduction of range finders depending upon a few simple principles, among which that of the Wheatstone bridge is prominent. The public is already familiar with some forms of Lieut. Fiske's range finders, which he has recently, however, simplified to a considerable extent, so much so, that the readings can now be taken direct from a graduated dial. The description in this issue of Lieut. Fiske's new range finder, shows it to be a neat application of the modified Wheatstone bridge principle, and not the least notable point in connection with it is, that the errors due to the variation of the conditions from actual theory are compensated for by the very construction of the apparatus. With all these refinements and means placed at the service of the commander of a modern war vessel, it is indeed problematical whether the carrying on of warfare would be a pleasant undertaking in the future, considering the enhanced probability of a shot taking effect. The fact may also be noted here that the U. S. S. "Baltimore" is probably the first naval vessel in which a telephone service has been established so as to enable the commander to communicate from the conning tower with the various parts of the ship.

TELEPHONIC SPECIFIC INDUCTIVE CAPACITY.

The necessarily enforced burying of many telephone wires in our cities cannot fail to affect the clearness of telephone transmission within cities, and in extra-territorial work where numerous stretches of cable are inserted at river crossings, etc., the effects are being more and more felt. This trouble becomes evident when we consider that the readiness with which a line transmits speech is dependent both upon the resistance and upon the capacity of the line, and further that while the aerial line has an average capacity of 1/100 of a microfarad, the average telephone cable has a capacity of about 1/5 of a microfarad. In other words, a single mile of cable is equivalent in this respect to 20 miles of overhead wire. This point is particularly dwelt upon by Dr. William W. Jacques, who points out in another column the necessity for keeping down as low as possible the specific inductive capacity of telephone cables, and shows that considerable difference exists among the various insulators in this respect. He also draws attention to the fact that a distinction must be made between the telegraphic specific inductive capacity of a cable or its capacity at slow rates of charge and discharge, and its telephonic specific inductive capacity, that is, its capacity at high rates of charge and discharge, and that in order to obtain accurate results in telephone work these measurements ought to be made on the latter plan. Attention is also drawn to the necessity of avoiding the presence of moisture, not only on account of its lowering effect on the insulation, but also on account of its high specific inductive capacity, which increases the difficulty of transmission through such cables. Dr. Jacques' article is worthy of careful reading.

New Electric Railway Construction.

The description which we give in another column of the new railway motor of the United Electric Traction Company is an indication of one of the principal directions in which modern practice of railway construction is apparently drifting. The almost universal employment of two motors mounted on either axle of a car, although possessing advantages in many ways, is nevertheless open to some objections which are not encountered with the use of a single motor. This is being recognized, and will no doubt result in a more general employment in the future of single motor trucks equipped with power equivalent to that of the two now employed. The construction shown on another page at once admits of a reduction in the number of gears and bearings, and affords a flexibility between the two axles which must be of considerable advantage when sharp curves are encountered.

AUTOMATIC REGULATION OF ACCUMULATOR CURRENTS.

One of the principal difficulties attending the use of accumulators in general electric lighting work, particularly in connection with their application as auxiliaries to direct lighting plants, is due to the characteristic rise and fall of their potential during charge and discharge, respectively. Even were it practicable, which ordinarily it is not, to charge a battery by means of a special dynamo to be after wards discharged on an independent working circuit, the reduction in pressure within the limits of its working capacity would still be marked. When, however, as is usually the condition in practice, the battery must be charged by a dynamo simultaneously furnishing current to lamps, the difference between the potential at the end of charge and at the end of discharge must be taken into consideration.

Various methods of compensating for these variations, so as to maintain an approximately uniform pressure at the lamp terminals independently of the potential of the battery as a whole, have been devised, such as manual switches for increasing or diminishing the number of active cells, and others for inserting and removing from the working circuit, as required, more or less dead or active resistance, in the form of wire or counter-electromotive force cells. Automatic apparatus for accomplishing the same end has also been introduced with more or less success, both in this country and abroad, but most of it has been somewhat cumbersome and expensive.

With the object of producing an entirely automatic pressure regulator for storage battery lighting plants, which would be free as much as possible from the objections above cited, Mr. Geo. B. Prescott, Jr., has devised and recently patented the method of regulation shown diagrammatically in the accompanying illustration.

Before proceeding to a description of this invention, it will not be out of place to refer to the results to be effected. Primarily, what is required according to the load, is a current in the working circuit, either from the dynamo alone, from both the dynamo and battery, or from the battery alone when the dynamo ceases to run. At times when the consumption of current in the working circuit will admit, the battery must be charged with the surplus current from the dynamo, and during all these various conditions and the changes accompanying them the potential of the lamp circuit must remain fairly constant.

Almost every governing device depends for its action on the variation of the force to be regulated. In this instance it is the potential at the lamp terminals that is to be governed; hence, it is evident that it must vary in some degree before the apparatus can act, and the amount will, of course, depend, as in all similar cases, upon the sensitiveness of the apparatus employed.

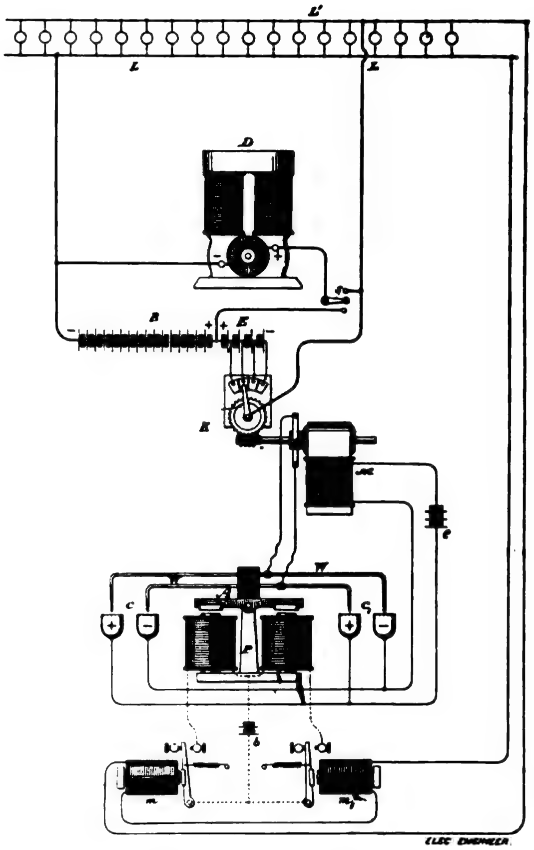
Any delicate potential indicator, if suitably connected, will respond to variations in pressure in the lamp mains, the resulting deflection being in one direction, or the opposite, as the variation is above, or below, normal.

If this movement of the indicator could be made sufficiently powerful, it might be utilized to perform directly the mechanical work, such as adding or removing resistance, necessary to restore the normal potential. The required sensitiveness of the indicating device forbids this, however, and although it may have sufficient force to exert the trifling power required to complete or sever a milliampere circuit, the ordinary devices have so far proved unsatisfactory when used in connection with storage batteries.

The essential features of Mr. Prescott's arrangement is the substitution of two ordinary telegraph relays wound to high resistance, for the various forms of instruments usually employed for similar purposes. By magnifying the slight movements of their armatures through the medium of local magnets and an electric motor, the latter finally performs the mechanical labor of cutting cells in and out of the circuit as the potential varies.

Referring to the accompanying diagram, L, L, is the working circuit containing the lamps, and D the dynamo which may be connected directly to the lamp circuit by closing switch S on its upper contact. B is the battery of accumulators and at E are several counter-electromotive force cells connected in series with the battery, but with opposing poles. The lower contact of switch S is connected, as shown, to the junction of the battery and counter-electromotive cells, and to a non-break cell-regulating switch K, to which the negative terminals of the counter-electromotive force cells are brought.

The arrangement so far described is the ordinary method of installing accumulators for hand regulation in connection with a simple multiple arc plant, and it is operated as follows: Supposing the dynamo to be running, the switch S is on its upper contact, and the lever of switch K turned to the left so as to break contact; then the current from



Prescott's Method of Regulating Storage Batteries.

the dynamo flows directly into the lamp circuit while the battery circuit is open at K. If the switch K is now closed, the battery will be joined in parallel with the dynamo and will add its current to the lamp circuit. A galvanometer placed in the wire leading from K to S would show the amount of current flowing out of the battery and this could be increased, or diminished, by turning the switch K to the left, or right, respectively, and thus removing from, or placing in, the battery circuit more or less of the counter-electromotive force cells.

Assuming now that the lamp load is diminished and that the dynamo can generate sufficient current to charge the batteries as well as supply the number of lamps required, the switch S is quickly moved to its lower contact. The positive current from the dynamo passing through S has now two paths when it reaches the junction between the battery and counter-electromotive force cells, one through the battery, which thus receives a charge, and back to the

other pole of the dynamo; and the other through such of the counter-electromotive force cells as may be in circuit, depending upon the position of switch K, then on through the lamps and back to the negative pole of the dynamo. The potential of the dynamo must now be increased in order to force current through the battery, while the switch K is simultaneously moved to the right, thus opposing additional counter-electromotive cells to that part of the dynamo current going to lamps, until the pressure at the terminals of the working circuit is normally restored.

It is of course to be understood that the attendant who moves the switches is governed by a pressure indicator located in the dynamo room and connected with the lamp terminals. When the battery is sufficiently charged the operation described is merely reversed.

While not an essential part of this method of regulation, although a valuable adjunct, it is pertinent to mention that there are several forms of these switches which are entirely automatic in their action, cutting the battery in or out of circuit when the dynamo starts or stops, or when the potential of the battery varies to require it. One of the earliest and most practical forms of such an instrument was also devised by Mr. Prescott several years ago.

In the light of what has preceded, it will readily be seen that the switch K may be operated by a motor automatically controlled through the medium of local magnets, by a delicate potential indicator connected to the lamp terminals.

In this system the potential instrument consists of two ordinary, but very sensitive, high resistance telegraph relays. These are shown in the figure at m, m_1, the coils of the two relays being joined in series and connected to the lamp mains, at a point of average pressure.

Again referring to the diagram, it will be seen that the local armature circuits of the two relays are each in the circuit of one of the magnets of the local instrument P, the local battery b being common to both. The device P is an electro-magnetic pole changer, consisting of two pairs of electro-magnets standing vertically side by side, between which is a pillar carrying a centrally pivoted armature A, normally occupying a horizontal position. This armature is tilted to the right or left, respectively, as the circuit of the right or left magnet is closed. Mounted co-axially on this armature, but insulated from it, are two horizontal copper rods W, their ends bent down so that when in the normal horizontal position they just clear the mercury cups C C_1. These two copper rods and the four mercury cups constitute an ordinary reversing switch. The mercury cups are connected through the local battery e, with the field of the motor M; the armature of the motor being in turn connected with the rods W.

The operation of the regulator is as follows: Assuming the dynamo to be running and the pressure on the lamp circuit to be normal, the retractile springs of the relays are so adjusted that the armature of m is barely attracted, and the armature of m_1 is barely released, so that the local circuits of both magnets of the pole changer are open. When a delicate adjustment has been made, a slight increase of the pressure on the lamp circuit will cause the armature of magnet m to be more strongly attracted, still keeping its local circuit open. The armature of magnet m_1 will also be attracted, but will move and close the circuit of the battery b through the right hand magnet of P, causing the armature A to be tilted to the right and to plunge the ends of the wires W into the mercury cups C. This closes the circuit of the battery e through the motor, and causes it to revolve the switch k in such a direction that counter-electromotive force cells are inserted in the lamp circuit, thus reducing the pressure. When the pressure again becomes normal the armature of m_1 is pulled back by its retractile spring, breaking the local circuit and allowing the armature A to resume its normal position and stop the motor.

When the potential becomes reduced from any cause, both relay armatures are pulled back by the springs, that of m_1 still retaining its position on back contact and leaving the local circuit open; while that of m moves against its back contact and closes the local battery b through the left hand magnet of P. This causes the armature A to tilt to the left and plunge the opposite ends of the wires W into the mercury cups C. As previously, the circuit of the local batery e is closed through the motor, but this time the current is reversed through the armature of the motor and causes it to revolve the other way. This moves the switch K in a direction opposite to that in which it turned before and cuts out counter-electromotive force cells until the normal potential is again restored; and so on, whenever the pressure changes, whether from variation in the potential of the battery, alteration in the speed of the dynamo or change in the lamp load. It is hardly necessary to state that the counter-electromotive force cells serve as the local batteries b and e, these having been shown as they are in the diagram for the sake of clearness.

The apparatus described has been made by The Accumulator Co., of this city, and the method found to give very satisfactory results.

TELEPHONIC SPECIFIC INDUCTIVE CAPACITY.

BY WILLIAM W. JACQUES.

Electrician of the American Bell Telephone Co.

In a paper on "The Construction of Telephone Circuits," read before the American Academy of Arts and Sciences on the 15th of June, 1887, the writer of the present article pointed out, "that the readiness with which telephonic conversation may be carried on over any circuit, whether made up of cables or pole lines, or both, depends,—

"1. On the total electrical resistance of the circuit joining together the two stations.

"2. On the total electrostatic capacity of this circuit."

And the general rule was laid down:—"No matter what may be the distance between two points, good business conversation may be carried on between them, provided they be connected by a pole line or cable, or both, the product of whose total resistance by its total capacity is less than 2,000, if transmitters of the Blake type be used, and less than 4,500 if transmitters of the Hunnings type be used."

This rule was enunciated as the result of an extended series of experiments carried out in England, France, Germany, and the United States on pole lines, cables, and mixed pole and cable lines, varying widely in mechanical and electrical dimensions.

The same law, only applied to the transmission of signals through submarine cables, had been previously worked out mathematically by Sir William Thomson, and amply confirmed by experience, so that to-day there can be no doubt of its truthfulness. It is evident, therefore, that in the construction of a telephone line, it is desirable to reduce both the *resistance* and the *capacity* to a minimum.

In a pole line, since the wire is suspended high above the earth, the capacity is always small, and the resistance is the factor that we must try to keep down. In cable lines, however, where the conductor is necessarily brought near to other conductors, or a metal shield, or the earth, the capacity becomes quite an important factor to be respected. In lines made up, as is most generally the case, of a comparatively short section of cable and a larger section of iron pole wire, the capacity of the cable becomes pre-eminently the factor to be respected; for, since the limit of conversation is here determined by the product of the capacity of the cable and the resistance of the whole line, a small percentage of saving in the capacity of the cable gives an enormous gain in the readiness with which conversation may be carried on over the line.

It becomes of vital importance, therefore, to choose an insulating material for telephone cables of low specific

inductive capacity. Further than this, since it is well known (Gordon's "Electricity and Magnetism," Chap. XI) that the specific inductive capacity of any insulating material, and consequently the capacity of any cable insulated with it, is very different for telephone currents from what it is for telegraph currents, because the charge and discharge take place so much more frequently, we may say that it is of vital importance to choose an insulating material of low "telephonic specific inductive capacity," using this expression in contradistinction to "telegraphic specific inductive capacity," by which we mean the values measured in the old-fashioned way.

In the *Proceedings* of the American Academy for Dec. 11, 1889, Messrs. Safford and Holman, two graduates of the Massachusetts Institute of Technology, in the Department of Electrical Engineering, have published the following table of telephonic specific inductive capacity of various insulators used in cable construction. This table is a result of an elaborate and careful research undertaken by them.

TABLE OF SPECIFIC INDUCTIVE CAPACITIES, MEASURED BY TELEPHONE CURRENTS.

1. Petroleum	1.6
2. Solid paraffine	2.0
3. Cotton saturated with paraffine in vacuum	2.0
4. Cotton boiled in paraffine	2.6
5. India-rubber	3.7
6. Artificial gutta-percha	3.9
7. Gutta-percha	4.2
8. Glass	4.6
9. Water	6.3

Realizing that these results were of great practical importance in the construction of telephone cables, the writer has repeated the experiments of Messrs. Safford and Holman with entirely concordant results.

Let us see some of the conclusions we are obliged to draw from the data thus furnished, and then, in order to confirm these conclusions, we will describe some further experiments in this line.

I. The specific inductive capacity of any insulator used in the construction of telephone cables, and, consequently, the actual electrostatic capacity of any given telephone cable, ought to be measured with charges and discharges of telephonic frequency, and not by the old-fashioned method of measuring capacities by slow charge and discharge. This last is of no value, while the telephonic capacity is of vital importance.

II. The presence of water in an insulating material greatly increases its telephonic specific inductive capacity. An inspection of this table shows that, so far as capacity is concerned, petroleum is the best substance to be used, and doubtless this would be the case were it possible to keep it free from water, but water, we see from the table, has a specific inductive capacity of 6.3, so that its presence in the petroleum raises the capacity from the lowest to the highest in the list.

This observation is borne out by actual experience with cable No. 1 in telephony. When new, and the petroleum dry, it works excellently; but as water finds its way in, the cable rapidly loses its efficiency for telephonic work.

This action of the water is quite different from its action as a *conductor* to produce leakage, for the loss of electricity due to leakage in such a cable that has lost its efficiency from the presence of moisture, is entirely insufficient to account for the deterioration.

So, too, in the cable, No. 4, the presence of moisture exercises a detrimental effect on the power of the cable to transmit telephonic currents, and increases the inductive cross-talk to a degree that cannot be accounted for by the diminished insulation resistance.

It is proposed to show later that the presence of moisture in a lead covered cable, does actually increase very greatly its telephonic capacity, and, consequently, both the retardation and cross-talk.

III. Next to petroleum, solid paraffine is seen to be the best substance to use; but on account of mechanical difficulties it has never been found practicable to coat wires directly with solid paraffine.

If the wires are wound with cotton and then boiled in paraffine, as they are in making cable No. 4, the specific inductive capacity is raised to 2.6, an increase of 30 per cent., which, we have seen, is a very great detriment.

If, however, the wires are wound with cotton, and the air and moisture removed by the aid of heat and a vacuum, and they are then boiled in paraffine, from which the air and moisture have also been removed by heat and vacuum, the specific inductive capacity again falls to 2.0, which is the same as that of solid paraffine. This is the process used in preparing the cable No. 3.

It is probable that the inferiority of cable No. 4, as compared with No. 3, is due largely to the moisture retained in the cotton, which we have seen has a capacity of 6.3.

Leaving the paraffine cables, rubber is the next best, then gutta-percha, and poorest of all is glass; but all of these latter substances have so high a specific inductive capacity as to entirely unfit them for telephonic work.

It now becomes desirable to put this information in more available form, for the use of those upon whom the selection of the best cables for use in telephone construction devolves.

Accordingly, I have given in the following table, first, the telegraphic capacity; second, the calculated telephonic capacity; and third, the measured telephonic capacity of one mile each of cables Nos. 3, 4, 5 and 7, all constructed on the dimensions of the "conference standard."

The measurements of the cables Nos. 3 and 4, were made on cables actually constructed in accordance with the requirements of the conference standard. Those of the rubber and gutta-percha cables were made on cables of a different specification, but reduced to the conference standard by well known and accurate methods of calculation.

Capacity of One Mile of Conference Standard Cable, in Microfarads.

	Measured telegraphic capacity.	Calculated telephonic capacity.	Measured telephonic capacity.
Cable No. 3	.18	.18	.18
" " 4	.19	.24	.26
" " 5	.27	.30	.30
" " 7	.40	.46	.40

In order to show how great a difference in the practical working of a line this difference in telephonic capacity makes, let us assume a conversation to be carried on between two subscribers, connected by five miles of conference cable, and 40 miles of No. 12 iron pole wire.

Let us first suppose cable No. 3 of the conference specification be used.

Resistance 40 miles No. 12 iron wire	=	1,184 ohms.
" 5 " cable,	=	175 "
Total line resistance,	=	1,359 "
Capacity 40 miles No. 12 iron wire (30-foot poles),	=	.48 micro-farad.
Capacity 5 miles No. 3 cable,	=	.90 "
Total line capacity,	=	1.38 "

Product of total resistance and total capacity (1,359 × 1.38) = 1,875, which product, being considerably less than 2,000, shows us that conversation could easily be carried on over such a line with Blake transmitters.

Let us next suppose cable No. 4 of the conference specification to be used.

Resistance 40 miles No. 12 iron wire = 1,184 ohms.

" 5 " cable,	=	175 "
Total line resistance,		1,359 "
Capacity 40 miles No. 12 iron wire (30-foot poles),	=	.48 micro-farad.
Capacity 5 miles cable No. 4	=	1.30 "
Total line capacity,		1.78 "

Product of total resistance and total capacity (1,359 × 1.78) = 2,419, which product is considerably above 2,000, and good commercial conversation could not be carried on with Blake transmitters.

NEW THOMSON-HOUSTON ELECTRIC SNOW-PLOW AND SNOW-SWEEPER.

Past experience in operating electric railways in winter has demonstrated the fact that some appliance is needed for keeping the tracks as free from snow as possible. That the Thomson-Houston Electric Company fully realized this is shown by the forethought manifested in preparing the snow-plow, Fig. 1, and snow-sweeper, Fig. 2, shown in the accompanying illustrations. Last winter's experience with snow showed just what was needed in this direction, and in the new appliances will be found many improvements over the old types. The details of the snow-plow are as follows: Length over all, 20 feet; width, 7 feet; height from rail to floor of car, 3 feet, 6 inches. The truck has four 36 inch wheels, in front of which is placed a digger which scrapes the snow from the track, thereby securing a good contact for the wheels. These diggers, or scrapers, are controlled by levers placed at each end of the car, and may be raised and lowered at will. One of the main plows is placed diagonally across the car, one end being in front of the forward wheel on one side, the other end coming out between the front and rear wheels on the opposite side, at an angle of about 60 degrees. By placing the plow in this manner a position is secured where the least oscillation occurs. Although the plows extend 2 feet beyond the wheels, each is provided with an extension, by means of which a path of any desired width, depending upon local conditions, can be plowed out. The second main plow is hung parallel to, and in the same manner as, the first, each, however, being independent, and controlled by levers placed upon the car platform. One or both can be used as the circumstances require. The plows are kept at a proper angle by means of chains and iron rods, so arranged as to permit great freedom of movement in a vertical direction.

The car is propelled by two 20 h. p. motors, of the consequent pole type, one being geared to each axle by means of sprocket chains and chain gear wheels. They are capable of propelling the car at a speed of 10 miles an hour. The sprocket chains run as slowly as possible, since the total reduction in speed is made by gears on the motor frames. They are enclosed in closed iron boxes. In circuit with the motors is placed a reversing switch and rheostat, also placed in a closed iron box. The trolley arm is supported by a post placed in the centre of the car platform, and which is also used as a support for a number of incandescent lamps. The car can be operated in either direction.

Fig. 1.—New Thomson-Houston Electric Snow-Plow.

The car for the snow-sweeper is of the same dimensions as that used for the plow, the wheels being 36 inches in diameter, and mounted on a $3\frac{1}{2}$ inch axle. The motors for driving the car are of 15 h. p. each, and are entirely independent of the motors used for driving the brushes, being provided with separate reversing switch and rheostat, enclosed in an iron box, and placed on the platform in easy reach of the operator. The motors for operating the brushes are placed on the car platform, with a shaft parallel to that of the broom, and connected to it by means of sprocket chains, so as to run at a speed of 200 revolutions per minute. The brushes, which are placed in advance of the truck, are two in number, and are made in sections to facilitate taking apart and placing upon the drum to which

they are fastened. On the platform of the car on both sides are handles operating clutches by means of which the brooms can be thrown in or out of operation. Levers are also provided for raising and lowering the broom, thereby rendering it possible to operate them at any desired height. To insure the snow being thrown off the track, the brooms are set at an angle of 60 degrees to the rail. The electrical connections are the same as found on the passenger cars, the motors for propulsion being connected in multiple, but independently of the motors used for driving the brushes. The current is taken from the overhead conductor by means of a trolley, supported on a post eight feet high placed in the centre of the car. Around this post are grouped incandescent lamps which are employed when the car is required for night service. Both the snow-plow and sweeper are made for severe work, and have proved in previous tests to be fully capable of responding to every demand made upon them.

FIG. 2.—NEW THOMSON-HOUSTON SNOW-SWEEPER.

TALK OF A NEW TELEGRAPH COMPANY.

It has been whispered on the stock exchange, and the rumor has gained general circulation among down town business men, that three or four New Yorkers had started out to form a new telegraph company. If the story is to be believed, the intention of the enterprising New York men is to enlist English and French capitalists in the scheme. The Western Union people have received no definite information in the matter and are inclined to discredit the rumor. A member of the governing committee of the stock exchange said: "I have my suspicions that somebody has been inventing a yarn for the purpose of depressing the prices of the stocks in the existing companies. My opinion is that neither the Western Union nor the Postal people have any good reason to fear that there will be a new rival in the field."

OTTAWA, CAN.—The Chaudiere Electric Light and Power Co. has increased its capital stock to $500,000.

When all the cars are run by electricity, the term "lightning express" will be no misnomer.—*Boston Gazette.*

WENSTROM ELECTRIC MINING PLANT AT CLEARFIELD, PA.

The Clearfield Bituminous Coal Corporation have just completed an electric pumping plant at their "Grass Flat" mine at Peale, Clearfield County, Pa. This mine is opened by three drifts, Nos. 9, 10 and 11; the headings of Nos. 9 and 10 are parallel, but distant from each other about 1,200 feet.

On the surface a stream runs between these two headings and affords no cover for their connection and without offering the necessary level for a water drift. Three thousand feet from the drift mouth heavy dips in both drifts were met, producing large quantities of water.

To meet the difficulty by steam power would have necessitated two shafts, approximately 100 feet deep, to be sunk, and two pumps and boilers to be located inside of the mine. To obviate this, expedite the work and to avoid large first cost, the electric plant was put in with marked success. The apparatus consists of an eight h. p. Wenstrom compound dynamo, a five h. p. Wenstrom motor for the pump in No. 9, and the same make of motor of one and one-half h. p. for the pump in No. 10.

The dynamo, with Lidgerwood engine and boiler, is located at the mouth of the drifts and furnishes power to both pumps. The five h. p. motor located 3,000 feet from the dynamo is running a Gould rotary bronze pump with capacity of 15,000 gallons per hour, elevating the water 22 feet for a distance of 520 feet, whence it flows off by natural drainage. The smaller motor in No. 10 will control a centrifugal pump with a capacity of 2,400 gallons per hour, elevating 15 feet for a distance of 400 feet. The larger pump is in daily operation, running, when needed, to its full capacity and giving complete satisfaction. The small pump will be put in on completion of some connections in the mine.

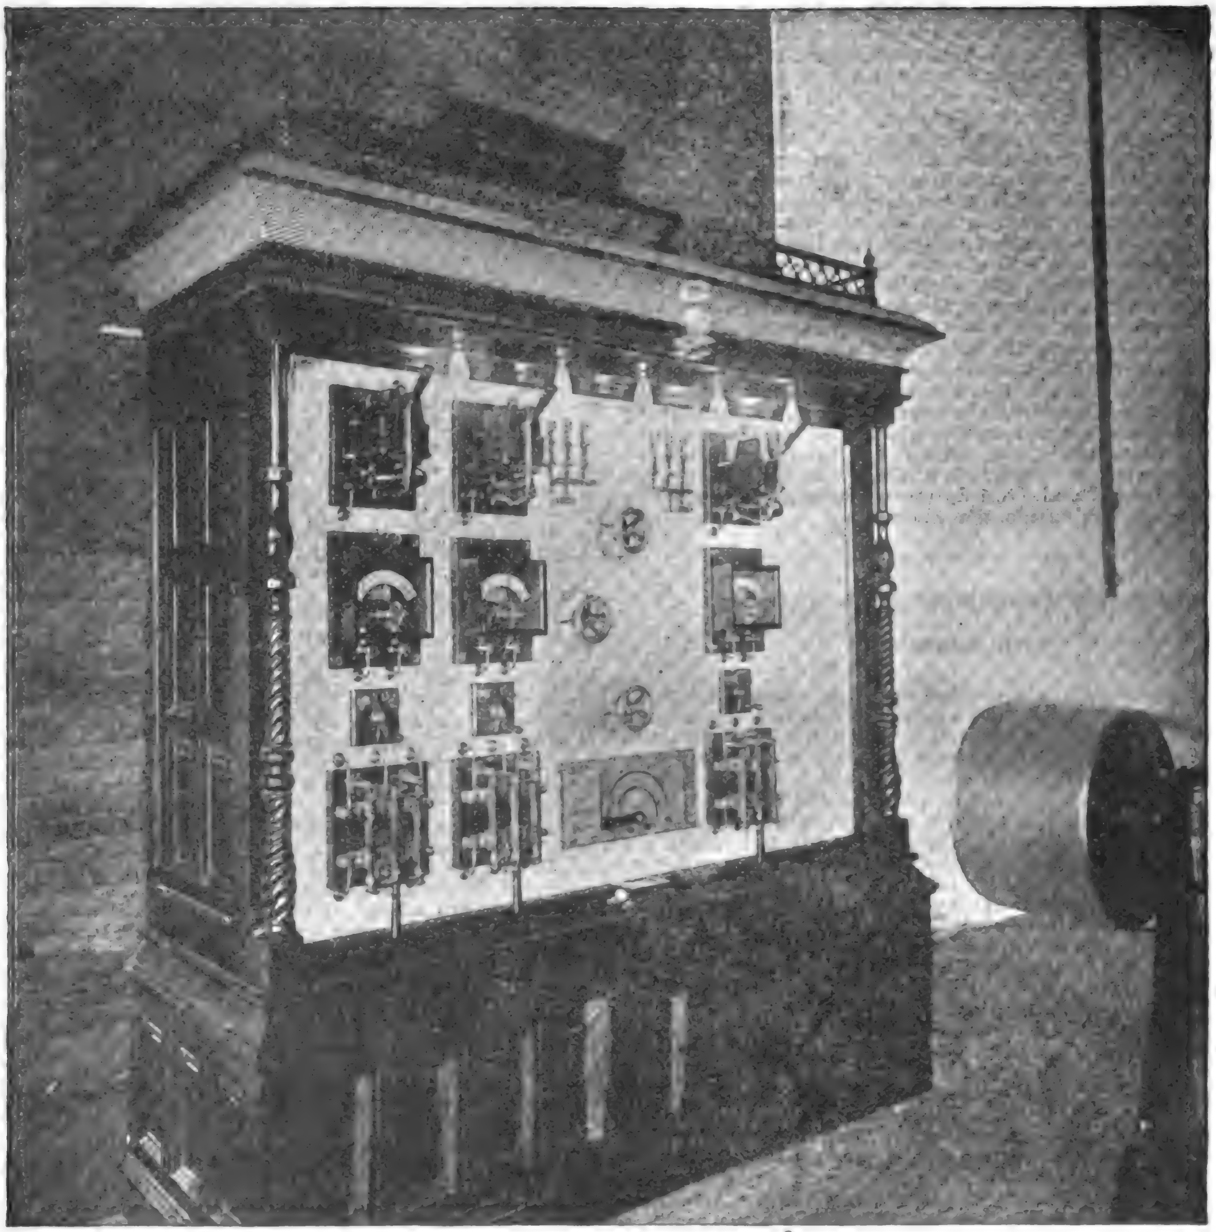
Two men operate this plant; one as engineer attending engine-boiler and dynamo, and one looking after both pumps, as the only attention needed is the oiling. Mine owners will be interested in this system of pumping which is somewhat of an innovation in the region, and which Superintendent Shillingford has demonstrated to be a great success.

WESTERN UNION IN LONDON.—News comes from London of a revival of the scheme to list Western Union stock upon the London Exchange. It is said that John Mackay's influential friends there will not oppose the plan this time.

MR. PAUL T. BRADY, of Cooperstown, N. Y., is to have charge of Thomson-Houston interests in this State outside of New York city, with headquarters at Syracuse.

THE MARBLE SWITCHBOARD OF THE CITIZENS' STREET RAILWAY, INDIANAPOLIS, IND.

The Citizens' Street Railway, Indianapolis, Ind., has been in operation since June 8th, 1890, and is asserted to be the best constructed electric railway in the country. The central pole double bracket construction has been used throughout, the poles being of heavy iron pipe with fancy bracket and arm attached to each side of the pole, extending over the centre of each track, supporting the trolley wire. This construction runs through the business portion of the city. On this line are a number of difficult curves, which required considerable engineering skill to conform the overhead wire to the line of track. They are at present operating 10 motor cars, equipped with two 15 h. p. motors, and each motor car at all times hauling a trail car. The traffic on this road since starting has been larger than the most sanguine had anticipated, and has been in operation without the slightest delay or trouble. The cars were manufactured by the St. Louis Car Co., of St. Louis, Mo. The power station is equipped with one 250 h. p. Wheelock engine, Corliss type, and one 500 h. p. Hazelton boiler, and natural gas is used instead of coal. Two 30 h. p. Thomson-Houston generators are installed in this station, together with an elegant marble switchboard, here shown, which has upon it circuit breakers, amperemeters, voltmeters, switches, rheostats and potential boards, and taken altogether it is one of the finest stations which has been equipped in this country. The Thomson-Houston Electric Co. is at present building one large electric snow-sweeper for this railway, which will be used to remove the snow from their tracks during the winter months.



Marble Switchboard, Citizens' Street Railway, Indianapolis, Ind.

VISIT OF ENGLISH ENGINEERS TO AMERICA.

The present week sees gathered in this city about 150 to 200 English engineers and capitalists interested in metal working. The visitors include Mr. F. W. Siemens, Mr. James Dredge, Prof. Kennedy and others known in the electrical field. Monday and Tuesday will be devoted to the sessions at Chickering Hall of the American Institute of Mining Engineers. On Wednesday and Thursday will follow the session of the International Iron & Steel Institute, at which Prof. Elihu Thomson will read a paper on electric welding. On Friday, a party will visit the Edison Laboratory. After this week the visitors scatter, to gather here again in November for the homeward voyage to England.

AN EASY MODE OF PRODUCING THE ACTIVE SPARK IN HERTZ'S EXPERIMENTS.[1]

BY H. CLASSEN.

In repeating Hertz's experiments in the State Physical Laboratory at Hamburg, an observation was made which shows how in a simple manner we can overcome the difficulty experienced by many observers of keeping the primary spark effective for a long time together. In the same manner in which Rijke used the action of a current of air on the make-and-break spark of an induction-coil in order to produce a stronger action in the secondary coil, so may the spark of the coil itself, and therefore also its inductive action on any other conductor, be similarly influenced.

In the experiments a large Ruhmkorff's coil was used which had a very rapid contact-maker, and which gave sparks up to 14 centimetres. If the ends of the secondary coil are loaded with conductors, and the discharging knobs are brought within a distance of a few centimetres, the discharge takes place mostly in the form of a continuous rose-colored strip of light, and is useless for Hertz's experiments. But when this band is blown away so that flames a centimetre in length project on the side, sharp, brightly luminous sparks occur between the knobs. The current of air produced by a Münke's water-pump was now blown continuously between the knobs, and thus a series of sharp cracking sparks passed quite continuously, and could without difficulty be continuously maintained for hours. A series of Hertz's experiments could now be repeated, and even when the current of air was replaced by one of steam the action was the same. The whole process suggests the idea that, in the ordinary discharge with a luminous band of light, detached metallic particles effect a permanent conduction, and that the essential discharge-spark is only produced as these particles are blown away. The influence of the ultra-violet illumination, too, which has been designated by various observers as highly disturbing, would, after the researches of Lenard and Wolf on the pulverization of bodies by illumination, find an explanation in this.

ON THE EXPERIMENTS OF HERTZ.[2]

BY L. BOLTZMANN.

I have successfully demonstrated to a large audience the sparks which pass between a knob and a point in Hertz's experiments on rays of electrical force, by connecting the knob with a very sensitive electroscope, and the point with the pole of a suitable galvanic battery the other pole of which was put to earth. As long as there were no minute sparks or *scintillæ* the electroscope remained uncharged; but when these were formed they established a connection between the knob and the point and caused the leaves to diverge. In this manner I was able to show with certainty the scintilla produced by a single primary spark when the primary and secondary inductors were at a distance of 36.8 metres apart, the greatest distance available.

At a distance of 8.7 metres all the Hertz experiments could be most conveniently demonstrated before an audience of about 200, so as to be visible to every one; only three or four primary sparks were required for each experiment, by which the electrodes could be kept brightly polished. Dust, cracks in the metal, or an impure greasy condition of the surface, appeared more injurious than the layer of oxide; cleaning with dilute sulphuric acid, distilled water, and then dry rubbing was found to be the best; a thicker layer of oxide is removed by polishing with French chalk (moisttened with spirit), in which case dry rubbing is sufficient. I was not able to see any advantage in a current of air as recommended by Dr. Classen.

The length of the secondary spark produced at the great distance of 36.8 metres I estimated at $\frac{1}{5000}$ millimetre as the maximum. As the dry pile which served to charge the electroscope had a potential of 200 volts, the knob and the point were adjusted at a distance which exceeded by about $\frac{1}{5000}$ the striking distance of the dry pile, the discharge of which was then set up by the addition of Hertz's waves to the tension of the dry pile. By using a much more feebly charged battery instead of the dry pile, and a much more delicate galvanoscope, Hankel's for example, the rays might be perceived at still greater distances. In the latter case it might not be impossible to measure the deflection with a view to quantitative determinations. The regulation of the distance between the knob and the point must then be made so much the finer.

I also made experiments on interference by reflecting the waves from the primary parabolic mirror through two plane mirrors, which, like those of Fresnel, formed an obtuse angle, and whose planes were at a distance of fourfold a half wave-length. This method seems well suited for accurate measurements of the wave-length and of the decrement of the vibration.

HOW TELEGRAMS ARE SENT IN LONDON.[1]

Suppose you want to send a telegram from the City to Charing Cross. You go to an office—say that in Threadneedle street—write your telegram, put the stamp on it, and hand it over to the clerk, satisfied that it will go. It does go, and in the following manner: The clerk numbers it (for every message sent is numbered), obliterates the postage-stamp in the usual way, and hands it over to a boy. The latter folds it up lengthwise and places it in a "carrier," which is a tube about eight inches in length and two inches in diameter, made of India-rubber covered with felt. Of course one carrier will hold several messages; it is closed at one end, open at the other, but provided at the open end with an elastic band which keeps the messages securely inside. The carrier is then put into the pneumatic "shoot," which is a metal tube or pipe laid under ground and leading into the Central Telegraph Office at St. Martin's-le-Grand. The felt-covered carrier exactly fits the interior of the pipe and is drawn along by suction. In the course of a minute or so it arrives at the central hall on the ground floor in the Telegraph Department of the General Post-office. Here its approach is signalled by an automatic indicator, and presently a click announces its arrival. It is at once withdrawn from the shoot by a boy, who takes out the messages contained and hands them over to a sorter. The sorters sit, some six or eight in a row, at a long table opposite the row of pneumatic tubes, each of which is connected with a City or West-Central office, and rapidly sort the continually arriving messages as they are handed to them by the boys who attend the tubes. The messages are sorted according as they are metropolitan, provincial, foreign, or for central London, and placed in corresponding pigeonholes; from which they are immediately removed by more boys. Our Charing Cross message is for central London; so it is carried, of course with many others, to the other side of the same hall, where the corresponding departure tubes are situated, handed again to a sorter, sorted, pigeonholed, and again removed, to be despatched by the Charing Cross tube. Arrived there it is copied out and sent to its destination by the hands of the familiar telegraph boy.

In all this, it will be seen, there is no telegraphing. The messages are despatched bodily from a branch office to a central and again sent out bodily to the office of destination. This, however, only applies to the city offices, those of Fleet Street and the Strand, and the W. C. office in Holborn. All these are provided with tubes in connection with St. Martin's-le-Grand, as are also some of the foreign cable offices. Some offices have two—one "up" and one "down"; but most are served both ways by the same tube. There are in all forty-two of them—exclusive of thirty-one working locally within the building—and they are worked by four large steam-engines on the premises; "up" messages going by suction, "down" by pressure. The longest is an extension of the Charing Cross tube to the reporters' lobby in the House of Commons, and is two and a half miles long. Messages take from five to seven minutes on the journey. So much for central London telegrams.

If now we want to send one from the city to Hampstead, its course is the same as that already described as far as the sorters' table, in the tube-room of the central office. There it will be put among metropolitan messages and despatched by another tube to the "Metropolitan" Gallery, on the fourth floor of the same building. Once more it is collected and passed through the sorters' hands, and then taken to the Hampstead table, where a telegraphist despatches it by wire to the office of destination. A return telegram from Hampstead to the city traverses precisely the reverse route. It is received by wire at the Hampstead table, collected, sorted, sent by tube to the ground floor, sorted again, and despatched by tube to the city office. A London telegram to the provinces, or one from a town in the south to a town in the north, goes similarily through the central office. On arriving there (either by tube or wire) it passes through the sorters' hands, is despatched to the "Provincial" Gallery, sorted again, and then sent off by wire.

The Central Telegraph Office is the very heart of the machine, through which every drop of blood passes, to be transmitted in one direction or another. The activity of that vast industrial hive is prodigious. It has been often described; but some of the facts will bear repetition. The staff of telegraphists numbers 1,845 males and 807 females, and there are in addition 627 messengers. Something like 100,000 telegrams are dealt with every day, the half of which are really double, having to be both received and forwarded. On busy Parliamentary nights the number of words despatched is not infrequently over half a million, and the total has exceeded a million. Perhaps the most remarkable room in the building is the "Provincial" Gallery. The telegraphists sit at tables bearing the names of the towns with which their wires are connected, and work the various instruments, while the destributors bring and take away the messages. There are 421 instruments in this room, of no fewer than ten different kinds. Some idea of the work done may be gathered from the fact that the Liverpool wires alone are served by forty telegraphists; and how it is done on the whole the public knows very well in spite of occasional grumbling.

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.
Anonymous communications cannot be noticed.
The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.
In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.
Sketches and drawings for illustrations should be on separate pieces of paper.
All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, *150 Broadway, New York city.*

THE "HEDGEHOG" TRANSFORMER DISCUSSION.

[140.]—I was much interested in Mr. Nikola Tesla's arraignment of Mr. Swinburne's "hedgehog transformer," which appeared in your last issue (Sept. 24, p. 332), and especially so for the reason that I have for some time favored the open circuit transformer as superior to the closed circuit in point of efficiency, and I was anxious to hear the arguments on the other side. Mr. Tesla's article was rather disappointing, however, as I was unable to see the force of most of his arguments.

Mr. Tesla says, for example: "In order that the loss in the iron should be reduced to one-tenth, it is necessary to reduce the weight of the iron to one-tenth, and subject every unit length of the same to the same magneto-motive force." The laws of hysteresis, as given by Ewing and Hopkinson, state that hysteresis loss varies directly as the weight of iron, and as some function of the density of magnetization, or number of lines per square centimetre. The hysteresis loss can, therefore, be lessened by increasing the cross section of the core, as well as by decreasing the weight, and Mr. Swinburne states that the cross section in his transformer is increased.

A little further on Mr. Tesla remarks that the loss in the iron is proportional to the square of the M. M. F. per unit length of core. If I have not misunderstood this, Mr. Tesla must have discovered some law of hysteresis which has not yet been published, for I can find no statement in Ewing's or Hopkinson's paper that M. M. F. affects hysteresis in any way.

Some other statements of Mr. Tesla are rather hard to reconcile; as, for instance, he says: "In this case * * an advantage will be gained, as the total magnetic resistance will be diminished. The four transformers will now demand less excitation, and since * * * the gain depends on the square of the exciting current, it is by no means insignificant." And in the next paragraph: "Mr. Swinburne is in error as to the motive which caused the tendency to shorten the magnetic circuit in closed circuit transformers; it was * * * not to reduce the magnetic resistance, which has little to do with efficiency." These two statements do not seem to agree remarkably well, and a little further explanation would be of advantage.

Further on Mr. Tesla says that if the wires are "wound side by side" (a rather obscure expression) a shorter magnetic circuit will give a better result. He does not mention in what regard the result would be better, and it would be interesting to know. I presume, that he does not mean that the result would be better efficiency, for he has said that efficiency does not depend on length of magnetic circuit.

Finally, Mr. Tesla says: "Mr. Swinburne states that in his transformer the loss in iron is under 1 per cent. of the full load; all the balance of the loss must, therefore, be in copper. But since, according to him, the wires are of larger section, his transformer can hardly be an improvement in that direction." It appears to me that any increase in the cross-section of the wires will decrease their resistance, and thus decrease their C^2R loss. The change in the angle of lag, if it be appreciable, would be in the direction of less loss.

The objection to the gun metal casting appears to be well taken; but as this applies merely to Mr. Swinburne's transformer and not to open circuit transformers in general, in which I am especially interested, I will leave Mr. Swinburne to defend that for himself.

In conclusion, the fact that the open circuit transformer that Mr. Tesla designed required a larger number of alternations than are commonly used, does not prove that an open circuit transformer may not be designed to use the ordinary rate of alternation. I hope Mr. Tesla will clear up these matters, since his article is, to say the least, a little obscure. THORBURN REID.

NEWARK, N. J., September 26, 1890.

AN ELECTRICAL CONUNDRUM.

[141.] The following passages occur in a set of specifications for an electric light plant for a Philadelphia concern, and the writer was applied to by one of the bidders to explain the meaning of the two restrictions. It is rather an electrical conundrum and I should like to have some of your readers furnish the answer if possible. PUZZLED.

"The loss of electromotive force will not exceed five (5) volts from the terminals of either dynamo—when run at 110 volts between said terminals—and any lamp when the full complement of lamps are burning at their standard c. p. This result will be strictly adhered to."

"The lamps will be 110 volts, 16 c. p. and average not more than 6-10 of an ampere per lamp."

EUROPEAN CORRESPONDENCE.

LONDON.

The British Association.—The Value of the Ohm.—Lighting of English Towns.—Electric Traction.—Electric Lighting of London.—Lighting of Newspaper Offices.—Train Lighting.—Berlin Post Office.

THE meeting recently concluded at Leeds did not collect so large a number of persons as is usually to be found at such gatherings. A good many electrical papers were presented, and in one or two cases excited considerable discussion. By far the most interesting was the report of the Committee on Electrical Standards, many leading scientists taking part in the discussion. Mr. Glazebrook on behalf of the committee said the conclusion arrived at was that the time was ripe for taking into account an alteration of the ohm. Sir William Thomson, Lord Rayleigh, and Mr. Preece entered into the discussion, and the views expressed by the speakers were entirely in accord with the recommendation of the committee. Prof. Rowland gave a short account of the experiments that had been made in America. Prof. Barker following, said they would be fully prepared in America to adopt as the length of a column of mercury of one square millimetre section 106.3 laid down by the committee. He asked Englishmen to assist them in return to get in the name of Franklin somewhere as the name of a unit.

In virtue of this action of the British Association, it will probably not be long before something definite is done.

Sir Wm. Thomson's paper on anti-effective copper proved one of the best practical papers presented during the meeting. As you will see by the paper, though the resistance of a conductor may be reduced as its cross section is increased, a thickness is soon reached at which an addition of copper causes an increase in the heat generated by the alternating current. When one is therefore limited to a given weight of copper to produce the most economical results, it is evident that the metals should be of the highest purity, and I imagine that there is a great field in this direction for the electrically deposited copper wire manufactured by the Elmore Company.

The figures given in Mr. Preece's paper "On the Character of Steel used for Permanent Magnets," show that the French specimens of magnet steel are much superior to the English. Prof. John Perry said that the fact gave rise to the question whether they had not some secret method of tempering not possessed by them in England.

Among the grants made for scientific purposes, there was one for £100 granted to the Committee on Electrical Standards. Next year the meetings will take place at Cardiff under the presidency of Dr. Huggins, the astronomer.

There is considerable activity shown at this period in the lighting by electricity of English towns. A notable example is Bristol, at which place the Town Council have taken the lighting into their own hands. It is proposed to erect about one-hundred lamps of 1000 c. p. each in the streets. The work will be begun shortly. We may expect in the next two or three months considerable development in this direction in Huddersfield, Derby, Dundee and several other large places. In connection with municipal lighting, I may mention that the town authorities appear very anxious to keep the lighting in their own hands, and thus prevent what is by them termed a hurtful monopoly. They ever keep in their minds the gas interests, which are widely different from anything that could arise under the Electric Lighting Acts. If they do the lighting well, it may certainly be good for the consumers, though many authorities here declare it cannot be done so well as by private companies.

Seven electric omnibuses will be placed on the road between Kings Cross and Victoria (3¼ miles) in a few days by Ward & Co. They will run at the same fare as the horse cars now on the road. Each bus will carry 26 passengers, 12 inside and 14 outside, attended by the usual driver and conductor. The vehicles are worked by 60 19-plate E. P. S. accumulators fixed in the bottom. They work about three hours a day and are then recharged. For the past few months one or two cars have made experimental journeys through the most crowded streets of London.

It is said that the City & South London Railway, running from London to Stockwell, which will be entirely worked by electricity, is to be opened in one or two months, although up to the present time no information of a technical nature has been given to the electrical press. The engineers are evidently anxious to keep out criticism on the incomplete work. One or two schemes, I may say, are waiting the trial of this one before proceeding any further with their work.

The Corporations of Leeds and Edinburgh are considering the question of electric traction, and according to the latest accounts it is probable that the former place will make the experiment of running electric cars.

One of the earliest companies to supply electric light under the provisional order, for the whole of the allotted area, will be the Westminster Electric Supply Corporation. This company has the best districts in London, which includes Westminster, Belgravia, and Mayfair. The central station in Westminster fitted

with Goolden dynamos is almost complete. A temporary station alongside has supplied light to the Houses of Parliament and the mansions about for a considerable period.

The proprietors of the *Manchester Examiner and Times* have lately installed a complete system of electric light in their Manchester office. I am informed that the lighting arrangements have been well carried out by the Manchester Edison-Swan Co.

A few trains running between London and Richmond are supplied with a penny-in-the-slot system of electric light. For the sum of one penny a traveller obtains a good light which lasts for a quarter of an hour.

A *Times* correspondent this morning says that storage batteries have been dispensed with at the Berlin Central Post Office. An accumulator supplied by the Berlin Electric Light Company is used instead.

LONDON, Sept. 15, 1890.

CORRESPONDENCE.

PITTSBURGH.

Putting the Wires Underground.—Electric Railway Notes.—Voting on Electrocution.

THE municipal authorities in this city are going to make a great effort shortly to have all the electric wires now strung along the streets put under ground. The plan so far is to start with police telephone and fire department wires as well as the private lines operated by the city, amounting altogether to 550 miles of wires. For this purpose, the department is going to make an appropriation to defray the cost of the undertaking. Then when these wires are underground, an ordinance is to be offered to councils compelling all the local electric light and street railway companies to put their wires underground also. Superintendent Mead, of the bureau of electricity, has had several interviews already with the chief of the department of public safety, and it is expected that the plans are about formulated which will bring all the wires underground.

The South Side residents of this city are objecting to the Birmingham Traction Company's electric poles, and their opposition became so pronounced a few days ago that the police authorities had to be asked to interfere. It is pleasant to record that this settled the trouble for the time, but it seems extraordinary for people to object to the introduction of rapid transit, especially for those on the South Side of Pittsburgh, who have for years complained that the old horse cars were a nuisance.

According to the popular verdict of a large number of visitors to the Pittsburgh Exposition, it is thought that Pennsylvania ought to introduce electrocution as the most accomplished method of capital punishment. A popular vote on the question: "Should electrocution take the place of hanging for capital punishment in the State of Pennsylvania?" was taken a few days ago and the result was that out of 13,000 visitors, the majority voted "Yes." The peculiar feature in Pittsburgh, however, is that during the last five years, not a man has been executed here at all, not even for the most heinous of crimes.

The latest appliance for simplifying the use of electricity as the motive power on street cars is brought out by a gentleman from Allegheny, who has invented a device whereby the motor and brake power of electric cars may be more easily applied than at present. This device consists of an arrangement which combines the use of the rheostat with the brake. The brake wheel rod is run through the centre of the rheostat and has the spring contact affixed to it in a similar manner as at present. The affair is now being experimented with on one of the electric street cars in this city, and if it is successful, it will be very beneficial to the motor man.

The Duquesne Traction Company proposed to build a tunnel under the Pennsylvania railroad tracks at Penn avenue, near Wilkinsburg, in order to get a direct route from Pittsburgh to Wilkinsburg, a distance of seven miles. The councils of Wilkinsburg have been asked to grant the permission to the Traction company and there is no doubt this will be done.

PITTSBURGH, Sep. 24, 1890.

The Pittsburgh Exposition.—The Allegheny County Light Co.—The East End Electric Light Co.

THERE is no doubt that a great deal of the success of the Pittsburgh Exposition is due to the fact that electricity constitutes one of the attractive features. Then again, it is more than likely that all the other exhibits would be robbed very largely of their beauty were it not that the entire buildings are illuminated with the electric light. There are 1,700 incandescent and 63 arc lights distributed. These are furnished by the Allegheny County Light Company. There are, however, a good many more electric lights, but they are used individually by the Westinghouse and Thomson-Houston Companies. Hughes and Gawthrop, the agents of the latter concern, occupy quite a large space in Mechanical Hall. Here they have displayed a number of incandescent and arc light machines, as well as a motor generator. This generator is of 30 h. p., and it furnishes the power to a number of fans and other small motors throughout the buildings. In a few days it is expected that a number of welding machines will arrive, and the visitors will have an opportunity of viewing the interesting process of welding by electricity.

All the ice-cream eaten at the various stands in the exhibition is made by a machine connected with an electric motor; then there is a cider press also operated by the same means. Owing to the heat from the different engines and boilers, motors attached to fans abound everywhere and the breezes are generally enjoyed.

The Allegheny County Light Company has now a capacity of 35,000 incandescent lamps and 1,000 arc lights, Westinghouse alternating current system, and runs the largest combination central station in Pennsylvania. The company is constantly increasing its capacity, at present at the rate of 1,000 lights per month. The company's plant is in the centre of the city, and another building will have to be added very soon.

The East End Electric Light Company, another corporation operating the Westinghouse system, is also complaining of cramped quarters. Pittsburgh people are certainly very partial to electric illumination, which proves that they know a good thing when they see it. The city has about 250,000 inhabitants and there are now close upon one hundred thousand incandescent and 2,000 arc lamps burning here every night. All the new houses put up, either for residence or business purposes, are also wired for the use of electric lights, and no one thinks any more of putting in gas pipes. A good many of the churches are lit by electricity, as well as the theatres. This, of course, causes the great demand for electric lights and keeps the light companies busy to supply all the demand. The East End Company, which has now a capacity of alternating current apparatus for 20,000 incandescent and 500 arc lamps, increases at the rate of 1,200 lights per month; in fact, the management is now getting ready to devise the plans for an additional power house, giving it space to double the present plant. It is expected to have 25,000 lights going by New Year's eve.

The Westinghouse Electric and Manufacturing Company is adding one of its "Noiseless" motors to the handsome display at the Pittsburgh exposition. The motor will be put on a truck and the whole will add greatly to the interesting features of the exhibit.

PITTSBURGH, Sept. 26, 1890.

CHICAGO.

Northwest Chicago Electric Railway—Plans for Electric Roads at Alton, Ill.

LETTERS of incorporation have been taken out by the Northwest Chicago Electric Street Railway Co. Mr. William Boldenweck, one of the incorporators, states that nothing definite will be decided upon until a franchise has been obtained. The new road is to run through a portion of the city where rapid transit has not heretofore received attention. The electric motors will be operated by means of storage batteries, thus obviating the necessity for overhead wires, and the cars will be similar to those now in use on the West Side cable road. It is proposed to start at the corner of Milwaukee and Western avenues and run north on Elston to Montrose. A branch line will run from Elston avenue along Kedzie avenue to Logan Square, thence down Milwaukee avenue, and another branch will run from Elston avenue along Crawford avenue. The company says it will be ready for business in ninety days from the time it obtains a franchise.

Messrs. Rodgers and Donovan, representing the Holmes street railway syndicate, have been to Alton, Ill., and secured an option on the two street railways between Alton and Upper Alton. If they conclude the purchase, a road will be built to North Alton, and all three operated by electricity.

CHICAGO, Sept. 26, 1890.

DINNER OF THE NEW YORK ELECTRIC CLUB.

This week, on Thursday, October 2, the New York Electric Club will inaugurate its winter season with a subscription dinner, which promises to be a magnificent success. Under the brilliant management of its versatile president, Gen. O. E. Madden, the club has lately been making many steps forward. A great number of its bondholders have been induced by him to cancel the obligations, and thus the debt has been reduced by several thousand dollars. The club finances are, in fact, in better shape than they have been for some time past. Various improvements in the club house and its service have been made, and when the members and their friends sit down on Thursday night they will do so with justifiable feelings of pride in the success of the club as a social institution, for the promotion of hospitality and friendship.

REPORTS OF COMPANIES.

THE NEW YORK PHONOGRAPH CO.

A certificate of the consolidation of the Metropolitan Phonograph Company and the New York Phonograph Company, under the name of the New York Phonograph Company, was filed last week, at Albany, N. Y. The capital of the new company, which equals the aggregate amount of the two companies, is $2,500,000. The trustees of the consolidated company are, John P. Haines, John D. Cheever, R. D. Haines, Noah Davis, William Fahenstock, W. Seward Webb and John L. Martin.

CONSOLIDATED ELECTRIC LIGHT CO.

At the annual meeting of the Consolidated Electric Light Company, held in this city, on September 17th, the following were elected directors:—Hugh R. Garden, Geo. Westinghouse, Jr., Amos Broadnax, Jacob Hays, Thomas B. Kerr, Geo. H. Lewars and John Rooney. At the subsequent meeting of the directors, Hugh R. Garden was elected president; Jacob Hays, vice-president; Geo. H. Lewars, secretary and treasurer. The regular quarterly dividend of 1¼ per cent. was declared payable October 1.

MEXICAN TELEGRAPH CO.

The Mexican Telegraph Company has declared a quarterly dividend of 2½ per cent., payable Oct. 13 to stock of Oct. 4. The operations for the quarter, partly estimated, were:

Receipts June 30 to Sept. 30	$90,618
Operating expenses	16,500
Net income	$74,118
Less dividend Oct. 13	47,815
Surplus for quarter	$26,303
Surplus above dividend July 12	92,072
Total surplus	$118,375
Receipts nine months, 1890	299,576
Receipts nine months, 1889	266,473

Also in treasury 1634 shares Central & South American Company stock, costing $127,886.

CENTRAL AND SOUTH AMERICAN TELEGRAPH CO.

The Central and South American Telegraph Company has declared a quarterly dividend of 1¾ per cent., payable October 6, to stock of September 27. The statement, partly estimated, shows:

Receipts June 30 to Sept. 30	$134,445
Operating expenses	38,000
Balance	$96,445
Less dividend Oct. 6	84,140
Surplus for quarter	$12,305
Surplus June 30 above dividend of July 6	582,459
Total surplus Sept. 30	$594,764
Deduct betterments June 30	286,417
Surplus above October dividend	$308,346
Receipts nine months to Sept. 30, 1890	433,974
Receipts nine months to Sept. 30, 1889	490,663

Eight thousand tons of material for the cable extension to Valparaiso are to be shipped from London, October 8, and the cable is expected to be in operation next January. The $1,000,000 construction certificates, already subscribed for at par, will more than meet the expense. The decrease in receipts for the quarter was caused by unusual receipts in 1889, consequent upon the interruption of the Western and Brazilian cables.

UNITED ELECTRIC SECURITIES CO.

Lee, Higginson & Co. and Parkinson & Burr offer to Thomson-Houston stockholders $1,000,000 of the collateral trust, 5 per cent. sinking fund bonds of the United Electric Securities Co. at 95 and accrued interest, 10 per cent. in the capital stock of the said company as a bonus. The first indenture is down for $500,000 collateral trust bonds, secured by the following first mortgage bonds taken at their par value: Third Ward Railway Co., $39,000; Toledo Electric Railway Co., $50,000; Thomson-Houston Carbon Co., $100,000; Scranton Suburban Railway Co., $9,500; McGavock and Mt. Vernon Horse R.R. Co., $30,000; Peninsula Electric Light and Power Co., $50,000; Jackson Electric Works, $35,000; Jacksonville Electric Light Co., $26,000; Toledo Electric Co., $83,000; Georgia Electric Light Co., $84,000; Palmer Electric Co., $8,500; Hyde Park Electric Light Co., $20,000; Utica Belt Line Street R.C. Co., $25,000; Louisiana Electric Light Co., $66,000. Total, $626,000. The deed of trust provides that the company shall redeem, commencing Aug. 1, 1895, $10,000 bonds a year for five years, in the next five years $15,000 a year and in the succeeding five years $20,000 a year. During the remaining ten years the company shall redeem such an amount of bonds as will retire the whole issue at maturity, Aug. 1, 1920. The bonds may be drawn at 103. The authorized issue of the United Electric Securities Co. is $5,000,000 bonds and $1,000,000 stock, but probably not more than $2,500,000 bonds will be issued. The bonds are $1,000 bonds, and the American Loan and Trust Co. is trustee under trust indenture No. 1. Mr. Thomas E. Proctor is president of the new company, and the following named constitute the executive committee, who will decide upon the bonds to be admitted as collateral for the second series of $500,000, and the subsequent series: Francis Peabody, Jr., Samuel Carr and C. A. Coffin. An important feature of the trust indenture is that no other bonds than those mentioned in the indenture can be substituted, and if any of the collateral bonds are drawn or paid off the money must be used in the redemption of this issue.

BONDS.

La Grange, Ga.—Bonds will be issued by the city to the amount of $50,000 to be spent on the construction of an electric light plant and water works.

DIVIDENDS.

Mt. Carmel, Pa.—A dividend of 5 per cent. has been declared by the Edison Electric Illuminating Company, and a meeting of stockholders will be held November 22 for the purpose of voting for or against an increase of capital stock.

METAL AND SUPPLY MARKET.

REDUCTION IN THE PRICE OF ALUMINIUM.

A special dispatch from Cleveland, O., of Sept. 26, says:—"An announcement of interest to the metal trade is made to-day by the Cowles Electric Smelting and Aluminium Co., of this city. Heretofore the lowest prices made to the public on aluminium in small lots has been $2.50 per pound. The Cowles Co., who are the largest manufacturers of aluminium in the world, issue a circular to the trade to-day cutting this price to $1 per pound for the aluminium contained in any of their alloys. Five years ago, when the Cowles aluminium was first offered for sale, the current price of the metal was $20 per pound, and little if any was obtainable even at that figure, and this without any guarantee of chemical purity. The first price made on the Cowles aluminium was $5 per pound as against the above figure. At $1 per pound aluminium will become a serious competitor with both nickel and tin. At 50 cents pure aluminium would become a formidable competitor with copper."

INVENTORS' RECORD.

Patents issued September 23.

Alarms and Signals:—*Portable Electric Fire-Alarm*, F. R. Upton and F. J. Dibble, 436,961. *Electric Signal for Velocipedes*, C. G. Jiran, 436,979. *Electric Distance Heat-Indicator and Alarm*. F. W. Wiesenbrock, 437,069.

Conductors, Conduits and Insulators:—*Coupling for Electric Wires*, F. R. Jones, 436,857. *Coupling for Electric Wires*, J. J. Hinphey, 437,116. *Underground Electric Conduit*, C. E. Loth, 437,126.

Dynamos and Motors:—*Speed-Regulator for Dynamos*, S. E. Nutting, 436,901. *Commutator-Brush*, C. Wirt, 436,964. *Dynamo-Electric Machine or Motor*, M. Mayer, 437,160.

Electrolysis:—*Process of Electro-depositing Aluminum*, J. A. Jeançon, 436,895.

Heating:—*Electric Heater*, E. Abshagen, 436,864.

Lamps and Appurtenances:—*Electric-Arc Lamp*, A. Wagniere, 436,814. *Holder for Electric Light Shades*, L. J. Atwood, 437,008.

Medical and Surgical:—*Electro-Osteotome*, M. J. Roberts, 436,804. *Electric Belt*, L. D. Ashbrook, 437,079.

Miscellaneous:—*Electric Controller for Power Mechanisms*, R. D. O. Smith, 436,843. *Electrical Weighing Machine*, W. Snelgrove, 436,910. *Thermal Cut-Out*, G. H. Whittingham, 436,952. *Artificial Resistance*, E. M. Bentley, 437,011. *Method of Impregnating Parts of Electrical Apparatus*. F. L. Rawson, 437,044. *Rheostat*, J. H. Gunning, 437,111. *Nautical Magnetic Tracer Apparatus*, F. Aramburu, 437,169.

Telephones and Apparatus:—*Telephone-Exchange System*, E. M. Bentley, 437,010 and 437,012.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

ALEXANDER, BARNEY & CHAPIN.

From the way things have started there is every promise that the fine store at 20 Cortlandt street of this popular new supply house will soon become known as the "Down-town Electric Club." It is at the very heart of things electrical, and, although the store does not open until October 6, there is already an incessant influx of callers and visitors. One feature of the scene is that the guests of the concern belong to all branches of the profession and industry. This, however, is not to be wondered at in view of the prominence of the members of the firm in their late respective fields. In fact, the unsolicited influx of well-wishers has already been so great that Mr. Alexander has set aside a very cozy corner of the store as a kind of correspondence and exchange room. It will be fitted up in a social, clubbable way, and anyone coming to town or desiring to meet a business friend down town will be fully at liberty to make himself at home there, not only leaving his baggage there, but also receiving his mail and telegrams at the same headquarters. A convenience of this nature has long been needed for business purposes in electrical work, and there is every probability that the A. B. C. store will soon become in this manner an Electrical Exchange at the midday hour. At any rate, Mr. Alexander will address his energies and talents to that point, and with the help of his able colleagues he bids fair to succeed to admiration.

The store will be about ready this week, and in the meantime a large amount of work has been done in mapping out departments, fitting up, upholstering, disposition of stock, etc. A little delay and difficulty has arisen from the desire of a large number of individuals and companies to place their product in such good hands.

ELECTRICAL FEATURES OF THE PITTSBURGH EXPOSITION.

ONE of the most important and interesting features of the Pittsburgh Exposition is that made by the Westinghouse Electric and Manufacturing Co., whose mammoth establishments are situated in that place.

As the pioneer and chief promoter of the alternating current system of electric lighting, the company confines itself simply to a display of alternating current apparatus, and it is safe to say that no other electrical concern, either in this country or in Europe, has made a show so manifold and so complete in its illustration of the development of the alternating current system.

On entering what is known as Mechanical Hall of the Exposition building, the display of the Westinghouse company occupies the entire view on the right hand side, and one of the first pieces of machinery is a 3000-light alternating current dynamo, belted to a rotary engine of four hundred horse power. The latter was designed and invented by Mr. George Westinghouse, Jr., and its peculiar shape and appearance for a steam engine attracts great attention. Next to the large arc apparatus is another of 1500 lights capacity, belted to a Westinghouse compound engine. Then follow all in a row a 750-light dynamo, belted to a Westinghouse Junior engine of 60 horse power; a 2000 volt, self-exciting machine of 1000 incandescent lights, also belted to a Westinghouse Junior engine; a 25-light alternating current arc machine, attached to a Westinghouse Standard engine, and at last, a 30 horse power arc motor generator, also belted to a Westinghouse Standard engine.

In the evening, all the apparatus and the engine are in operation. The incandescent machine generates the current for all the lights used in and about the building. The 3000 light dynamo, however, is operated exclusively to light up an illuminating sign, which is put up in the form of an immense arch on the grounds surrounding the Exposition. This arch carries the following lettering on both sides: "Westinghouse—Pioneers of the Alternating System."

The two signs contain over 2000 incandescent lamps of 16 candle power each, and their effect in the evening gives a very good idea of the artistic capabilities of electrical illumination.

The other light machines operate the lights throughout the buildings as well as those utilized in the display. The arc dynamo operates the well known flat carbon lamps, of which the Westinghouse Electric and Manufacturing Company are the makers.

The arc motor generator operates about a dozen Tesla and other arc motors, and if any one is desirious of having proof of the commercial usefulness of the Tesla motor, he can have it in this exhibition. For light manufacturing purposes, especially, there is claimed to be no motor superior. In this display, one motor operates a small printing press, several of them operate fans, while in one part of the exhibition another runs a carpet loom, again another, a stone crusher, a third rotates a six foot circular saw, a fourth the Hercules mining machine, a fifth operates a soap wrapping machine and a caramel wrapping machine of the Nuttall Manufacturing Company.

Adjoining the motor generator is a pavilion handsomely furnished in antique oak, decorated with tropical plants and draped in the most elegant and tasteful manner. In a corner of this pavilion stands a Domestic sewing machine, fitted up with a new type of alternating current motor, brought out not long ago by the Westinghouse company. The peculiarity of this motor is that its brushes are utilized as a regulator of the speed of the motor. This method of regulation is operated by the treadle of the sewing machine, the harder the treadle being pressed the lower will be the speed. The working of the apparatus is constantly explained to the many interested housewives who are crowding around the pavilion all day long.

In front of the pavilion stands an experimental table filled with all kinds of peculiar contrivances of the alternating system. There is the Shallenberger meter, the converter, a stage regulator and a number of motors, the smallest one having only sufficient power to blow out a match. An electrician of the company is constantly in attendance here for the purpose of illustrating the workings of the different appliances. He shows the action of the meter when attached to one lamp, ten lamps, up to 50 lamps. He explains the street converter system. He shows the manner in which the stage regulator operates. The latter is connected with five switches, each controlling ten lamps.

Altogether the display is one of the most wonderful that has ever been gotten up for any exhibition.

It has not only been the object of the company to prove to the visitors that Pittsburgh stands to-day unrivaled in the electrical industry of the world, but the company is also anxious to explain to everybody who cares to learn, the intricacies and wonders which are constantly confronting the uninitiated in electrical science.

NOTES ON MINNEAPOLIS INDUSTRIAL EXPOSITION.

Westinghouse, Church, Kerr & Co. show three of the Westinghouse engines in operation, a "Standard" automatic, compound automatic and "Junior" automatic. These engines run very nicely and attract a great deal of attention on account of the small floor space they occupy. The exhibit is in charge of Mr. W. O. Everett and his assistant, Mr. S. J. Reed, is running the engines.

The Northwestern Thomson-Houston Company are also making a very fine exhibit, and doing the largest part of the lighting for the Exposition. They have in operation four Thomson-Houston arc machines of 50-light capacity each, two alternating incandescent machines, one of 1,300 lights and the other of 650 lights, a direct current machine of 60 h. p., run at a pressure of 250 volts; used for generating current to operate motors.

Cooley & Vater exhibit, among other specialties for power work, a 300 h. p. Weisel and Vilter Corliss engine which has a cylinder 20x42 and runs at 86 revolutions per minute under 100 lbs. steam pressure. This engine is employed to run a line of shafting to which are belted four Thomson-Houston 50-light arc machines, one Brush 30-light arc machine, one 1,300, and one 650-light alternating machines.

The Interior Conduit and Insulation Company make a very handsome showing of their interior fireproof insulating conduit tubes for house and underground use. This is one of the most useful systems that could possibly be devised and has found immense favor among electricians by reason of its flexibility as regards the system of wiring and its safety. It is also coming rapidly into use in underground work, and over 150 miles are now being used in Minneapolis and St. Paul for the electric street railways. Samples of the underground system and all the various tubes for interior building wiring are on exhibition.

W. S. Nott has a piece of the leather belting manufactured by him for the Minneapolis Street Railway Co. which is no less than 75 inches in width and which is claimed to be the widest leather belt in the world.

One of the most interesting and thoroughly practical exhibits shown is that of the Thomson Welding Company. There are several different sizes of welding machines shown in practical operation, and welds are made in the finest wire up to heavy bars of iron and steel. The sample boards shown present some very remarkable combinations of the various metals which are capable of being welded together by this method, and articles of all shapes and sizes can be turned out. The space of time occupied in making the weld is very short. Insulated wires can be welded together without injuring the insulation, which it is only necessary to strip off right at the point of junction.

The Carpenter-Nevens Electro Heating Co. are making a very handsome exhibit of the application of electricity to heat sad irons, soldering irons, stamps, cooking utensils, and numerous other devices. They appear to have got this method to a state of perfection which has not heretofore been reached. Their apparatus is very handy and convenient, while the amount of current absorbed is small, as all their apparatus is so constructed that the heat evolved from the resistance is concentrated upon the parts to

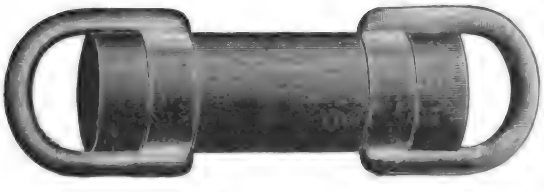
be heated, a very small percentage being lost in heating the surrounding atmosphere.

One of the most striking applications of the phonograph is shown by Mr. A. Theo. E. Wangeman, in the Art Gallery. A phonograph is connected with a long distance telephone instrument and music or talking emitted from it is sent over the telephone line, and can be heard by placing the receiver at the other end of the line to the ear with the greatest distinctness and accuracy. It is possible to connect all subscribers so that they can hear at the same time with their instruments, and it will, ere long, save them the trouble of going to church or the opera.

The Edison Co. make a large exhibition of their underground tube system which has been successfully in operation for many years. Various sizes of the 3-wire feeders and mains are shown with junction boxes and all the parts of the system, making a very fine exhibit.

ENGLUND'S CENTRE CURVE INSULATOR.

The insulator shown in the accompanying cut is for use where unusual strains have to be met. The managers of the Electric Merchandise Company, Chicago, who are the owners of this patent, have, during the last few years, experimented very largely with a view of securing a centre curve insulator which, while being neat in appearance, would have the requisite strength needed for all demands. The objection offered to those heretofore made has been that, to get the needed strength, it has been necessary to have the insulator so heavy that it has been unwieldy to handle, and heavy in appearance on the line; while if attempts



ENGLUND'S CENTRE CURVE INSULATOR.

have been made to lighten it, openings have had to be made, which, filling with rain and snow, have destroyed the insulation.

The insulator illustrated is a solid but very neat coil of rubber, but nine inches in length, and when placed on the line, it is scarcely discernible. It is, however, protected on the inside of the rubber so securely that it will stand any strain which may be put upon it, even to holding the extreme ends of the line.

RAPID CENTRAL STATION CONSTRUCTION IN CHICAGO.

One of the most remarkable feats in the rapid construction of a central station has recently been accomplished in Chicago by Mr. W. H. Harding, manager of the South Side Electric Company, in building and completely equipping the company's new station at Twentieth and State streets, from laying the boiler foundations to the lamps, in the space of exactly fourteen days.

The plant now installed comprises two boilers and two high-speed automatic Bass engines of 100 h. p. each, running at 265 revolutions per minute, which drive two 1,000-light Slattery alternators and one 25-light Wood arc machine. With the boiler plant is installed a 200 h. p. Kroeschell feed heater and a duplex Deane pump. The new Alhambra Theatre is lighted from this station; and the illumination and regulation of the lamps has been effected in a very neat and effective manner, the decorative effects being particularly striking. Mr. Harding has been ably assisted in carrying out this work by Mr. F. L. Webster, his superintendent, and it is due to their united and indefatigable efforts that the work has been so expeditiously and thoroughly done.

PROSPERITY OF THE GREAT WESTERN ELECTRIC SUPPLY CO.

So phenomenally rapid has been the growth and extension of the above company, some people have, perhaps not unnaturally, supposed that it must be doing a business far beyond its pecuniary resources, and it was possibly in this way that unfavorable rumors were recently set in circulation as to the financial standing of the concern. With the very wise determination to nip in the bud any talk that might thus be injurious to them by affecting their credit and checking the influx of orders, Mr. George Cutter, the able general manager of the company, has come out with a flat-footed, categorical denial of the reports. He says that they are altogether unwarranted and utterly without foundation. The more positively to put a summary end to such rumors, Mr. Gilman, the energetic president of the company, has paid out during the last few days over $110,000, anticipating in fact many of the claims still to come due on them. It has been and still is definitely the intention of the company to buy large quantities of goods of all kinds for spot cash, thereby taking advantage of the very favorable terms which can thus be obtained. Mr. Cutter has a list of merchandise, for example, to be purchased in this manner aggregating over $130,000.

RAPID CONSTRUCTION FOR THE ELMIRA, N. Y., ELECTRIC RAILWAY.

A REMARKABLE feat of electrical railway construction has recently been completed at Elmira, N. Y. On the 30th of July the Elmira and Horseheads Railway Co. placed a contract with the Edison General Electric Company for the equipment of seven thousand feet of track, six motor cars, and a full station equipment. At the same time, a contract was placed with the John Stephenson Car Company for six new cars of solid and elegant construction. The contracts were made, in both cases, with the strong guarantee that the roads should go into operation on September 1, in order to be ready for the Great International Fair which was to open on that day. Both the Edison Company and the Stephenson Company put their best men upon the work, and forwarded supplies with the utmost possible despatch. On or about the fifteenth day of August the Stephenson Company announced that its cars were ready for equipment, and at about the same time, the motors were shipped from the great Schenectady Works of the Edison Company, which have a capacity of from 15 to 20 street car motors per day. The strike on the New York Central at this time bid fair to cause very serious delays as the cars were to be equipped in New York. A special consultation between the Edison Company and the Stephenson Company was held at Schenectady, with the result of causing the motors to be shipped via the Delaware & Hudson R. R., and the Delaware, Lackawanna & Western R. R. Companies, a round-about route, which necessitated special cars and unusul expedition. On about the 20th of August the completed cars began to go out from the Stephenson factory, two being shipped each day. In the meantime a contract had been placed with the Simplex Company, of Boston, for the feed wire, the Edison Company had forwarded all line material and supplies, and everything was on the ground but the poles, which were held in Northern New York awaiting arrival of cars that had been delayed on account of the New York Central strike. In this emergency every one turned in to help. Poles were gathered around Elmira, and at 12 o'clock on the night of August 23d, the street construction work commenced. Provision for the dynamos and appliances had been made by engaging a part of the Westinghouse station at Elmira. On August 31st notice was sent to the Railway Company that the road would begin operation on the following morning, and promptly at 6 A. M. on the first day of September, the road carried its first passengers. For the next few days the strains on the new machinery were excessive, the cars frequently having to carry two loaded trailers, and to remain in service from early morning until late at night. The number of passengers carried by these electric cars, with their complement of trail cars, in a day, was over twenty-five thousand. The road was entirely satisfactory in every respect, and Col. Robinson and Messrs. I. B. Newton & Co., the present owners of the road, have every reason to be grateful to both the Stephenson and the Edison Companies for this phenomenal execution of a time contract.

CONSOLIDATED ELECTRIC STORAGE CO.

Mr. Henry C. Whitney, late of the Crosby Electric Co., has been appointed the Superintendent of Agencies, by the Consolidated Electric Storage Co., and his office address will be at 120 Broadway, this city.

RECENT EDISON STREET RAILWAY CONTRACTS.

Among the recent railway contracts closed by the Edison General Electric Company may be mentioned the following: The Minneapolis, Minn., Street Railway Company; The Savannah, Ga., Street and Rural Resort Co.; The Dallas, Tex., Consolidated Traction Co.; St. Johns, N. B., City Railway Co.; James Street Belt Line Railway Co., of Seattle, Washington; St. Paul, Minn., City Railway Co.; Tacoma, Wash., Railway & Motor Co.; Richmond, Va., City Railway Co.; Utica and Mohawk Railway Co., of Utica, N. Y.; Elmira and Horseheads Railway Co., of Elmira, N. Y.; Elgin, Ill., City Railway Co.; People's Street Railway Co., of Scranton, Pa.; Fort Scott, Kan., Railway Co.; Louisville, Ky., Railway Co.; Pittsburgh, Pa., Railway Co.

The Edison Company is doing a large amount of foreign business, one of its recent contracts being for the equipment of the St. Johns City Railway Co., of St. Johns, New Brunswick, which is one of the strongest roads in the Dominion. The contract was closed through Mr. John F. Zebley, of New York, the president of the road, and the Edison system was determined upon by Mr. Zebley after a most thorough and careful examination of the different railway systems in this country.

THE DETROIT MOTOR CO.

The Detroit Motor Company have about completed their magnificent new factory in Detroit, situated on Cass avenue, beside the Michigan Central tracks. The ground occupied by them is 2½ acres in extent, giving them ample space for one of the largest electrical factories in the country, and we opine it will not be long before they add new buildings to the present. Their new factory has a frontage of 100 feet and is 250 feet deep. It has been completely built and equipped in two months. It is entirely illuminated by a special electric light and power plant, all the machinery being directly operated by motors.

The front portion of the building is three stories high. On the ground floor are the offices and motor room, and in a large one-story extension is the machine shop, fitted with the latest and most approved machinery. The second floor comprises stockroom, brass finishers' room and winding room for small work, and on the third floor is the main winding room. The Hon. Wm. C. Maybury is president, Mr. F. A. Blades, secretary and treasurer, and Mr. Henry H. Blades, the inventor of this excellent motor, electrician.

"ELECTRICITY IN DAILY LIFE."

The series of electrical articles that has been a leading feature of *Scribner's Magazine* for some time past, is brought to a conclusion this month with the appearance of an admirable sketch by Mr. H. L. Webb, of the details and incidents connected with laying an ocean cable. It is in fact one of the most interesting of the series, and is certainly one of the best written. The following important announcement has just been issued by Charles Scribner's Sons:—"The electric articles, which have attracted wide popular interest during their appearance in *Scribner's Magazine*, have been collected into a handsomely printed volume which presents a clear and adequate account of the applications of electricity to the needs of modern life. The ten writers of these papers were selected for their eminence as acknowledged authorities in various fields, both as theorists and practical electricians. They include the Patent Attorney for the Western Union, Edison's Chief Electrician, the President of the Stevens Institute, the Professor of Physics at Princeton, the Editor of The Electrical Engineer, and other prominent experts—all of them men who possess the faculty of imparting information entertainingly. The volume is profusely illustrated by the best artists and engravers. The work will give to the non-technical reader a definite idea of a group of new industries, already employing about 300,000 men and millions of capital." This volume will appear under the title of "Electricity in Daily Life," and will undoubtedly enjoy a wide circulation.

THE JOLIET, ILL., ELECTRIC STREET RAILWAY.

The Joliet Electric Street Railway Company, which has adopted the Thomson-Houston Electric Railway System, completed the electrical equipment of its road, and was put in operation on Feb. 3d, 1890. It is four miles in length, and part of it is built with bracket suspension, and the remainder with the cross suspension method. The overhead line is built upon 30 feet cedar poles, tastefully painted. It has a number of difficult curves, crossings and switches, for which the overhead line is arranged, and, since starting, it has had an exceedingly heavy traffic, but has been in constant operation without the slightest delay or trouble. They are at present operating 9 motor cars, each equipped with two 10 h. p. railway motors. The power station is equipped with two 80 h. p. Thomson-Houston generators, with switch-board fitted with all the necessary appliances for the manipulation of the current. The management of this road is so well pleased with its operation that they have placed orders with the Thomson-Houston Electric Company for additional equipment. It is a saying with the citizens of Joliet, that the Joliet Electric Railway Company's cars are "always on time."

STANLEY & HALL.

At a meeting of the board of directors, Sept. 20, it was decided to change the name of the corporation from Hazazer & Stanley to Stanley & Hall, by which it will now be known. It is understood that Mr. E. W. Hazazer is going West. Mr. A. F. Stanley, president and general manager, will continue in active charge of this progressive business.

A UNIQUE SWITCH

Embodying many new features will be brought out by The Great Western Electric Supply Co. in about ten days. It works on a new principle, and judging from the rumors which have been circulated during the past month, is destined to create a sensation in switch circles. The same firm is also getting a new fire-alarm system ready for the market. This is said to possess many advantages over the release-key system now in general use, and will probably find special favor in small towns.

THE PATTEE LAMP HOUR RECORDER.

The Great Western Electric Supply Co. write us that their orders on Pattee lamp hour recorders have outrun the capacity of production, and that they will have to strain every nerve to catch up.

HERING & DAVIDS.

The above firm have established themselves at 308 Walnut street, Philadelphia, as consulting electrical engineers, and make a specialty of testing dynamos, motors, batteries, etc. They also make examinations and reports of inventions; deliver expert opinions and testimony in patent causes, and undertake the calibration of instruments. They confine themselves to technical work as distinguished from contracting, but draw plans and specifications for, and supervise the erection of, any electrical work.

BARAGA FOR BATTERIES.

Several shipments of baraga have been made from an island near the north shore of Lake Superior recently. It is a clay-like mineral used in pottery ware and for foundry facings, but electrical experts at Detroit have found a new use for the mineral that will have a bearing on the production of electricity. The clay, as it comes from the ground, when placed in a cell with common brine, and the usual amount of zinc, produces a two-volt E. M. F. After three months the baraga is dissolved and then it is found to be pure graphite and more valuable than before using. A $200,000 stock company has been formed at Detroit.

WESTERN TRADE NOTES.

Mr. Pulsifer, of the Mather Electric Company, is in town for a few day looking after his company's interests here.

Mr. L. W. Magee, formerly with the Thomson-Houston Company, has accepted a position as general sales agent of the Excelsior Electric Company.

Mr. Walter J. Floyd, till recently general sales agent of the Excelsior Electric Company, has accepted a similar position with the Sperry Electric Company.

The Ft. Wayne Electric Company, through their Chicago office, have just sold a 1,500 light Slattery induction system plant at Atlantic, Ia., for street and commercial lighting.

The Electric Merchandise Company, 11 Adams Street, Chicago, have issued a very handsome little circular setting forth the many advantages of their improved rawhide pinions for armatuer and intermediate shaft. Their business in electric railway supplies, to whch line they devote their exclusive attention, is increasing all the time, and they find it hard work to keep up with their numerous orders which come in from almost each and every electric street railway company in the country. Mr. Mason is a most able and courteous manager and certainly deserves the magnificent success he has made of so recently organized a business.

NEW ENGLAND TRADE NOTES.

The Standard Electric Company, of Vermont, have sold a 100 light dynamo to the Evans Artificial Leather Company, Salem, N. H.

Mr. A. E. Davis has opened an office at 620 Atlantic avenue, Boston, and will look after the interests in New England of our esteemed contemporary, *Electric Power*.

Mr. C. W. Cartwright, a gentleman well-known to the electrical fraternity, has issued invitations for the occasion of his marriage to Miss Lottie Jane McKenney, on October 8th, 1890. Mr. Cartwright has the good wishes of his numerous friends in the electrical business.

The American Circular Loom Company, of Boston, have issued a neat little pamphlet giving the price of their patent woven insulated wires and cables, with several interesting reports of tests by eminent authorities on the insulating and abrasion resisting qualities of their covering. The booklet contains a few useful tables of weights and sizes of wires, and forms a very convenient memorandum book for purchasers of insulated wires.

A. W. Whitcomb, Worcester, Mass., is making a specialty of the manufacture of electric motors and dynamos, and is making quite a success of them. Mr. Whitcomb has had a long experience in mechanical engineering and is now connected with one of the largest machine shops in Worcester, so that he brings a thoroughly practical mind to bear on the electrical problems. The motors and generators are simple, well constructed, and compare very favorably with those of other manufacture in general appearance and in tests of economy and efficiency.

Departments of Lighting, Power, Electric Railway, &c., will be found in the advertisement pages.

THE

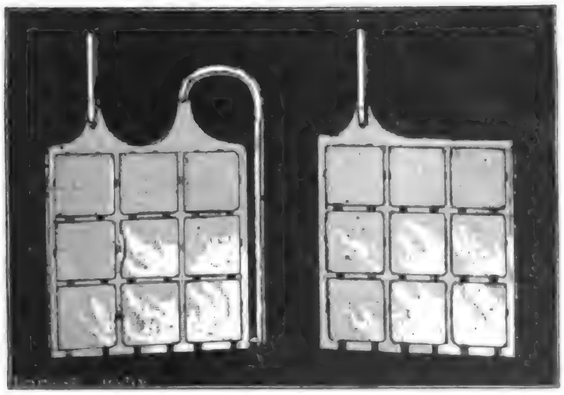
Electrical Engineer.

Vol. X. OCTOBER 8, 1890. No. 127.

THE SYSTEM OF THE ELECTRIC STORAGE BATTERY CO.

FOR some time past there has been operated at Germantown, Pa., a storage battery station deriving current from generators situated at the station of the Germantown Electric Light Co., and distributing it to lamps in the immediate vicinity in stores and dwellings, as well as operating a number of motors. This plant consists of 512 cells in 8 series of 64 each and has a capacity of 1,600 ampere hours. The results obtained in this plant have been so satisfactory and the arrangements adopted for proper regulation are of so simple a nature, that a more detailed description of the system will not fail to interest our readers. We may remark here that the greater part of the apparatus has been designed by Mr. Stanley C. C. Currie, the electrician of the Electric Storage Battery Co., of Philadelphia, and all parts involve novel features.

We propose to begin with the storage battery and its method of manufacture, which is now being regularly carried on in the company's factory at Gloucester, N. J. The results of numerous experiments have shown that the spongy lead reduced from different lead salts has a varying structure and consistency and that the number which can be employed for battery purposes is limited. This subject has been very carefully studied by the company and the conclusion arrived at is that the lead reduced from the chloride possesses the best properties for battery



Figs. 1 and 2.—Cast and Finished Grid.

purposes. In order to obtain a cheap and homogeneous product, however, certain precautions are necessary in manufacture. To obtain the chloride, commercial lead is melted and converted into a finely divided form by a special process. The finely divided lead is then dissolved in nitric acid and is then precipitated as chloride of lead by the addition of hydrochloric acid.

The white chloride of lead so obtained, after being thoroughly washed and dried, is mixed with a certain proportion of chloride of zinc and the mixture brought to a molten state in a furnace. The fused mixed chlorides are then poured into square molds and allowed to cool and crystalize. The square blocks of chloride so formed and which are destined as the active matter in the plates are then placed in a mold prepared for their reception and a grid of lead cast around them, binding the blocks into a compact plate, as shown in Fig. 1.

The method usually employed for making the lead grids of storage batteries consists in pouring the molten metal into a suitable mold. In the present instance, however, an improved method is employed, which not only effects great economy in time but brings the lead in inti-

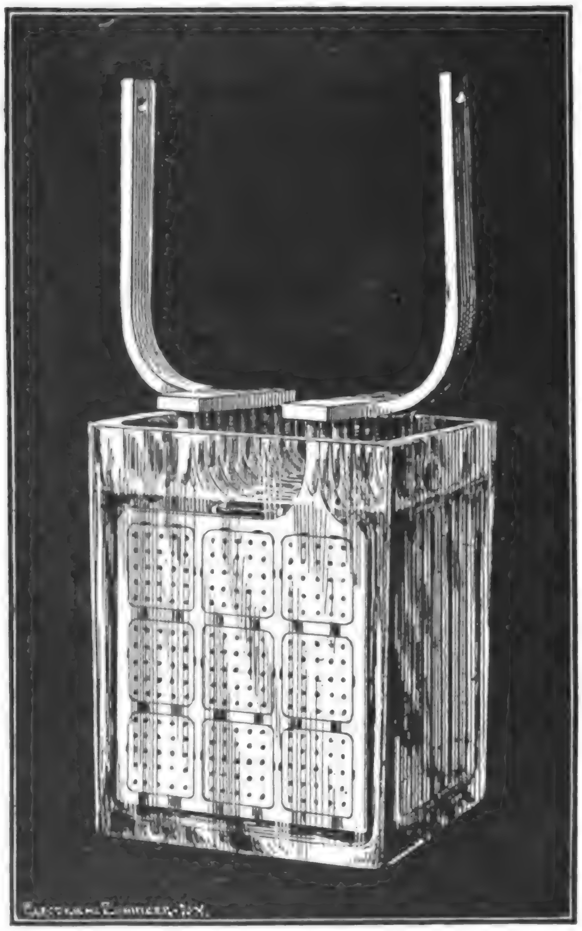


Fig. 4.—The Complete Cell.

mate contact with the blocks of chloride. This is accomplished by forcing the molten lead around the blocks under pressure. Our engraving, Fig. 3, shows the room in which the plates are prepared, with the casting press against the rear wall. The mold with the chloride blocks in position is placed in the press and connected to the lead outlet by a simple coupling. By the turn of a handle the lead is forced through the outlet into the mold and around the chloride blocks, gripping the latter tightly. When taken from the casting mold, the grid has the appearance shown in Fig. 1, being provided with a curved extension by which it can be conveniently handled for the subsequent operations.

The grids in their present condition are now packed between zinc plates and placed in a tank containing a dilute solution of chloride of zinc. There is thus formed a voltaic couple the action of which is to dissolve the zinc chloride and to extract the chlorine from the lead chloride contained in the blocks, thus leaving the lead sponge in their place. The last trace of chlorine is removed from the plates by washing and then placing them in a tank con-

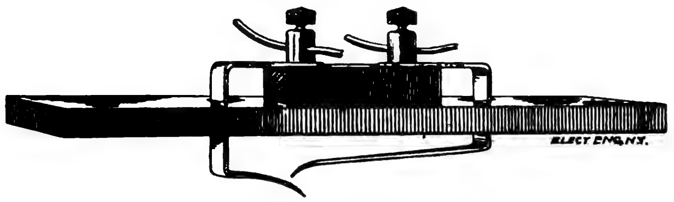

FIG. 5.—FULL CHARGE INDICATOR.

taining nitric acid, and passing a current through them. This action also opens the pores and leaves a pure lead sponge in the grid. The plates intended for the anodes or positives of the batteries are then packed tightly between perforated ebonite boards and formed into peroxide in dilute sulphuric acid.

The finished plate is shown in Fig. 2. The standard cell shown complete in Fig. 4, consists of 9 positive and 10

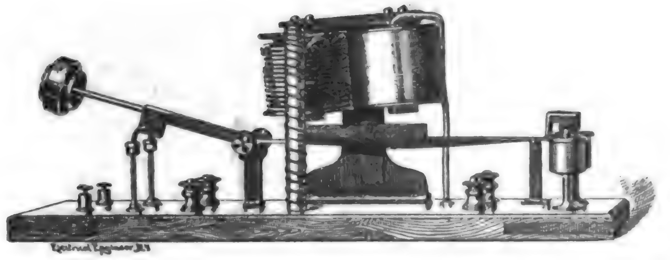

FIG. 6.—AUTOMATIC BATTERY CUT-OUT.

negative plates, having a capacity of 230 ampere hours and weighing, complete, 34 pounds. This gives as a result a capacity of 9.9 ampere hours per pound of plate and 18 ampere hours per pound of total active material. In size the plate is 5¾ inches wide by 6 inches high.

In the special street car cell of 1·9 plates the weight of active material and of the grids is, respectively, 12½ and 10⅝ pounds.

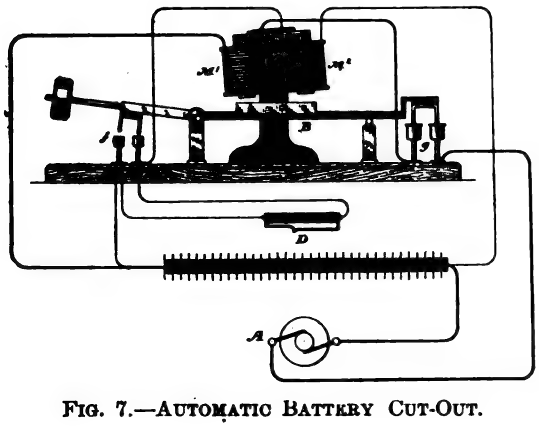

FIG. 7.—AUTOMATIC BATTERY CUT-OUT.

Next to a good storage cell itself, its regulation is of the utmost importance in a battery installation, not only to avoid rapid deterioration of the cells themselves and to prevent the destruction of the dynamo by reversing, but also to insure constant potential on the leads in order to secure uniform brilliancy and long life in the lamps.

The devices designed by Mr. Currie and employed in the Germantown station are designed to take care of all these points, and we will begin their description by noticing an ingenious little device for indicating in a prominent way the moment when the battery is fully charged.

It is well known that, when fully charged, storage cells begin to "boil," due to the rapid development and escape of gas. This creates a spray of the acid which is projected upward a short distance from the surface of the liquid in the cell. Mr. Currie utilizes this property by placing over the top of the liquid the device illustrated in Fig. 5. This consists of an ebonite block provided with terminals to which are connected two lead strips shaped in the manner shown, connected to the terminals of some indicating device, such as a vibrating bell and battery.

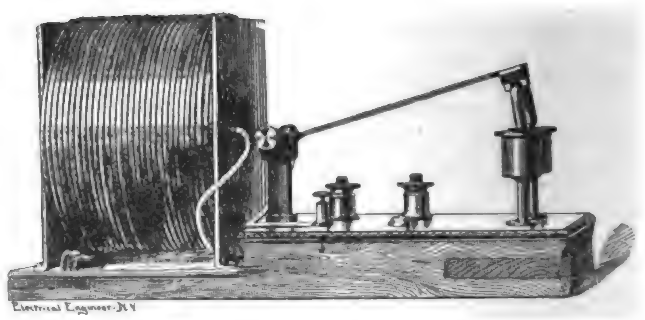

FIG. 8.—AUTOMATIC CUT-OUT FOR PREVENTING REVERSAL OF POLARITY.

Under normal condition this bell circuit is open, being broken at the point separating the two lead strips in Fig. 5. But as soon as the battery becomes fully charged the spray thrown up accumulates on the upper strip and forms a drop which flows down towards the point and bridges the gap between the two strips. This immediately closes the indicating circuit, and rings the bell which notifies the attendant of the fact.

This simple device is, however, used in connection with an automatic cut-out which makes the presence of an attendant unnecessary and which we now propose to describe. This apparatus which is shown in the engraving,

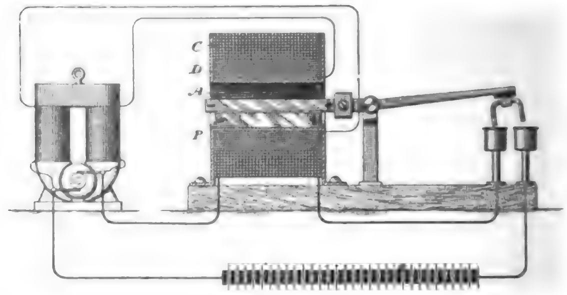

FIG. 9.—AUTOMATIC CUT-OUT FOR PREVENTING REVERSAL OF POLARITY.

Fig. 6, is designed to automatically throw the batteries into the generator circuit when their potential has fallen to the limit allowable, and, on the other hand, to automatically cut them out of circuit when fully charged, or when the current exceeds the normal charging rate. The cut-out, the operation of which is shown diagrammatically in Fig. 7, consists of an electro-magnet, one leg of which is wound with coarse wire M_1 and which is placed in series with the dynamo A and batteries, the circuit passing through the mercury cups g. The other leg of the magnet, consisting of fine wire M_2, is connected to the terminals of the battery through the mercury cups f. To these cups also are connected the terminals of the cut-out device described above, which is indicated at D.

The operation will now be readily understood. When the normal current is passing into the cells the connections are as indicated in Fig. 7, with the armature B unattracted by the magnet, the current only passing through coil M_1. Any excess of current above the normal, however, causes the armature B to be raised, breaking the main charging circuit at the point *g*. At the same time, however, it closes the circuit of coil M_2 at *f*, causing the armature to be permanently attracted and keeping the main circuit open. The employment of the two coils is necessary, since it is evident that the breaking of the main circuit de-energizes the coil M_1. The maintenance of an abnormally high current in charging the cells is thus avoided.

To effect the cutting out of the battery when it is fully charged the device shown in Fig. 5 and indicated at D, is employed. The formation of a drop by the accumulation of spray closes the circuit of coil M_2 in the same way as if the point *f* were bridged, and causes the armature B to be raised, so as to break the main circuit in the manner just described. In this way overcharging is prevented.

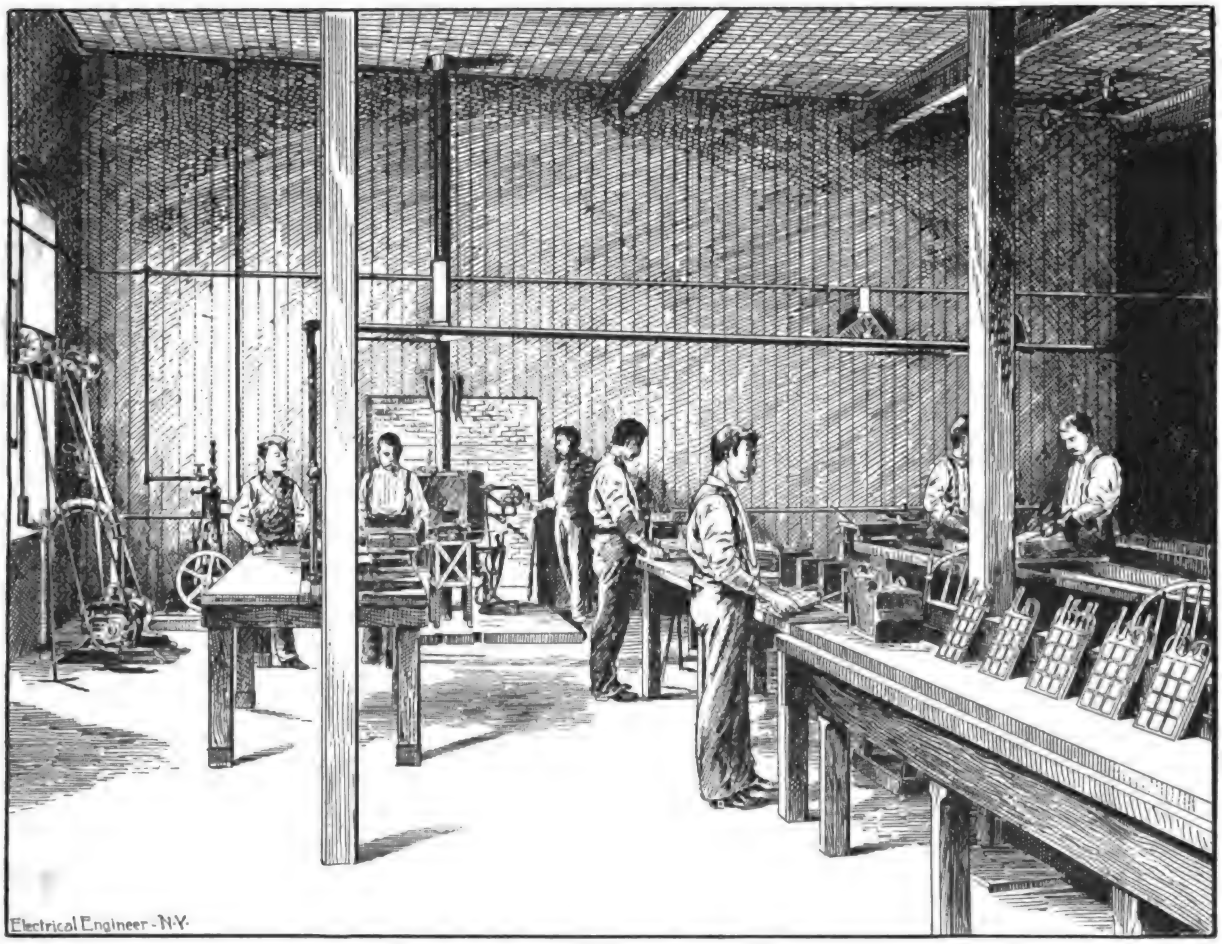

FIG. 3.—GRID CASTING ROOM IN THE ELECTRIC STORAGE BATTERY CO.'S FACTORY.

In storage battery installations provision must also be made against a reversal of polarity in the circuit which would tend to send current from the battery into the dynamo, and tend to reverse its action by driving it as a motor, or possibly burn it out, if the current be heavy, besides draining the battery of current.

To avoid such a reversal of polarity, therefore, Mr. Currie makes use of the cut-out illustrated in perspective in the engraving, Fig. 8, and the action of which will be readily understood by reference to the diagram, Fig. 9. The apparatus consists of a solenoid wound with two coils; one of these, of coarse wire C, is placed in direct circuit with the batteries, and the other, of fine wire D, in circuit with the shunt field of the dynamo.

Within the hollow of the coils there is fixed a permanent bar magnet P covered with a sheet of brass and immediately above it is pivoted a movable core A of soft iron, and having a counterpoise which tends normally to hold the armature close to the magnet P. The opposite end of the rocking arm carries a fork which dips into mercury cups placed in the battery circuit.

The object of the apparatus is evidently to complete the main charging circuit when the electromotive force of the dynamo exceeds that of the accumulator, and to maintain this position as long as their relative condition remains unchanged, and promptly to open the main circuit and thus cut out the dynamo whenever the electromotive force of the accumulator exceeds that of the dynamo, thus preventing the injurious action of reverse currents.

When no current traverses the coils C D, the armature A is normally attracted by the permanent magnet P and held close thereto. This lifts the forks and breaks the main circuit, as shown. Now, when the dynamo starts, as soon as its electromotive force rises to the requisite intensity in excess of that of the battery, the fine wire coil D, being properly wound for that purpose, creates in the armature A magnetism similar in polarity to that of the permanent magnet P. The armature, consequently, is repelled by the magnet and forced to the opposite side of the cavity in the coils. The intensity of the field-magnets, or, in other words, the electromotive force required to do this work, can be regulated by adjusting the counterpoise. This repulsion of the armature closes the main circuit by inserting the forks in the mercury-cups. As the coarse coil C, which is included in the main circuit, is wound correspondingly with the fine coil D, both co-operate in actuating the armature and in maintaining the magnetism of the permanent magnet P, and the main circuit remains closed as long as this condition exists.

Now, should the electromotive force of the dynamo di-

minish from any cause until it only equaled that of the accumulator, the current in the coarse coil C would cease or fall to zero, while the current in the fine coil would be insufficient to maintain the repulsion of the armature, which would promptly fall, and thus break the main circuit. On the other hand, should the battery-current become so strong as to reverse the current in the main circuit, the polarity of the coarse-coil C would at once become opposed to that of the fine coil D, and the preponderating influence of the permanent magnet P would at once attract the armature and break the main circuit. This property constitutes the main reason for the use of a permanent magnet, as it retains its polarity, instead of having it reversed by reversals of the current. Ordinarily the currents of the coils C D re-enforce the polarity of the permanent magnetism, and thus prevent its loss or change.

The advantage of employing the repulsive action of the magnets and currents, instead of the attractive, will be recognized when we consider the fact that sudden strong reversals of polarity frequently result in still retaining the circuit closed; in the arrangement above described, however, such a result is practically impossible, as both the currents and permanent magnet co-act to open the circuit.

These constitute the main features of the system adopted by the Electric Storage Battery Co., and the results obtained have been so satisfactory that a large extension of such storage battery plants is contemplated.

We may also note the fact that four cars on the Lehigh Avenue Street Railroad, in Philadelphia, have been operated continuously during the last four months with cells of the railroad type described above. This road has numerous curves, and grades as heavy as 5½ per cent. These have taxed the cells to their utmost, the 100 cells on each car frequently being discharged at the rate of 45 electrical horse power. During the month of August past, these cars alone carried 59,000 passengers, with frequent loads of 100 passengers on a car. The batteries have frequently made runs of 63 miles with a single charge under these conditions, thus giving a good indication of their increased efficiency where the conditions, are more favorable as to grades and curves.

A WIRING CHART.

BY JOHN WARING.

The accompanying chart for determining the size of wire was made over a year ago by the writer to illustrate a scheme for a chart which would have a large range and also be sufficiently accurate for ordinary use. In practice the chart should at least be extended to give loss in volts down to one volt. In designing the chart it was found necessary to assume the volts lost in the wire instead of the percentage of loss; otherwise a general chart could not be drawn.

The scheme for the whole design starts with Ohm's law that, $C R = E$; that is, the product of the current in any given wire by the resistance of that wire will give the potential difference necessary to force such current through the wire. Now if E be assumed constant we have the equation of a rectangular hyperbola referred to its asymptotes. The resistance of a wire varies directly with its length and inversely with its area of cross-section. It also depends on the kind of metal used. Hence the equation $R = \alpha \frac{L}{A}$; where L denotes length, A the area of cross-section, and α some constant depending on the kind of metal.

If we take the foot as the unit of length, and the circular mil as the unit of area, the constant for copper becomes about 10.3 in order to give ohms. By substituting the preceding value for R, the equation $C R = E$ now becomes $\frac{10.3\, C L}{A} = E$; or $\frac{10.3\, C L}{E} = A$. If E be now made equal to 10.3, then $C L = A$; which, interpreted, means that the product of amperes by feet will give the area of cross-section in circular mils, assuming the loss in volts to be 10.3.

It is evident that any arrangement of current and length whose product is constant, say 10,000, will give points on one hyperbolic curve, and that any other arrangement which will give another constant product, say, 20,000, will give points on another curve. Since in practice the product of current by length may give any value, there are an infinite number of hyperbolic curves to be drawn, each curve representing some fixed value for the area of cross-section. To prevent confusion only a few are drawn on the chart. The remaining values are interpolated by following along the imaginary curve to its intersection with the diagonal scale line. In the chart, distances on the scale of feet have greater value than on the ampere scale. The vertical scale has 200 feet to the division, the horizontal scale 50 amperes to the division.

Thus far the explanation has referred only to that part of the chart containing the curves. It has been shown that, if lines be drawn at right angles to the double-distance line and the initial line, their point of intersection lies on a curve whose value in circular mils is equal to the product of the intercepted values for feet and amperes, provided the loss in volts equals 10.3. Now, suppose that there is some other loss required than 10.3 volts, say, 4. Substituting this in a preceding equation, we have $\frac{10.3\, C L}{4} = A$; or $C L = A \frac{4}{10.3}$; that is, the product of current by distance only gives $\frac{4}{10.3}$ of the required area of cross-section. Hence, for 4 volts loss, the area required for 10.3 volts loss should be multiplied by $\frac{10.3}{4}$. This multiplication is done graphically on the lower part of the chart.

Following are the

GENERAL DIRECTIONS FOR USE.

The lines representing *amperes* are drawn below the initial line, and at various angles with the initial line. They would, if produced to the left and upward, all intersect at *.

The lines representing divisions of scale for *volts lost* are the horizontal lines below the initial line.

The lines representing divisions of scale for *complete length of circuit* in *feet*, are the horizontal lines above the initial line.

The lines representing the *area of cross-section* of wire in circular mils are the curved hyperbolas. The value of each is given at its intersection with the diagonal line.

Any one of the four quantities, *Complete length of circuit* in *feet*, *circular mils*, *amperes* and *volts lost*, may be found by selecting such a value for the desired quantity, that the intersection of *complete circuit* line and *circular mil* line is in a vertical line with the intersection of the *ampere* line and *volts lost* line.

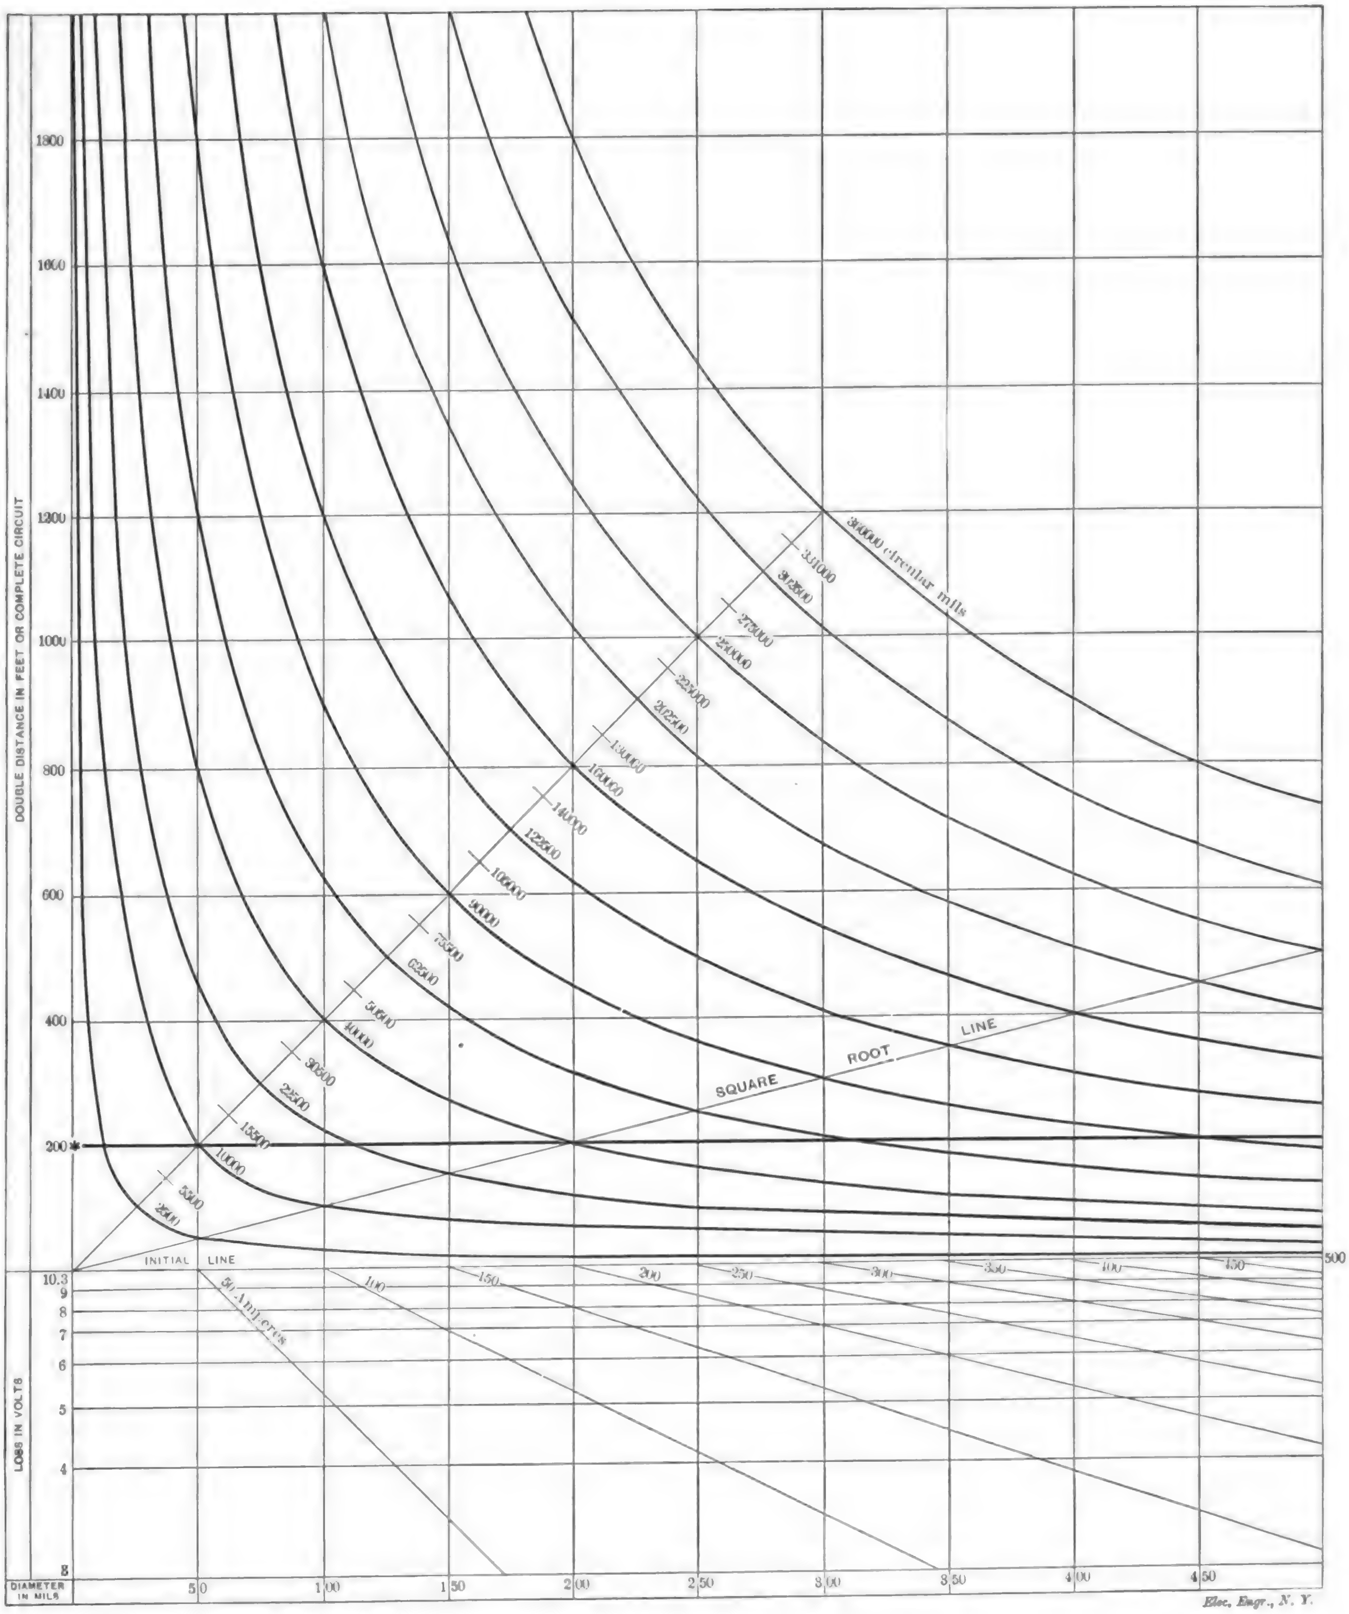
The scale may be changed by addding to or subtracting from *circular mil* values, the total number of ciphers added to or, subtracted from, values for *amperes* and *complete length of circuit*.

Below are given a few examples, illustrating the method of applying the chart :—

1. Required the size of wire to carry 125 amperes 800 feet complete circuit, with 4 volts loss. Note where the imaginary line for 125 amperes (this is a slanting line starting from 200 on the double distance line and passing half way between 100 and 150 on the initial line) intersects the line for 4 volts loss. Go vertically upward from this point to the 800 feet line. This latter point of intersection

gives a point on the required curve of area. Following this imaginary curve along to the scale, it gives a value of about 260,000 circular mils, or approximately the added areas of a No. 0000 wire and a No. 3 wire, B. & S. gauge. braic sum for the number of ciphers added and subtracted is 0, 122,500 is the correct result.

3. Required the size of wire to conduct 15,000 amperes 6,000 feet with 6 volts loss. Add two ciphers to the 150



Waring's Wiring Chart For Incandescent Lighting.

2. Required the size of wire to carry 5 amperes 12,000 feet with a loss of 5 volts. Drop a cipher from the 50 ampere line and add a cipher to the 1,200 feet line. Proceeding as in the previous example, the point comes about on the circular mils line marked 122,500. Since the alge- ampere line and one cipher to the 600 feet line. The required intersection is evidently a little more than 150,000 circular mils. Adding three ciphers to this, the result is 150,000,000 c. m. for the required wire—a pretty large wire. If the last example had called for 1.5 amperes to be carried 6

feet with 6 volts loss we should have dropped four ciphers and then obtained 15 c. m. as the required size. In a similar manner ciphers may be added to, or subtracted from, the volts lost; only in this case, when we divide volts lost by 10, we should multiply circular mils by 10. A current density scale might also be added to the diagram.

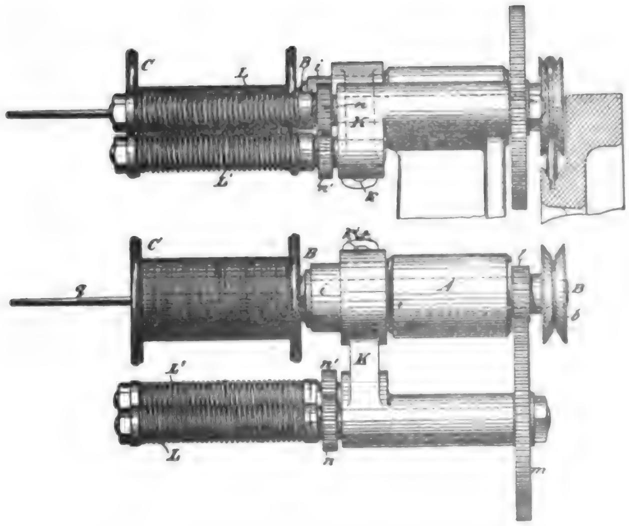
WOOD'S MAGNET WINDER.

THOSE of our readers who have had experience in electrical manufacturing will appreciate any device that facilitates the winding of magnet bobbins and at the same time secures an even distribution of the wire. To obtain these advantages Mr. J. J. Wood, the well known inventor of the Wood arc machine and lamp of the Fort Wayne Electric Co., has contrived a very simple and ingenious arrangement which he has used for some time in his work and which has been recently patented.

The idea embodied in the device consists in guiding the magnet wire to and fro across the bobbin at a uniform



FIGS. 1 AND 2.—WOOD'S MAGNET WINDER.

rate and for changing the direction to right or left at either end when a layer is completed. The manner in which this is carried out by Mr. Wood, is shown in the accompanying illustrations. As will be seen, a bearing frame K carrying two guide spindles L L′ is clamped to the sleeve *i* within which the spindle B turns. On the right hand end of the spindle L is fixed a gear wheel *m* which is driven by the pinion *l*, fixed to the spindle B. On this spindle L is fixed a pinion *n*, which meshes with a pinion *n′* on the spindle L′, so that the latter is driven from the former, the two rotating in opposite directions and at the same speed. The guide-spindles L and L′ have spiral grooves to engage and guide the wire as it is wound upon the spool. The grooves are practically screw threads with the bottom and top of the threads rounded off in order to avoid sharp corners.

In he operation of winding, the operator guides the wire with ne hand, the wire passing through between the spindles L L′. By drawing the wire upwards so that it enters a groove in the guide-spindle L, it is caused to travel laterally from one end of the magnet-spool to the other at a speed determined by the pitch of the spiral groove and the speed of the spindle L proportionally to that of the spindle B, so as to wind on the successive convolutions of the wire close together and make a continuous layer of wire. When the wire reaches the end of the spool, the operator has only to move his hand downwards to bring the wire into the groove of the guide-spindle L′, by which the wire is propelled in the opposite direction, and travels back to the opposite end of the spool.

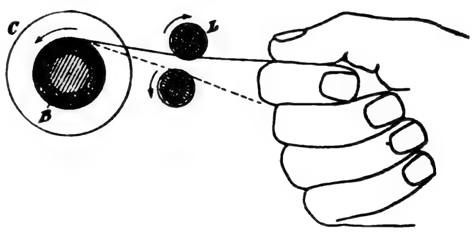


FIG. 3.—WOOD'S MAGNET WINDER.

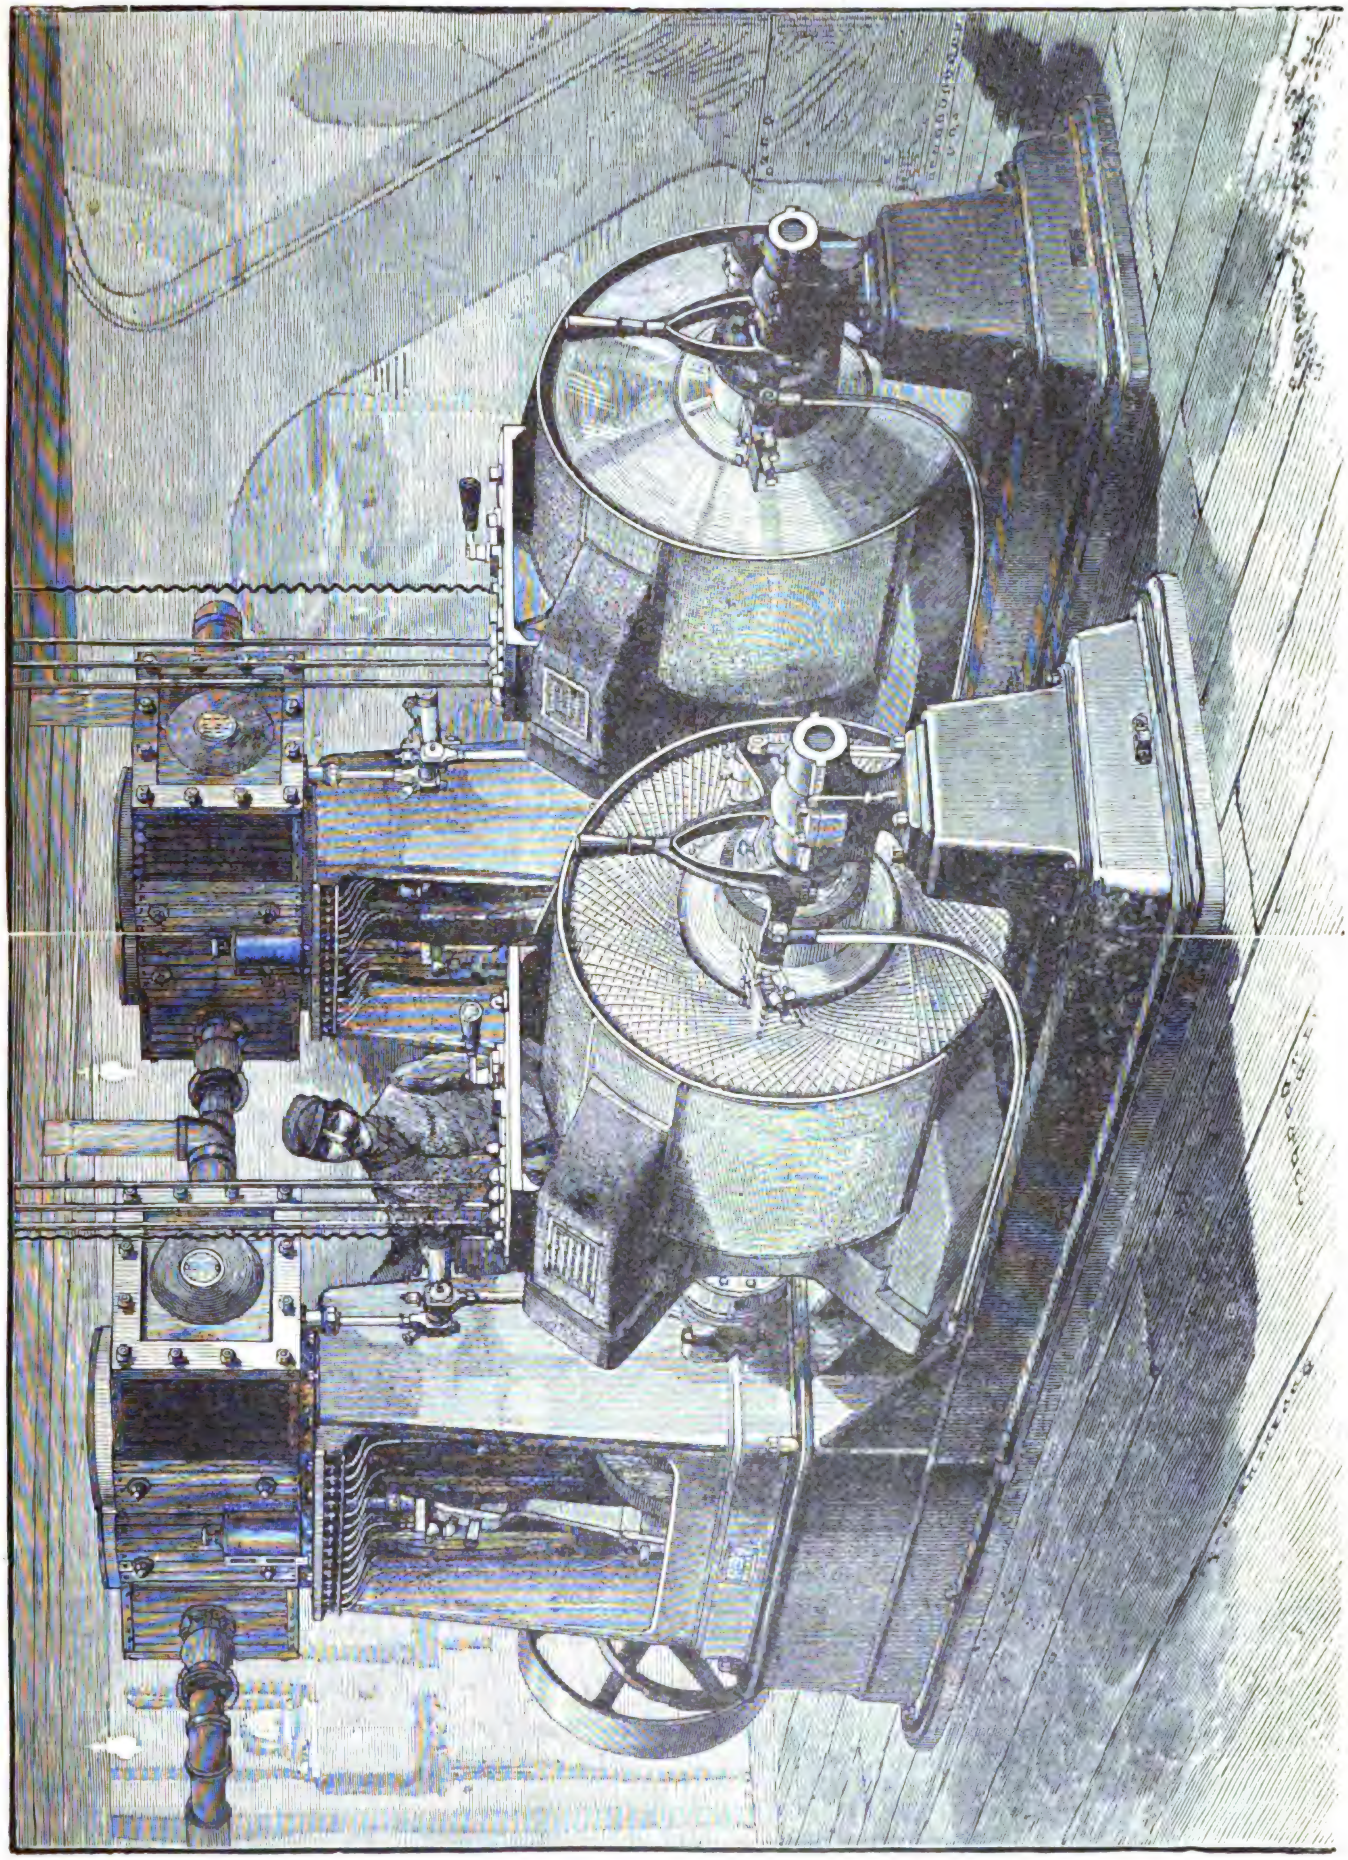
The operator has thus only to move his hand up when the wire reaches one end of the spool and down when the wire reaches the other end, keeping the wire at a proper tension by holding it between the thumb and finger, as is usual in winding magnets. In Fig. 3 the upper position of the wire is shown by a full line, and its lower position by a dotted line.

The sizes and proportions of the guide-spindles, L L′, the pitch of their grooves, and the proportionate speed of their rotation, must, of course, be varied according to the varying sizes of wire to be used and the sizes and proportions of magnets to be wound.

THE ELECTRIC LIGHTING PLANT ON BOARD THE "PLYMOUTH."

SOME of the most interesting electric light work of recent date is that done upon shipboard, for the reason that the exigencies of the case demand the utmost efficiency of apparatus within a limited space. The output per pound of material must be high, every inch of room that can be spared is an object to the ship builder and designer, the construction must be simple and strong, and the whole is subjected to conditions of a trying and exhaustive nature.

The new navy that this country is now putting afloat has offered some excellent opportunities to the electrical engineer, but others are found in the mercantile marine. A few weeks ago we took occasion to give details of the new plant on board of the "Seguranza," and now, thanks to the courtesy of our enterprising contemporary, the *Scientific American*, which has just published an article on the ship and her entire equipment, we are enabled to give a view, with data, of the plant on board the new Old Colony steamboat "Plymouth." This plant was put in by the Edison General Electric Co. under the special superintendence of Mr. W. H. Peirce, of the Old Colony Company. Two dynamos, driven each by an independent compound Ball engine of 65 horse-power at 120 pounds pressure, are used as generators. They are connected directly to the engine shaft, and run at 400 revolutions per minute. The field has eight poles, four external, all of one sign, and four internal of the opposite sign. Within the zone marked by the eight pole-pieces the armature which is a Gramme ring, rotates. The core of the ring is



Dynamo Room of The Old Colony Steamer "Plymouth."

of laminated sheet metal. Each dynamo has an output of 350 amperes at 115 volts potential, enough to supply 700 lamps. Each dynamo weighs 6,563 pounds, each armature, 1,950 pounds, and the dynamo and engine and appurtenances weigh about 13,000 pounds. The commercial efficiency is 81 per cent., and the heating is only 36° F. above the atmosphere. The machines are compound wound, and show a maximum variation in their characteristic curve of 1 volt. They are of a type conforming to specifications originally issued by the United States government.

The installation is on the two-wire system. The dynamos are connected in parallel so that one or both can be used to feed the circuits. From the generating plant double leads are taken fore and aft, and branching so as to terminate at four cut-outs. From these cut-outs the lamps are supplied directly or by feeders. The main leads are not tapped. As more work might be thrown upon one main lead than on the other, equalizing mains are carried from each forward cut-out to each of the after cut-outs. This gives four distributing points. Risers are carried through the decks to supply the lights at different elevations.

Below the main deck wherever moisture may be present, lead-covered wires and water-tight brass junction boxes containing safety fuses are used. Elsewhere Habirshaw marine core wire is employed.

The staterooms are grouped in eight divisions. For each of these a marbleized slate tablet placed so as to fill an alcove transom is provided, on which the switch boxes and general branch connections are made. This is done not only for the decorative effect, but also to provide security from deterioration by moisture and from fire.

There are 1,250 16 c. p. 110 volt lamps. The maximum variation in potential will not exceed 1½ volts. Each lamp has its own key switch, so as to be individually controllable. In the dining saloon the lamps are arranged in groups of ten, and connected with a main switchboard by which they can be turned off ten at a time as desired. The very elaborate saloon electroliers and other fixtures were supplied by the New York works of the Edison General Electric Co.

LIEBIG AND WILLMS'S PORTABLE CHLORIDE OF SILVER BATTERY.

The accompanying illustrations exhibit a new construction of galvanic cells, devised by Dr. G. A. Liebig and Mr. Charles Willms. The battery is designed for low internal resistance and to be safely and conveniently portable. Particular care has been given to provide a protection against injury to clothing or other objects from the escape of liquids upon the breaking of one or more cells, and to provide a vent for the injection of the fluid, and for allowing, when it is deemed advisable, any gases to pass off. The cells may be put up and used singly or in groups.

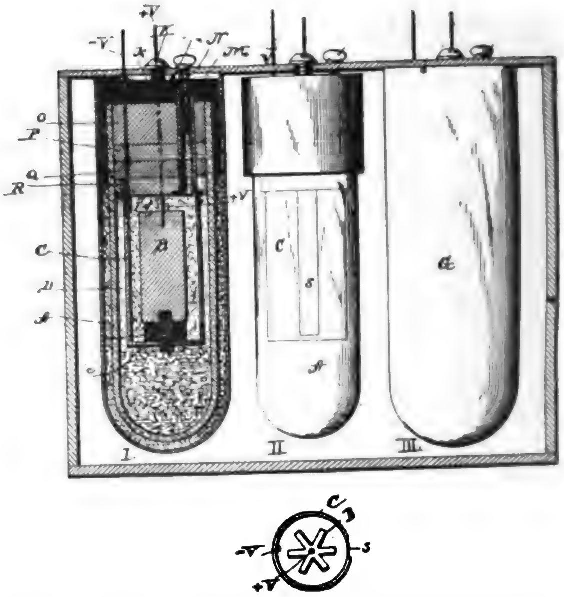
Fig. 1 represents a section through a battery of three cells, cell I in section, cell II with the metal case removed, and cell III with the metal case on. Fig. 2 represents a cross-section of the two electrodes at right angles to their axes.

The cell consists of a case A, of glass or other suitable material, sealed, containing the electrodes B and C and the exciting-fluid D. Over the glass case is cemented a hard-rubber cap. The cell is then wrapped with cotton cloth or other soft absorbent material, and pushed firmly into a metal envelope G, where it is held in place by a metallic pin, or by indenting the metal envelope, above the rubber cap. The object of the hard-rubber cap is to furnish a solid hold for the screw K, by which the cell is firmly held against the cover of the battery when used in groups.

The vent M and plug N are for injecting the fluid, and to allow the gases generated to escape when desired. The wrapping of cotton or other absorbent protects the glass from breaking in the metal envelope when carelessly handled, or in the event of such breakage it absorbs the liquid. The metal envelope protects the cell and contents and serves to retain the liquid if the glass cells be broken by accident.

The cell is hermetically sealed by no less than four layers of different compounds, one above the other, as shown in Fig. 1. The hard sealing R is a mixture of resin and gutta percha; Q is a viscous sealing of resin and resin-oil; P is the same mixture as R, and Q is a compound of plaster-of-paris and pine resin, or shellac.

The internal resistance is made small by increasing the surfaces of the electrodes and by bringing them into close proximity. The zinc electrode C is a cylindrical roll with one end turned over, forming a cylinder-head *c*. A longitudinal slot *s* is cut in the cylinder to allow free access of the fluid.



FIGS. 1 AND 2.—THE LIEBIG-WILLMS PORTABLE CELL.

The positive electrode is formed of a corrugated or star-shaped mass of chloride of silver fused about a piece of silver wire + V. This fits closely within, but nowhere touches the zinc electrode. The silver electrode is supported on and steadied by an insulating-disc which rests on the bottom of the zinc cylinder. The spaces between and around the electrodes are filled with filter-paper, cotton, or other absorbent material, and then the vent is closed, and after the fluid is injected the cell is ready for use. This absorbent material is well saturated with the zinc-sulphate solution, the absorbent being used to prevent the cell being emptied should it be overturned or laid on its side when the vent-plug is either loose or out. + V is the wire leading from the positive or silver pole, and — V that leading from the zinc-pole.

When a number of cells are used in a portable battery, they are screwed to the lid of the box containing them, and melted pitch or paraffine is poured into the box and allowed to solidify; but the melted pitch or paraffine is not necessary, as the screws are sufficient to hold the cells firmly in place against any ordinary jars or strains.

THE DEATH OF LINEMAN KOPP.

The Coroner's Jury has rendered a verdict that Kopp would not have lost his life had he exercised proper care, and further that "while said August Kopp did not exercise proper care, it has appeared in evidence that the defective insulation, which existed at various arc lamps was a necessary factor in causing his death; and that the existence of such defective insulation was countenanced by the Board of Electrical Control. It is the opinion of this jury that the operation of high tension electric circuits in such condition is a dangerous practice."

THE ROBERTSON FIBROUS CARBON BATTERY.

A LARGE number of modifications of the original Leclanché cell have appeared in the past, one of the principal objects being of course to obtain as large a surface as possible of the carbon in order to reduce the resistance and to prevent polarization. But the prevention of polarization depends to a large extent also upon the nature of the surface of the carbon, it being well known that a smooth surface retains the gases liberated, while a roughened surface allows the bubbles of gas to be readily detached. In order to retain both these advantages in a simple and cheap

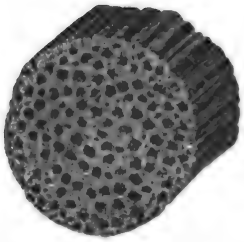


FIG. 1.—SECTION OF FIBROUS CARBON MAGNIFIED.

construction, Mr. J. Hart Robertson, of this city, has recently brought out a novel type of the sal-ammoniac cell, which is worthy of note. Mr. Robertson employs for his negative terminal a carbon made of vegetable fibre prepared and carbonized in a special way. This form of carbon is shown in magnified section in the accompanying engraving, Fig. 1. The corrugation of the fibre from which the carbon is made, delays the polarization, and is claimed to give the same result as is obtained by the use of the bioxide of manganese prisms in the Leclanché cells, but in

FIG. 2.—THE ROBERTSON FIBROUS BATTERY.

a more natural way, the carbon itself, unlike the ordinary granular form, doing what is done artificially in the Leclanché cell. The large surface exposed to the action of the liquid is evident. At the same time, in addition to the large surface, the resistance of the carbon itself is very small.

Two types of cells have been made by Mr. Robertson. In the first of these, shown in Fig. 2, the carbon fibre is arranged in horizontal spiral form, while in the other the carbon rods are arranged vertically surrounding the zinc cylinder fixed in the centre.

The battery is claimed to have very low external resistance and to be specially adapted for telephone purposes as well as for burglar alarm, annunciator and similar open circuit work. A departure is also being made in the application of battery jars made of the well known insulating material "fibrone," which is not only handsome

FIG. 3.—THE ROBERTSON FIBROUS BATTERY.

in appearance, but is safe from breakage, and in connection with a tight fitting cover effectually prevents leakage and the creeping of salts.

FIGURES OF THE FRENCH TELEGRAPH SYSTEM.

Referring to the recent international telegraph conference at Paris, *Le Figaro* gives an account of the development of the French telegraph system since the last international conference held at Berlin, Germany, in 1885.

In that year the total number of telegrams sent in the French Republic figured up 44,000,000. In 1889 it amounted to 55,000,000, showing an increase of about 25 per cent. in the four years. The percentage of increase in the number of telegrams sent to, and from, points outside of France is still greater, closely approximating to 40 per cent. For press dispatches a reduction in price of 50 per cent. has been effected. In the matter of cable service it is of interest to note that the control of the cable between France and England has passed into the hands of the government. The "Compagnie des Télégraphes de Paris à New York," further, has severed its connections with other companies, so that it now has its own independent cable to the United States. A new company, known as the "Société des Télégraphes Sousmarins," has been formed, and has commenced and partly completed cable lines to Venezuela, Curacao, San Domingo, Hayti and Cuba, as well as to the French colonies, Martinique and Guadeloupe.

In the matter of telephone communication the period from 1885 to 1890 marks the opening of the line between Paris and Brussels, and the completion of the 560-mile line between Paris and Marseilles.

BROOKLYN, N. Y.—President Lewis, of the Brooklyn City Railroad, and his Directors find it hard work to decide upon some system of electrical propulsion for his surface cars. He has just concluded a visit of inspection to Lansingburg, Waterford, and Cohoes, and is going to Boston, Buffalo, Cleveland, Utica, Syracuse and Rochester next week. So far he favors the overhead trolley system.

EDITORIAL ANNOUNCEMENTS

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. X. NEW YORK, OCTOBER 8, 1890. No. 127

The history of science teems with examples of discoveries which attracted but little notice at the time, but which afterwards have taken root downwards and borne much fruit upwards.—Lord Rayleigh.

ALUMINIUM IN THE ELECTRIC ARTS.

KEEN observers of the course of events and of the changes which have gone on in electrical construction cannot fail to be impressed with the difference in the relative positions occupied by the metals which are employed in the electric arts, as compared with their status ten, or even five, years ago. We refer not merely to the quality, as exhibited by the higher standard of purity now generally obtainable in copper, but also to what may be considered the economic aspect which the electrical engineer must take into consideration in his calculations. Thus what but a few years ago was considered sufficiently good material for most electric contacts is now in many cases discarded, and brass has given place to German silver and to platinum successively. With the increase in the use of the latter metal has come an increased scarcity of supply, so that the two causes have combined to raise the price of this material to nearly three times its value of but a few years ago. How important a factor this is may be recognized when we take into consideration the fact that the platinum leading-in wires of an incandescent lamp formerly costing but three cents now involve an expense of about eight cents per lamp, having become indeed the largest single item involved in the cost of manufacture. For this particular purpose there has been thus far no substitute even suggested, as the conditions to be fulfilled are very exacting and involve the very life of the lamp.

But in other directions we note a tendency to the substitution of a metal which by present indications is destined to play an important part in electro-technics. We refer to aluminium, the extraction of which is steadily advancing so that even to-day it is brought within the reach of economic application though selling at the rate of two dollars per pound. While formerly but sparsely employed in the construction of parts of delicate electric measuring instruments it has already found an application among others in the construction of electric contacts where its non-corroding properties make it eminently available, though its comparatively low fusing point hardly renders its use advisable in situations where actual sparking is likely to take place.

The present cost of aluminium would appear to prohibit its use for many purposes in which its qualities of lightness, strength, etc., would otherwise make it available, but upon closer investigation it may be found that even at its present price it may be advantageously employed. Thus there are many situations where nearly every other metal employed is found to give trouble and, indeed, would require renewal after but comparatively short life. Among these are the numerous electric fittings employed in mines subject to continual dampness and flow of water, and which are found to give out very rapidly. As their weight is comparatively small, it may not be found against the interests of economy to employ aluminium.

But looking further still, anticipating, as there seems every reason to hope for, a considerable reduction in the price of aluminium, we may count on an extended use of this metal in the electric arts. As one of these we need only refer to its use in connection with electric railway work. Its great lightness and strength make it eminently adapted for overhead line work, its specific gravity being but 2.6 as compared with copper which has a specific gravity of 8.9; in other words, being in the ratio of 3.5 to 1 in favor of aluminium. Its conductivity, it is true, is nearly twice that of copper, but on account of its low specific gravity, its weight would only be about four-sevenths that now required in copper for the same conductivity. Looking still further, there are many of the parts which go to make up an electric car that could be made of aluminium to-day and which would tend materially to reduce the car weight without affecting its strength or efficiency. Thus among other details, the trolley wheel and trolley pole might be made of aluminium to considerable advantage, and we believe we are not far from seeing such a practical application. If to this were added the substitution of aluminium for iron and brass now employed on the truck and motors, outside of the magnetic circuit, the reduction in weight would be an important factor tending to economy.

What has just been said with regard to overhead electric railways is still more applicable to storage battery cars. If it should, for example, be found practicable to construct storage batteries with plates of aluminium, the most serious question now confronting the workers in this field would be at once removed. Besides, with lighter mechanism to haul, there would be less drain of current.

It is true that we may be looking ahead slightly, but it is nevertheless well to call attention to facts which are clearly within the bounds of possibility and, indeed, of probability. The high cost of the metal even at the present time does not place it beyond all reach of application in its pure state, and if to this be added the fact that, like platinum, it would maintain nearly its full value even as old

material, the money invested in it could not by any means be looked upon as sunken capital. Aluminium is soon to be one of the best friends of the electrical engineer, and to-day it invites him to more intimate acquaintance.

ELECTRIC WELDING.

Among the papers read before the British Iron and Steel Institute, was one by Prof. Elihu Thomson, on electric welding. The process is now so well known that it is hardly necessary to call special attention to it as a novelty, but in the paper read by Prof. Thomson, the subject is discussed from the metallurgist's standpoint, and a variety of interesting facts not heretofore brought out are referred to. The peculiar actions of the various metals under the influence of the welder present a good field for experiment. The large number of machines already constructed for various purposes shows the extent of the field in this direction. Our readers will also note that Prof. Thomson considers welding by the arc to be impracticable, holding that all processes can be carried out completely and successfully by the "incandescent" method.

ELECTRICITY IN MINING AND METAL WORKING.

The large scope presented for the application of electricity and magnetism in mining and metallurgical operations is gradually obtaining proper recognition, and no better indication of this can be found than in the attention given to electricity at the meetings of the British Iron and Steel Institute and the American Institute of Mining Engineers held in this city last week. The papers there read covered a wide range of electrical subjects, and showed how, from the very first step in gaining the raw product in the mine, every stage in the operations leading to the last preparations for the market can be facilitated economically by electricity. Thus, Mr. H. C. Spaulding's paper gives an excellent résumé of what has been accomplished in electric mining work, including drilling, underground hauling, hoisting, lighting, etc. It is interesting to note, also, that the demands of mining work seem destined to call to renewed life a type of machine that has been abandoned for a long time as an electric motor, but which possesses certain advantages, and that is, the electric reciprocating engine. For drilling operations it is likely that thus we shall soon see a revival of this type, and the description by Mr. Van Depoele of his reciprocating drill shows in what manner the new apparatus differs from the original types of this class, among which the Page motor is perhaps the most generally known.

The progress made during the last few years in magnetic ore separation was also emphasized by the records presented in several papers, and we may look for a wide extension of this method of ore separation in the future. It is noticeable that in these machines the tendency at present is in the application of alternate polarity in the magnets, and with good reason, as explained in the description of the Monarch separator. With such a variety of electrical work confronting the mining engineer, his course of study must hereafter largely embrace electricity, a knowledge of which will, of necessity, be as valuable to him as expertness in assaying is at present.

Electric Cars.

The paper read lately by Mr. McNamara before the State Railway Convention is worthy of the attention of the manufacturers of street railway apparatus, in the first place, because it was an unqualified endorsement of electricity for street railway purposes, and, in the second place, as it pointed out certain directions in which improvements are desirable. Thus, he remarked that on account of the construction at present adopted the ease of access to and from the car is somewhat impaired on account of the raising of the car body above the height formerly in vogue. This has naturally been brought about by the increased height of the truck due to the placing of the motor upon it. The remedy must be looked for, therefore, in a more compact arrangement, or a possible recourse to an older form in which the motor is carried on the platform of the car in a compartment separated from the rest. Mr. McNamara also referred to the position of the motor as being subject to the accumulation of dirt and dust. This, no doubt, is true, but we think the time will come when every motor will be so thoroughly protected, even in its present position, that this objection cannot hold.

A New Tax System for Maine.

The special tax commissioners of the State of Maine have made a report to Governor Burleigh recommending radical and important changes in the system of taxation. One feature that we note is the taxing of telephone instruments leased or royalty paying. This is apt to go hard on companies that are already giving up a good share of their receipts, for the telephone rates in Maine are not very high. Another item that impresses us more favorably is the proposal to tax all new corporations for their charters and on their capital stock at par. Maine has been resorted to by a large number of speculative and rotten concerns. For the six months ended July 1, corporations with an aggregate of over $85,000,000 capital stock were formed there. Liberal corporation laws are a boon, but lax laws are an evil, and most of all to the companies formed with honest purpose for solid business. Maine can afford to make this reform.

New Storage Battery Work.

While not attracting as large an amount of attention as some of the other departments of electrical engineering, it is undeniable that the storage battery in its various applications is steadily forging ahead and securing a firm foothold both in lighting and traction work. As showing the latest progress in this direction in this country, we illustrate elsewhere the new system of the Electric Storage Battery Co., in which the method of preparing the storage battery plates varies considerably from that heretofore generally employed. The application of the chloride, after a long series of experiments, is also a new departure claiming attention, as up to the present the various lead oxides have been almost exclusively employed for the purpose. Mr. Currie has also combined with his system several novel regulating devices, among which the reversal preventer, acting by magnetic repulsion, and the ingenious little "full charge indicator" may be noted as exceedingly simple and effective.

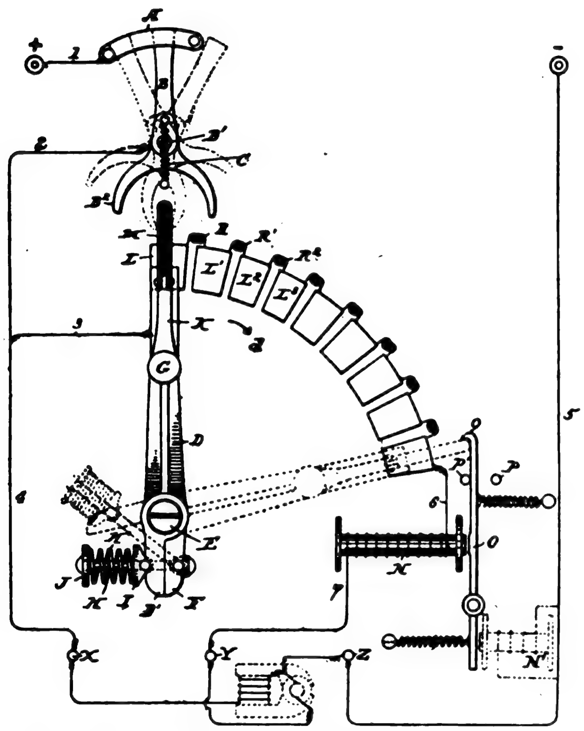
RAE'S AUTOMATIC SWITCH FOR STATIONARY MOTORS.

MR. FRANK B. RAE, of Detroit, who has of late been devoting his attention to power applications, after his extensive experiences in other fields of electrical work, has just brought out an ingenious automatic switch for the protection of motors against the consequences of a sudden rush of full current after a motor has been stopped by an interruption of current or greatly retarded by a diminution of current.

The switch is intended to be used in connection with the usual shunt-wound motors and provides an automatic device that breaks the connection between the main line and the motor in event of interruption or variation in the circuit.

The accompanying engraving represents diagrammatically the arrangement of the device.

In the use of electric motors on a power circuit it often happens that through accident or otherwise the circuit is interrupted or the current materially reduced, and more especially is this liable to occur when stationary motors are



RAE'S AUTOMATIC SWITCH FOR STATIONARY MOTORS.

operated on circuits supplying electric-railway motors, in which there may be sudden changes in the current, or the feeding-line may be broken, or the limit-switch may open at the station, or other contingency may arise which would cause the power-motor to stop or become considerably retarded; and if this happens when the motor is used with the ordinary switch, the subsequent closing of the main circuit is liable to cause injury or destruction to the motor, from the fact that the armature part of the motor is so connected that, practically, the whole current passes through the armature without meeting a proper resistance in the shape of counter electromotive force, and a burnout or injury to the armature ensues. Mr. Rae's switch first closes the circuit upon the shunt-field direct and through a resistance in the armature-circuit, which resistance is gradually and successively cut out by a continual movement of the switch-lever, and when the lever is fully closed the circuit is direct through both the field-coils and armature of the motor, and the switch is locked or held in place automatically as long as the current is flowing within its normal limits. An electro-magnet is connected in the armature-circuit, for holding the switch in position, and if from any cause the circuit is interrupted or materially lessened the magnet loses its attractive force and releases the switch-lever, which is operated by a spring or otherwise, to return to its normal position, the lever being so arranged that it will automatically operate a circuit-breaking switch to disconnect the motor from the feeding circuit.

Connected to the + terminal is a contact-piece, A, and arranged to co-operate with it is a break-switch, B. This break-switch is pivoted at B′, and it has a spring, C, attached to the lever between its pivot and contact-point at one end, the other end being fixed below the pivot-point; thus, if the lever, B, is carried past a perpendicular line in either direction the spring will tend to carry the lever to the extreme of its position on one side or the other, as indicated in the dotted lines, effecting a quick or snap make or break between the lever and the contact, A. The lower end of the lever, B, has two horn-like extensions, B², whereby it may be automatically moved in the manner to be described presently. Below the circuit-break is a lever, D, pivoted at E, and having a handle, G, for manipulation. Means are provided for normally maintaining the lever, D, in a vertical position and for returning it thereto automatically when released, through a projection, F, up the stationary support of the lever, to which projection a bolt, H, is secured, passing through, D′, and provided with a compression-spring, H′, held in place between the pivoted washer, I, and flat washer, J, and operating to restore the lever, D, to its normal vertical position. Upon the lever, D, is a contact-piece, K, pressing upon contact-blocks, L L′ L² L³, etc., connected in series by resistance-coils, R R′ R², etc. Extending upward from the lever, D, is a finger, M, of insulating material, arranged to impinge upon the horn-like projections of the circuit-breaking switch, and to operate it to break the circuit, as described below.

Arranged adjacent to the switch-arm and resistance-contacts is an electro-magnet, N, the coils of which are connected in the armature-circuit. The armature, O, for this magnet is under the stress of a spring, Q, which normally holds it against the stop, *p*. When, however, the magnet is energized, the armature is attracted, and its free upper end has a hooked projection, *o*, which is arranged to engage with the end, M, of the switch-lever, D, and to hold the lever in the position shown in dotted lines against the stress of the spring, H′, when the normal current is flowing.

The arrangement and purpose of the electrical connections of the switch are obvious and need no further explanation. When the switch-arm D, is moved to the position shown in dotted lines the resistance-coils are cut out of the armature-circuit and the current flows through the shunt-field and armature in the usual manner.

While, as shown, the magnet is arranged in the armature shunt-circuit, it is evident that it might be arranged, and in some conditions it is preferable to so arrange it, in the circuit, 5, as indicated in dotted lines, N′, when of course its operation would be the same, except that it would be controlled by the full current flowing through the switch, instead of the armature-shunt current only.

The operation of the switch is as follows: In the neutral position the lever, D, is perpendicular, the right-hand horn projection of the switch, B, resting against the insulating-piece, M. A movement of the switch to the right carries the arm, B, past the centre of its pivot toward the left and the spring, C, continues the movement, closing the circuit at the contact, A. This energizes the shunt-field coil of the motor, the circuit being completed, the armature-current passing through the branch conductor and the resistance-blocks, thence around the coils of the magnet to the binding-post, Y, of the motor. The continued movement of the lever cuts out the resistances until it reaches the position shown in dotted lines, when all of the resistances are out of the armature-circuit and the lever, D, is locked by the hook of the armature, O, and the magnet, N,

whether in the armature-circuit or the main-circuit, holds it in position under normal currents. If, however, from any cause the main circuit is interrupted or falls below a given strength, the armature will be retracted by its spring, Q, releasing the switch-arm, D, which will fly back to its upright position under the influence of the spring, H′, and when the lever nearly reaches its limit the projection, M, will strike the left-hand horn, B², of the switch-lever, B, and carry this lever past the central line toward the right, when the spring, C, will continue its movement, breaking the main circuit at A. If it is desired to stop the motor at any time when a normal current is flowing, the armature, O, may be pulled away manually, and the same operations will automatically cut-out the circuit and leave the switch in condition to receive the circuit properly when again applied to the motor.

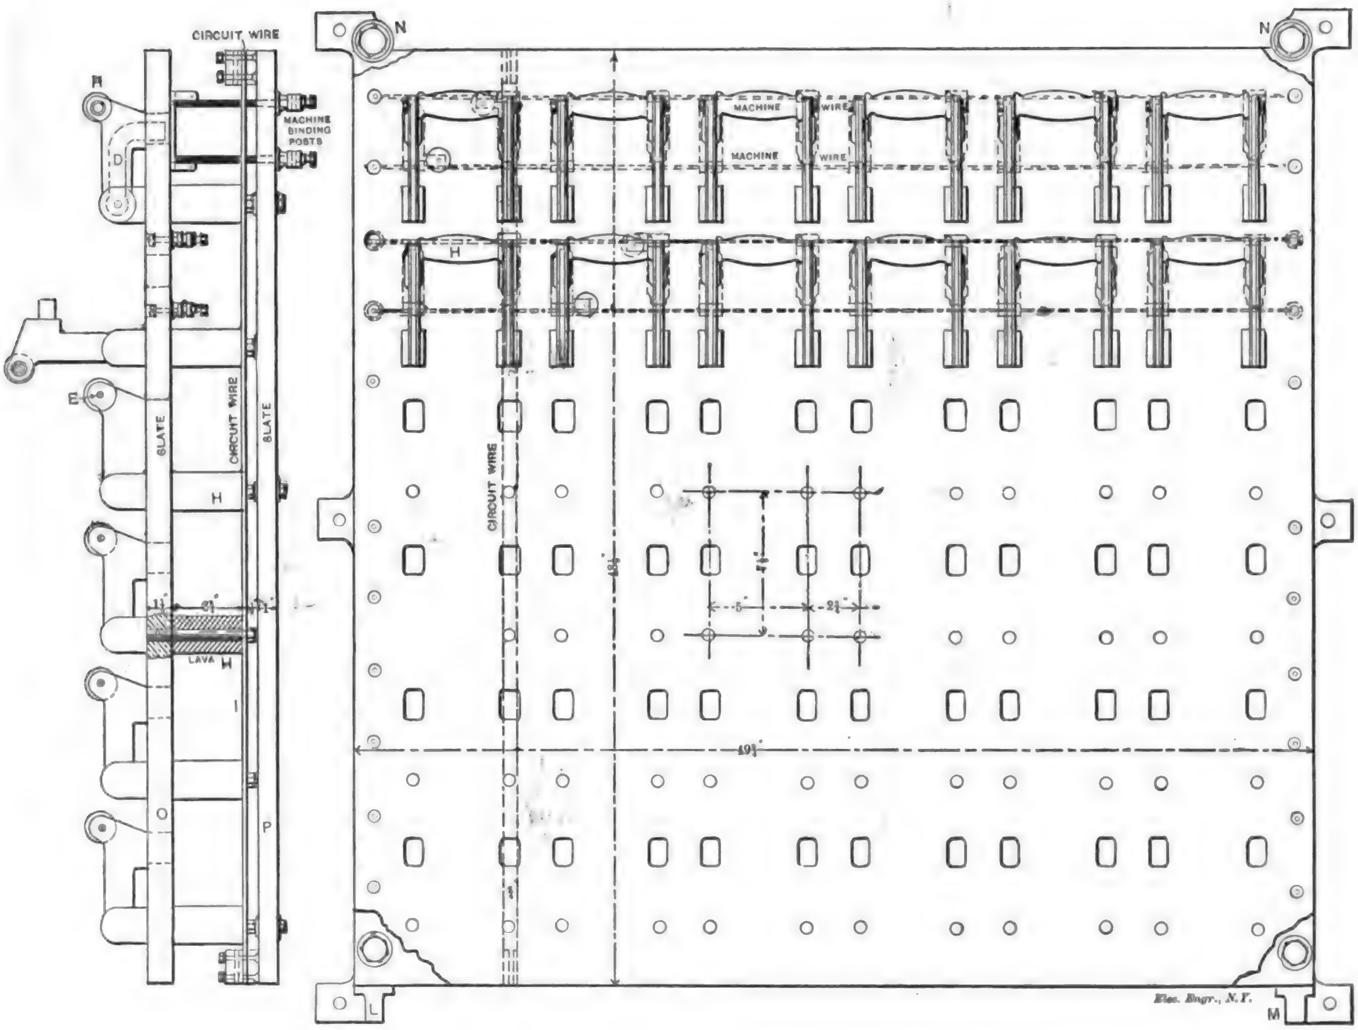
THE "FOSTER" STATION SWITCH-BOARD.

The experience of the past has shown that the prime requisite of a station switch-board is thorough insulation and fire-proof qualities. To this, in no less a degree, must be added a compact arrangement by which circuits and machines can be readily interchanged and in which the wiring can be readily inspected at all times. In carrying out this idea the Thomson-Houston Electric Company have recently brought out an exceedingly simple and effective arrangement, the design of Mr. Henry A. Foster, of this city.

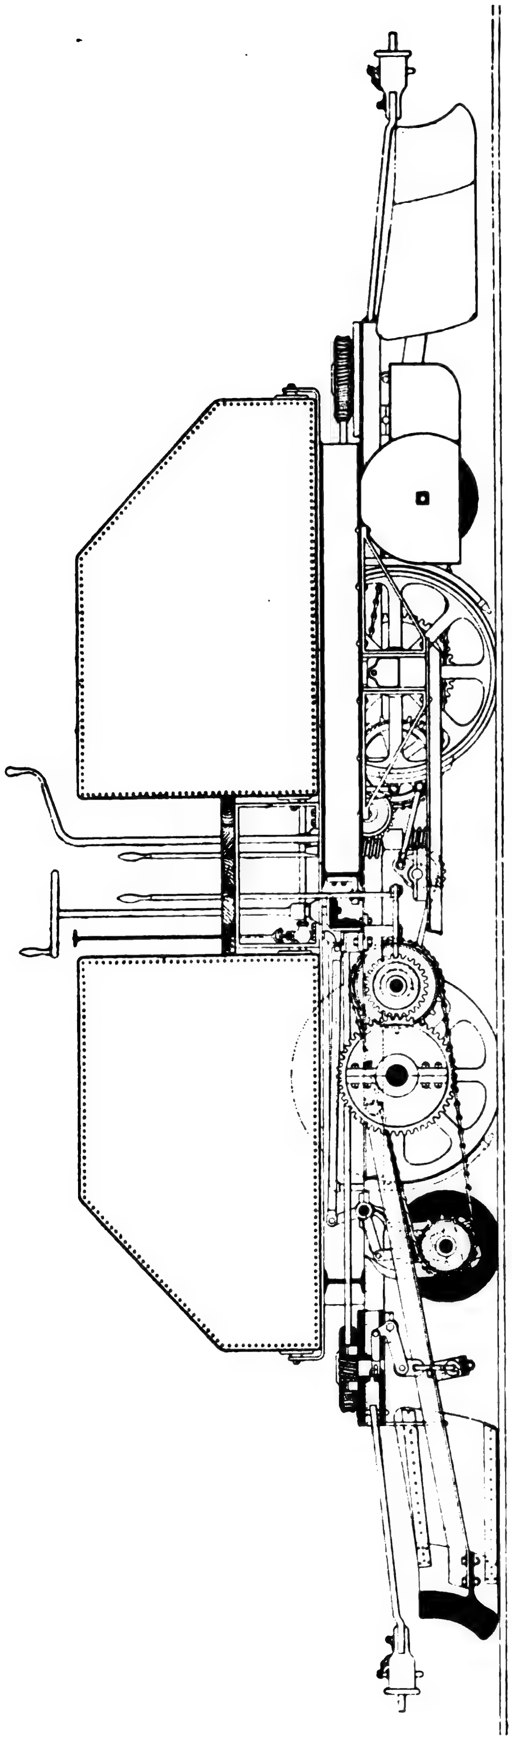
The board, which is shown in front elevation and in section in the accompanying illustrations, has been so designed that upon its exit from the factory it is, so to speak, completely wired up, so that all that is necessary is the leading of the wires from the machines and circuits to a set of binding posts attached to the board, thus making it unnecessary for the station operators to apply a single inch of wire to the back of the board. In order to obtain thorough fire-proof qualities, the base upon which the switches are mounted is made of slate, and the rear board is also of the same material. These two boards are separated by lava sleeves which encircle the bolts connecting the two boards.

It will be noted that the wires coming from the machines are connected to the horizontal circuits behind the board marked "Machine Wire"; while the circuits going out of the station are connected to the vertical bars marked "Circuit Wire." By means of the switches shown it is therefore evident that any machine can be connected to any circuit, at will, by simply throwing in the proper switch.

The switches themselves consist of brass tongues D which are entirely surrounded by the insulating material "fibrone" except at the points where the tongue enters the clips for connection. The switches, it will be noted, make a double break, the two tongues being connected by an insulating handle, also made of fibrone. It will be seen that the board occupies a wall space of only four feet square. Four of these boards have recently been placed in the station of the Manhattan Electric Light Company, in this city, and the ease of manipulation, as well as their absolute fire-proof qualities, have given great satisfaction. The board shown has a capacity for six circuits and six machines, and is open to inspection at all points.



THE FOSTER SWITCH-BOARD, MANHATTAN STATION, NEW YORK CITY.



THE "AJAX" ELECTRIC SNOW PLOW AND CLEANER.

THE AJAX SNOW PLOW AND TRACK CLEANER.

The accompanying cut represents a snow plow built for the St. Louis and East St. Louis Electric Railway Co. by Morris Wuerpel, Mechanical Engineer of the St. Louis Bridge and Tunnel Railroad. The machine is designed to perform three separate operations. The first removes the snow from the track by means of the plows seen at each end, either one of which can be raised or lowered according to the direction in which the machine is being run. The second sweeps the rails perfectly clean, which is done by the revolving metal brushes placed at each end just behind the plows and having motion transmitted to them from the main axles by chain and sprocket wheel arrangements from the motor, the revolving brushes being raised and lowered in the same manner as the plows, but independently of them. The third operation consists in sprinkling a solution of cloride of calcium on the rails, to melt the ice. The use of salt on street car tracks being now prohibited in many cities, the inventor sought to find some substitute which would be unobjectionable. A solution of cloride of calcium was found to be the thing desired; being a liquid it can be more effectually placed on the rails, and its efficiency as an ice destroyer is not equaled by any other material. It adheres to the rail readily, having a gummy consistency. The solution can be made at a cost not exceeding three cents per gallon. The solution is contained in the two tanks which are connected together at the bottom, the liquid being deposited on the rails by pipes with nozzles which extend down to the rails in front of each wheel. The machine is used by being placed ahead of the motor car.

STEAM ENGINEERING AT THE PHILADELPHIA EDISON STATION.

One after another the great cities of the country are evincing their appreciation of the electric light in an unmistakable manner. In spite of rapid increase of plant and facilities, the supply of current has not yet in a single one of them caught up to the demand and consumption. The last few years have seen not only the remodeling and enlargement of old stations but the building and equipment of new ones with whose vast proportions and massive machinery we are hardly yet familiar; and these in turn are likely to be running to their utmost capacity in a very short time.

An instance of this nature is afforded by the Edison station in Philadelphia, of which we here show a fine illustration of the exterior, Fig. 1, with a sectional view of the interior, Fig. 2. This station, which was built on plans of Prof. W. D. Marks, of the University of Pennsylvania, the engineer-in-chief of the company, will, when fully equipped contain a plant of 10,000 h. p. Large as the building is, however, it measures only 98 by 69 feet inside the walls, giving but one square foot to 1.4 h. p. The engines are those of the Armington & Sims Engine Co. There will in time be 20 of them, each of 500 h. p. and each driving 2 Edison dynamos. The engines are, as shown, on the first floor. The dynamos are on the second. The third floor is occupied by boiler flues, enclosed ash track, ash pit shutes from the floor above, blowers, blast pipes, a machine and repair shops, and store rooms. The fourth floor is devoted to boilers with a capacity of 5,000 h. p. The fifth and sixth floors are to be a repetition of the third and fourth. The seventh story is for coal storage, while the executive offices occupy the top. The coal is carried up in elevators and then dropped from the store bins to the boiler fronts by suitable shutes.

Owing to the rapid growth of business, the station equipment is to be increased this fall. The company has at present twelve No. 60 dynamos of 1,075 amperes each, and six more are to follow between now and December. Six fine Armington & Sims engines, of a nominal capacity of

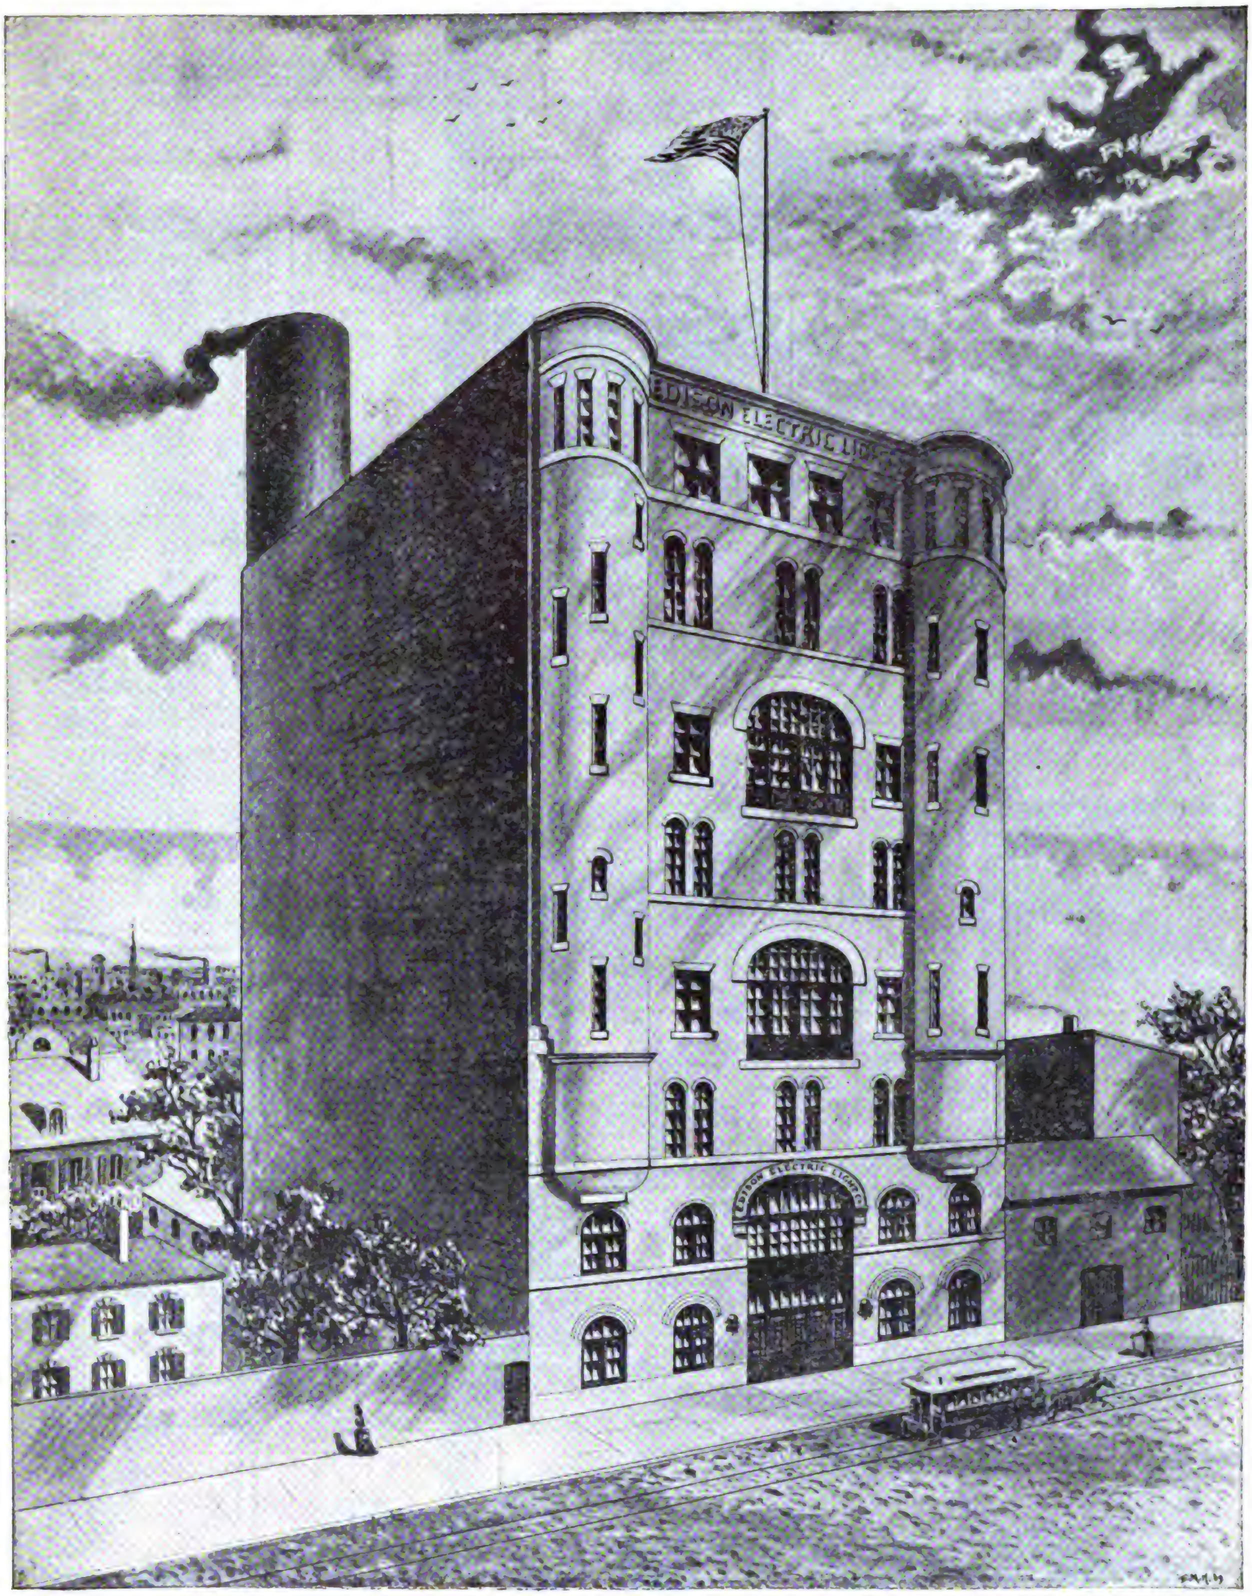


FIG. 1.—THE EDISON CENTRAL STATION, PHILADELPHIA.

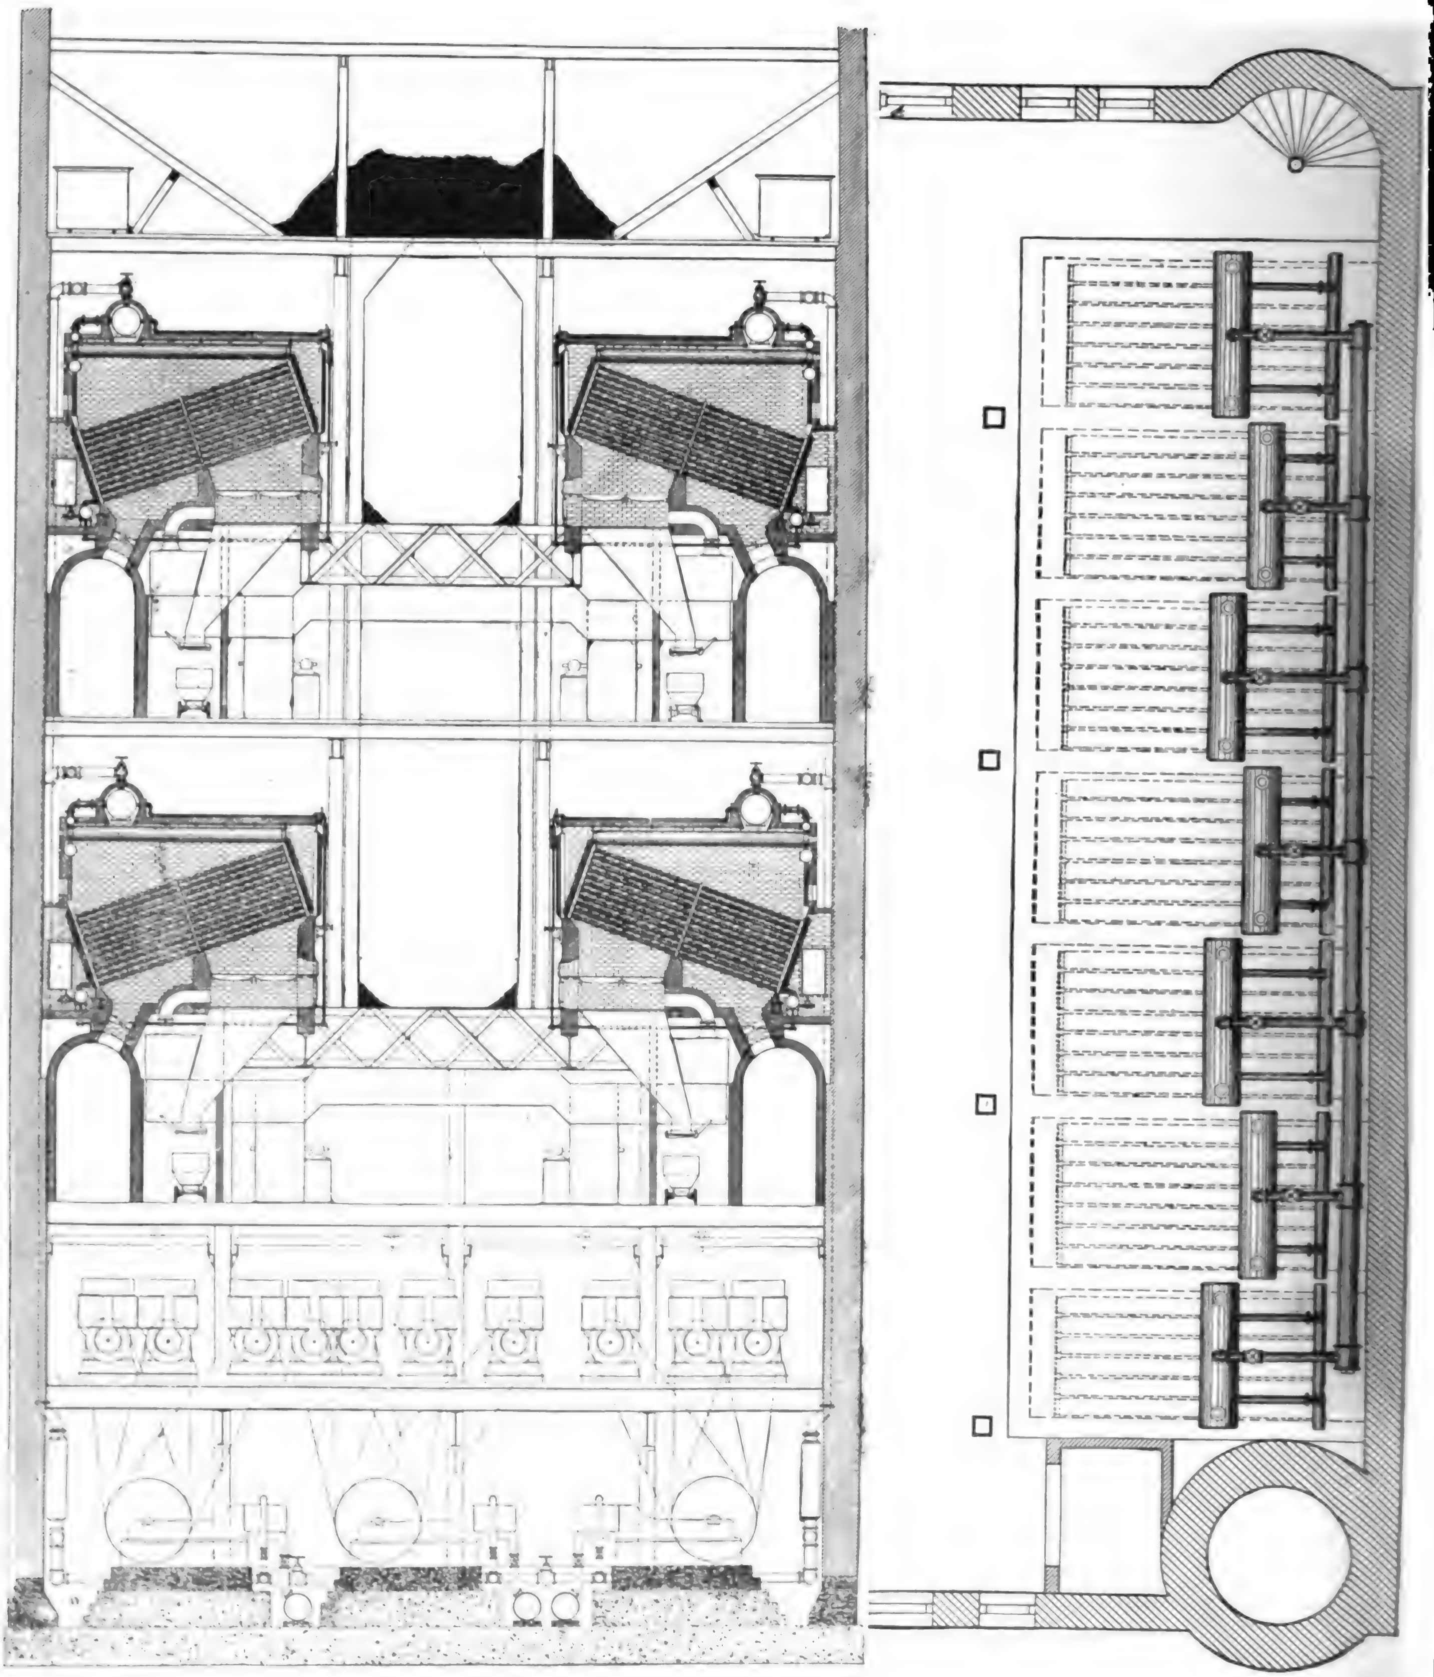
500 h. p. each, are already running and three more have been ordered, to be delivered by November 1, 1890. They will then have a capacity of 67,500 lights. At the middle of the present month they had applications for, and had connected up, 49,807 lights, and the demand for service is steady and persistent. A large quantity of current is also being disposed of for motor service.

Economical steaming is an essential feature of such a plant, and the boilers constitute an element of importance. The company have now in operation three batteries of Abendroth & Root boilers of 1,000 h. p. each. The fourth battery of 1,000 h. p. of this make has been ordered, and it is to be ready by November 15. These boilers are well-known to our readers, having made their way into many electric light and power plants, and do not need extended description. In general design they consist of a nest of inclined water tubes connected at their front and rear ends with a series of horizontal overhead drums, the water level



FIGS. 2 AND 3.—SECTIONAL VIEW OF EDISON STATION, PHILADELPHIA, AND BATTERY OF BOILERS.

being carried at the middle of the drums and the fire being applied under the front, raised ends of the tubes. The action of the fire causes an upward, forward flow in the tubes, the water thus forced from the tubes into the front end of the horizontal drums being replaced by a downward flow from the rear end of the drums. The success of the boiler is based upon the thorough operation of this principle of continuous circulation and upon the scientific accuracy of the various details. Fig. 3 shows diagramatically one side of the boiler room of the Philadelphia station equipped with the Abendroth & Root boilers. When complete the plant will be one of the largest in the country.

ELECTRIC POWER-TRANSMISSION IN MINING OPERATIONS.[1]

BY H. C. SPAULDING.

IT is the object of this paper to present briefly some of the work already done towards the application of electrical apparatus to mining processes, as well as to embody some practical suggestions and statements from those who have had personal experience in the operation of such apparatus.

Following the natural order of operations, let us consider drilling and cutting machinery in the first place. Fig. 1 shows the drill manufactured by the Diamond Prospecting Company of Chicago. This is designated by them as a Type "R" machine, nominal capacity 300 feet, and equipped with a motor of 3 horse-power, rated capacity. The total weight of the machine, set up and running, is 1,000 pounds, and the heaviest piece, when taken apart for shipment, weighs about 170 pounds. The machine is mounted on trucks fitting the gauge of the mine-track for easy handling, and can be taken apart in fifteen minutes, and put up in a half-

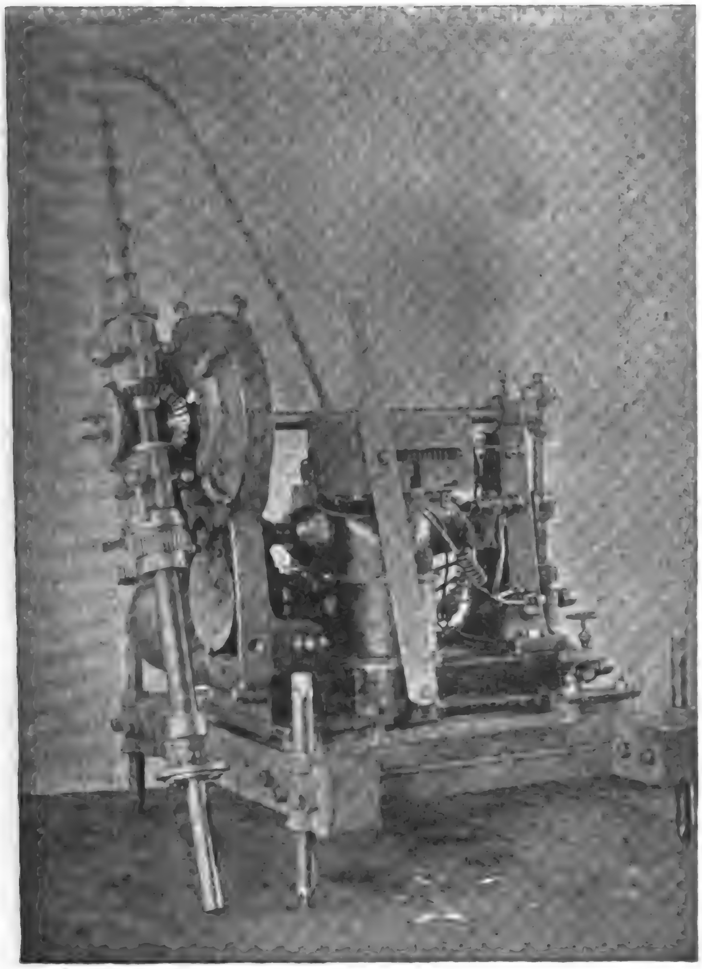


FIG. 1.—THE "DIAMOND" ELECTRIC DRILL.

hour without difficulty. The drill swivels so that holes can be put in at any angle, and can be operated in a space giving 5 feet in the line of the drill rods.

The general arrangement of electrical and mechanical parts is sufficiently evident from the illustration, though the pump is hidden by the pedestal on the right. This is operated by the horizontal shaft driven by the bevel-gearing shown, and supplies a constant stream of water to the diamonds through hose connected with the top of the drill-tube. In a recent test on a granite boulder, hole 1⅛ inches in diameter, with slow speed, this drill cut 22 inches in 40 minutes. When set up in the mine and working on hard compact limestone, it cut the rock at the rate of 1 inch per minute, not including stoppages for changing the rods.

The general principle of construction of most electro-dynamic machinery provides us with a rotary motion, which it is necessary to transform to a reciprocating in order to obtain drills of the Rand or Ingersoll type. Any such transformation, however, entails a considerable loss of power, and we are happily relieved of this necessity by recent inventions which are based on the general characteristics of the solenoid. Such a drill was recently constructed under the patents of H. N. Marvin, of Syracuse. Mr. C. J. Van Depoele, of Lynn, Mass., was one of the first to appreciate the demand for this class of apparatus, as well as the possibilities of the principle involved; and a large factory is under course of construction by the Thomson-Houston Company, which will be especially devoted to drilling and pumping machinery of the reciprocating type.

Many machines have been placed upon the market, in recent years, for making the under-cut in soft-coal mining. Several of them have met with a certain degree of success in clean and easily-worked veins, steam or compressed air (generally the latter) being the operating force. Perhaps the most successful of these machines has been that manufactured by the Jeffreys Mining Machine Company, of Columbus, Ohio. Appreciating the advantages of electric power for this class of work, Mr. Jeffreys was not slow in adopting a motor, and has used a number of those manufactured by Foree Bain, the coal-cutter being modified somewhat to utilize this power to the best advantage.

In the opinion of many practical coal-miners, the principle of the rotating drill has many points of superiority in under-cutting machines, and the result of considerable experimenting and outlay in this direction by the Hercules Mining Machine Company, of Pittsburgh, has resulted in a machine embodying a series of drills operated by a Tesla alternating motor, the power being transmitted by a belt and the current being supplied to the motor by three cables.[1] When in operation, the cutter is clamped upon rails parallel with the face of the coal, being shifted along this track after each cut, ready for another. Compressible springs are wound upon each drill-rod, and serve as conveyors for the coal-dust cut out by the drills.

A machine also embodying the boring principle, though entirely different in its mechanical and electrical design, has been devised. A Thomson-Houston motor of a special type is used in this machine, current being supplied from the main entry-wires (which may also be used for lighting, haulage, and pumping) by flexible wire-covered cables.

The series of cutters (nine in number, each 4 inches wide) is so arranged as to cut close to the wall beside which the machine is placed, and within ⅛ inch of the level of the floor.

Although the weight of the apparatus complete is less than 1,400 pounds, no clamping is needed, as the drills will "pull themselves into the coal," with only the friction of the machine behind them as it rests on the floor.

Having thus briefly examined the present electrical apparatus for boring into ore or coal, so that it may be blasted out, let us see what means are at disposal for hauling it out of the mine, or from one point to another under the surface.

To Mr. W. M. Schlesinger, of what was, at the period referred to, the Union Electric Company, is due the honor of constructing the first electric locomotive for strictly mining uses in the United States. This was of 35 horse-power rated capacity, and was put in by the Lykens Valley Coal Company, Lykens Valley, Pa.

A series of iron rails were joined together to form a conductor for the current, which, after passing through the motor, completed its circuit to the generator by the track-rails, which were connected also by copper wires.

A locomotive of 40 horse-power capacity has been for some past in operation at the Hillside Coal Company's Erie Colliery, near Scranton, Pa.

The power-plant consists of a standard Armington & Sims engine capable of developing 60 h. p., and a 50 h. p. Thomson-Houston generator wound for a current of 220 volts potential, and the necessary appliances for its operation. The engine and dynamo room at the top of the shaft are in charge of the engineer and assistant, who operate the other mining machinery.

From the dynamo to the foot of the shaft the current is conducted by No. 0 Clark wires, enclosed in gas-pipes to protect them from damage. From the bottom of the shaft the wires are carried overhead, about 12 inches outside of the low rail of each track, and are suspended from an insulator specially designed for this class of work, the construction of which can be readily seen from the accompanying illustration, Fig. 2.

The locomotive shown in the illustration, Fig. 3, embodies many new features in motor construction and general design, and, under practical test, has shown that it is particularly adapted to the work required of it. It is built for a 3 feet gauge, and is of the following dimensions: Length over all, 9 feet 7 inches; width, 5 feet 3 inches; and height, 5 feet 6 inches. This last dimension can be considerably reduced by placing the rheostat at one end instead of on the top, as has been done in the present instance. The weight of the locomotive is 10,500 pounds, to which 1,800 pounds has been added to increase traction. The motor employed is of the type "G" railway motor of 40 h. p.

The locomotive is run by one man, who is assisted by a boy in making up the trains and turning the switches. It displaces seven

1. Abstract of a Paper read before the Amer. Inst. of Mining Engineers, New York, Sept. 30.

1. For a full description of this machine see THE ELEC. ENGR., Aug. 20, 1890.

mules and three drivers. During a period of 11½ days the average number of cars delivered at the shaft bottom by the locomotive was 559.5, against 526.95 per day delivered by mule haulage, much time being consumed by waiting at the bottom of the shaft for empty cars. Thus far, the locomotive has shown that it will increase the daily output to 700 cars per day.

The Thomson-Houston Company has now under construction for another Pennsylvania mine a locomotive of 60 h. p. capacity, which (although of the same general type) will be so modified in design as to stand only 4 feet in the clear, above rails, the gauge being 3 feet. The same general plan is applicable to mine tramways of even 12 or 18 inches gauge, suitable for narrow entries, such as are found in some of the Western gold and silver mines.

For hoisting purposes, we may have a variety of forms and sizes, from a 3-horse whip, for hoisting small buckets, to a machine capable of operating a full-sized cage under its maximum load. Fig. 4 shows a hoist of the Webster, Camp & Lane make equipped with a motor, for use in the Ashland iron mine, at Ironwood, Michigan. In the Castle Gate mine, Utah, a 35 h. p. Lidgerwood Thomson-Houston hoist is located about 1,000 feet inside the main entry, for handling the trains at that point.

In pumping machinery, a peculiar apathy seems to exist among prominent manufacturers as to the demands of this kind of work. There are, of course, innumerable cases where centrifugal and plunger pumps have been belted or geared to motors to accomplish certain objects; but the Goulds pump is the first of considerable size which, to the writer's knowledge, has been designed, with special reference to operation by electric power, and which is in itself a mechanical unit, so to speak. This pump is manufactured by the Goulds Manufacturing Company, of Seneca Falls, N. Y. Tests were made, with a view to determining the general fitness of the type for deep mining pressures, and the results have been considered sufficiently satisfactory to warrant the designing of a standard line of pumps of from 50 to 500 gallons per minute capacity.

The pump as shown, consists of three vertical cylinders, within which are three single-acting plungers, their cranks being hung from the main shaft at 120° angles, in order to produce the most even application of power. In addition to this class of pumps for general hydraulic work, the Van Depoele type of reciprocating-engine is being adapted to a sinking-pump which has, as yet, not been sufficiently tested to warrant further mention here.

I need hardly mention the subject of ventilating apparatus, as the application of motors to revolving-fans of any kind is a mere question of belts or gears, though the fact that the fan, with its motor, may be located at any desired point within the mine, with an expenditure of power hardly greater than would be necessary outside, has a marked bearing upon the general arrangement and efficiency of ventilating systems.

The question of lighting, also, though a most interesting one to the engineer and operator, hardly falls within the scope of this paper. It is sufficient to call attention to the fact that the same wires which furnish current for a part or all of the apparatus enumerated above, will make the interior of the mines as light as day, and give a beneficial result, not only directly in the amount of product, but indirectly in the satisfaction and comfort of the men. This is not theory, but has been demonstrated to the satisfaction of all concerned, and in cases where there was, at the start, among the miners themselves, a hearty and bitter opposition to the new system.

A power-plant just erected by the Pleasant Valley Coal Company, at Castle Gate, Utah, is, in many respects, a model of its kind. It has a capacity of about 750 h. p. of generating machinery, which will be used for furnishing current to electric coal-cutters, drills, pumps, haulage engines, ventilating-fans, etc., the entire power needed for the various mining operations being transmitted electrically. As this is the first plant of such magnitude employing electric apparatus to the exclusion of other systems, the result will be watched with interest.

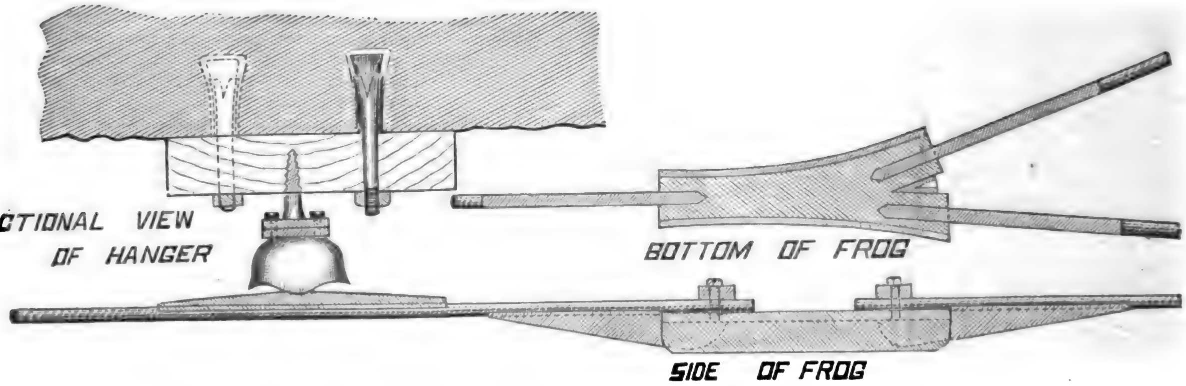

FIG. 2.—DETAILS OF SWITCH, ELECTRIC ROAD, ERIE COLLIERY, SCRANTON, PA.

THE ELECTRO-MAGNETIC RECIPROCATING ENGINE.[1]

BY CHARLES J. VAN DEPOELE.

ONE of the recent developments in the electric line is the perfection of a new electric-magnetic reciprocating engine.

For years past, and, indeed, ever since electricity was first used to magnetize an iron bar by means of a coil of wire, the idea of producing a reciprocating motion by the electric current has been entertained, and many unsuccessful attempts have been made to construct and operate such machines.

Not until the invention and construction by the writer of an electric generator which would give currents rising and falling at a definite speed, could the current be sent to the coils of a reciprocating engine, there alternately attracting and repelling its plunger. In this apparatus, however, as will be seen later on, the rising and falling of the current is produced in such a way that it is absolutely certain that no spark is produced either in the machine or in the generator producing the current. The current is caused to rise and fall in closed circuits, and actuates the plunger of the reciprocating engine with a speed corresponding absolutely to the speed of the defined rise and fall of currents produced by the generator. Thus, the generator can be caused to produce, say, 400 pulsations of current a minute, or it can be made to produce either a higher or lower number than this, so that the engine's speed can be regulated according to the size of its piston and the work it has to do.

The engine itself is a simple piece of machinery, consisting of two or more coils of copper wire, or solenoids, incased in an iron envelope protecting them from outside injury. Within these coils is placed a brass tube, and within this an iron plunger, capable of moving to an fro under the action of the currents in the coils. To the end of this iron plunger is attached a piston-rod, similar to that of an ordinary engine, and to this is attached the hammer, drill or whatever tool is to be operated by the engine.

It will readily be seen that one of the first applications of these machines will be to rock-drills, such as are now in use in nearly all mining and rock-work, for quarrying, prospecting, etc. The simplicity of the machine lends itself most readily to this application, as it will be seen that there are no movable parts on the whole machine, except the plunger and piston-rod carrying the tool.

There are no valves, as in steam-engines, no switches, no make and break of the circuit, and no exposed current-carrying parts, so that the whole can be handled with safety and without any skill above that of common laborers. By turning on the switch the machine is started; by turning off the current, it is stopped. There is absolutely nothing to be done to the machine, except occasionally to pour in a few drops of oil, to lubricate the piston and its rod.

For ordinary mining-work the drill is mounted on a tripod similar to that now in use with the steam and air-drills which are well known to-day, or it can be attached to horizontal bars or to vertical columns; in fact, it lends itself to absolutely the same work that has been done heretofore by the air and steam-drills. It will work in any position, from horizontal to vertical. The weight of these drills will be approximately the same as that of the steam or air-drills of the same capacity, and everything is so arranged that the men accustomed to work the latter machines will find no difficulty in operating the new electric drills.

1. Abstract of a paper read before the American Institute of Mining Engineers, New York, Sept. 30.

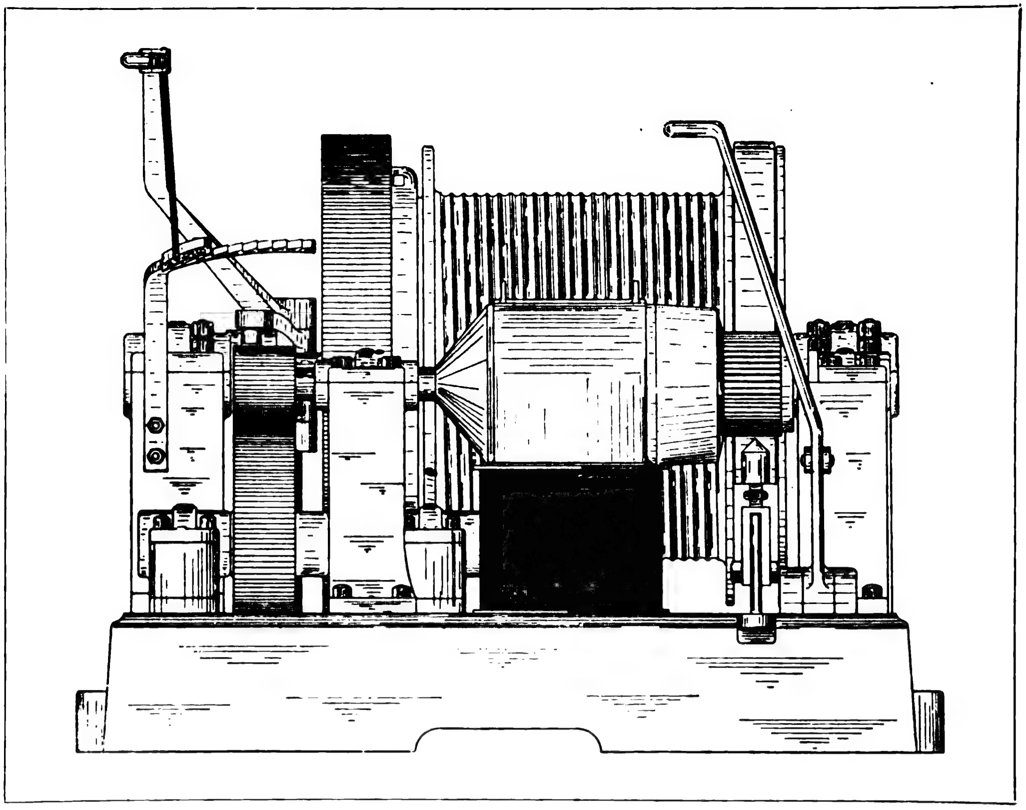

Fig. 4.—Electric Hoist, Ashland Mine, Ironwood, Mich.

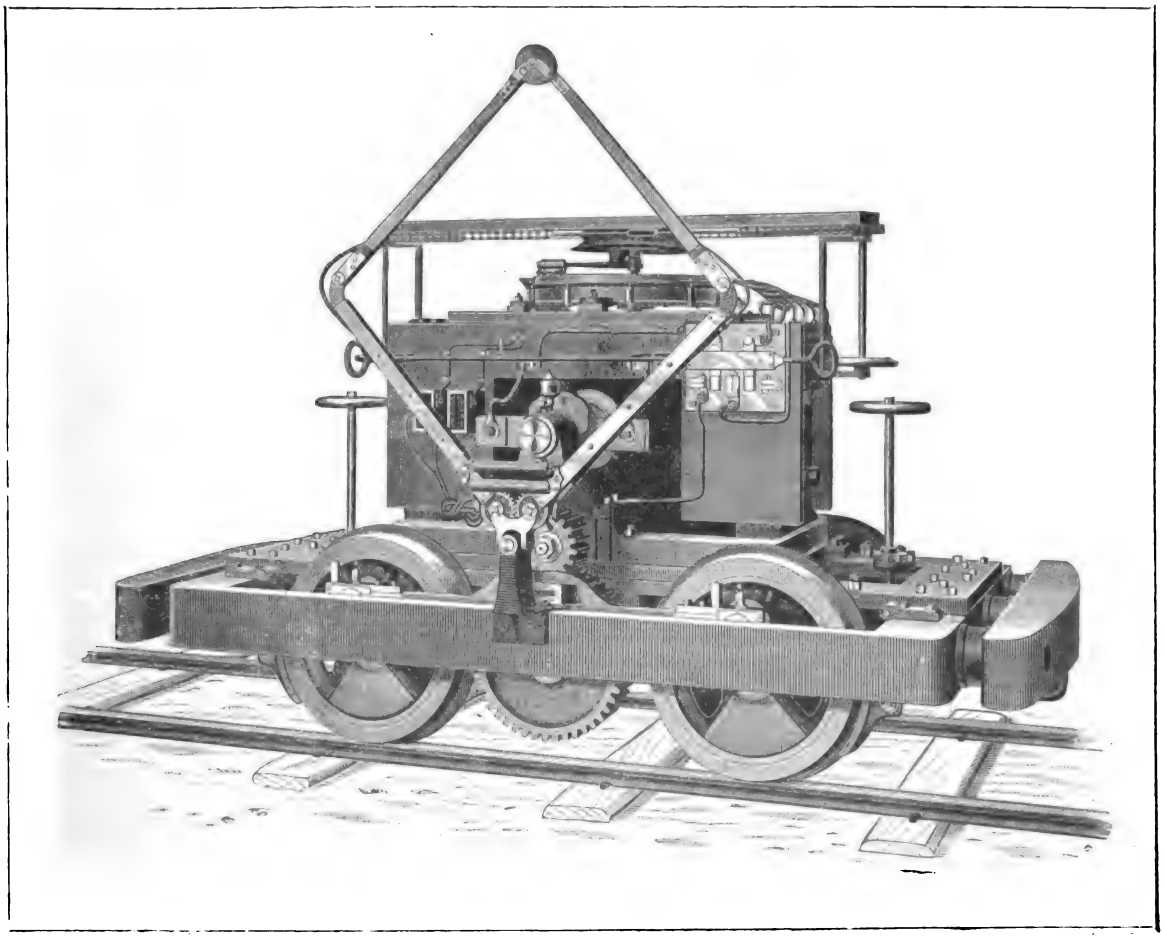

Fig. 3.—Electric Locomotive, Erie Colliery, Scranton, Pa.

THE BALL AND NORTON "MONARCH" MAGNETIC SEPARATOR.[1]

BY C. M. BALL.

THIS machine is the joint invention of Mr. Sheldon Norton, of Hokendauqua, Penna., and the writer, and has been patented in the United States, Canada, and other countries.

The figure shows a longitudinal vertical section of the perfected Monarch ore-separator, adapted for separating fine ore; another size is adapted for cobbing ore of the size of stove, or chestnut-coal. The two designs are identical in principle, and vary from each other in minor details only.

The apparatus consists of a partially closed chest, having an opening at *f*, from the feed-hopper *h*, through which the ore is delivered to the machine from an ore-pocket or storage-bin provided with means for regulating the flow of ore, so that, when the machine is in operation, the hopper is kept always full. Other openings are provided for the discharge, at *t*, of tailings; at *m*, of middlings; and at *c*, of concentrates; also, at *e*, for allowing free ingress of air to the chest at that point, and at *s*, where a powerful exhaust-fan is connected. The openings at *t* and *m* are kept sealed against ingress of air at those points by means of the hinged and weighted valves, *v*, *v*, which discharge the products from the hoppers *p* and *k* continuously, and in the same proportion as received from above, when a sufficient weight has accumulated upon the inside to cause the contents of the hoppers to leak by the valves.

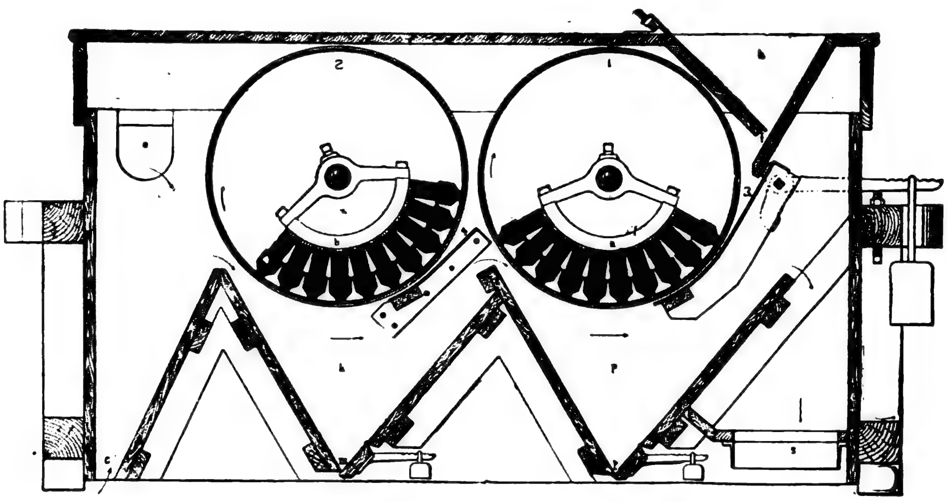
The machine is also provided, as shown, with two drums, 1 and 2, turning upon the shafts, *i* and *j*. These shafts, together with the magnets, *a* and *b*, which they also serve to support, stand still, while the drums may be rapidly revolved around the magnets and out of cantact therewith.

It will be noticed that the magnet occupies a section of the drum, the proportions being such that, approximately, one-third of the periphery of the drum is within the influence of the magnetic field, while the upper two-thirds is outside of the field and removed from the magnetic influence. The magnet is so constructed as to present a series of poles of alternately opposite polarity near the inner surface of the drum. In accordance with the well-known phenomena of magnetic attraction, which in the case of powerful magnets is exerted at a considerable distance from the magnetic poles, any magnetizable matter brought near the outer surface of the drum, within the arc covered by the magnet. will be powerfully attracted and drawn into firm contact with the outer surface of the drum. These drums are composed of a non-metallic and neutral material, such as wood, paper, etc., and they turn in the direction indicated by the arrows near the top of the drums.

Just below the feed-hopper an apron of neutral metal, 3, is arranged, curving downward and forward in the direction of the rotation of the drum, its lower portion describing a short arc concentric to the surface of the drum. This serves as a chute to direct the stream of ore falling from the feed hopper within the influence of the first two or three poles of the magnet. A similar but somewhat shorter apron, 4, is arranged in like relation to the second drum and magnet, *b*.

Attention is called to the provisions for applying and directing the air-current, which fulfills an important function in the process of separating ore as developed in this apparatus. The air may enter freely at the openings *c* and *e*, and is drawn through, and out of, the chest by the action of a powerful exhaust-fan connected at *s*. The air which passes through the chest containing the drums and magnets must, of necessity, follow the course indicated by the arrows in the space below the drums.

When the machine is put in operation the magnets are excited, the drums are revolved in the direction before indicated, the air-current is established through the machine in a direction opposite to that of the rotation of the drums, and ore is supplied through the feed-hopper which is kept always full. The ore passes down the chute under the first drum, and, as soon as it comes within the influence of the magnet, the magnetizable portions are drawn into contact with the drum and through friction upon its surface take on the forward movement of the drum. At this stage, a curious and important result takes place. The particles of ore in contact with the drum opposite one of the poles of the magnet stand on end, forming tufts, spreading away from each other at their outer ends. As they are drawn along, however, by friction against the moving drum, when they get to a point midway between two poles they lie down flat against the surface of the drum, and, as they are drawn still further along, they again stand on end—but this time the other end out. So, in passing through the magnetic field, they are tumbled end over end as many times as there are poles in the field. The result is, that every time they are reversed in position opportunity is afforded for any non-magnetic particles of gangue, which may have been entangled with the ore, to fall away from the tufts of magnetite; and this result is still further facilitated by the centrifugal tendency and by the counter-current of air.



THE BALL AND NORTON MAGNETIC ORE SEPARATOR.

When the ore reaches the limit of the arc covered by the magnetic field it is no longer attracted, and takes on a tangential movement, which carries it away from the drum. It has now, however, passed the edge of the second apron, and, on leaving the first drum, comes within the influence of the magnet of the second drum, where similar operations are repeated, a portion being finally discharged as concentrate at *c*. The function of the second drum and magnet is to differentiate the product from the first drum into two portions, which may be conveniently designated as middlings, discharged at *m*, and concentrate, discharged at *c*. The middlings consist of particles of ore with adhering portions of gangue, which may require a little finer crushing to effect their mechanical liberation: or, they may consist in part of iron compounds having a smaller degree of magnetic susceptibility than the pure magnetite. The separation of the middlings from the mass delivered to the second drum may be effected in two ways: If the drums have the same speed of rotation, a weaker magnetism in the second magnet will allow these less magnetic particles to drop away; or, if the magnets have approximately the same force in the two drums, a higher speed of rotation of the second drum will throw these particles off by reason of the centrifugal force overpowering the centripetal magnetic attraction, the magnet having the smallest influence upon the leaner portions of the mass.

Modifications of this apparatus have been designed, which adapt it for use in conjunction with a stream of water mingled with the ore, so constituting a wet process.

The positive character of the functions above enumerated renders it possible to make an effective separation under the con-

1. Abstract of a paper read before the Amer. Inst. of Mining Engineers, New York, Sept. 30, 1890.

ditions of a very heavy supply of ore to the machine. The easy working-capacity of a machine having drums of 24 inches diameter and 24 inches working-face is from 15 to 20 tons per hour of ore granulated to pass 16- to 20-mesh screens.

The power required is from 1 to 1½ horse-power in electricity for each drum, and ½ to ¾ horse-power to drive the machine.

These machines have been applied to the treatment of a considerable number of ores. The most remarkable of these was the conversion of Port Henry Old Bed ore into a Bessemer ore, carrying Fe 71.10, P 0.037. This concentration was made from the crude ore, carrying Fe 58.7, P_2O 2.25, the Bessemer concentrate representing about 65 per cent. of the original mass.

MAGNETIC CONCENTRATION AT THE MICHIGAMME IRON-MINE, LAKE SUPERIOR.[1]

BY JOHN C. FOWLE.

HAVING had for many years the management of magnetite mines, and having noted the various admixtures, such as jasper, "green rock," actinolite, etc., that occur so frequently in the deposits and make the fine ore so difficult, as well as expensive, to sort by hand, I studied the different ways of mechanical sorting, but found none satisfactory—the universal objections being the expense, the small quantity that could be handled per hour, and the low grade of ore produced after all.

Careful investigations showed that neither dry nor wet concentration was the right process for us; and I finally studied the magnetic process. Not knowing of any magnetic separator in this country that would handle such large pieces of ore as I wished to treat, I looked abroad and found in Sweden the Wenström separator. One of these machines was brought to the United States and tested in New Jersey and other places. (See the papers of Messrs. Cook and Birkinbine, *Trans.* xvii., 599 and 728.) This original separator, having 15-inch face of drum, I brought to the Michigamme mines, and, no one having confidence in it, placed it in operation at my own expense. Finding that in this way large ore could be treated much better by magnetic separators than by hand, and with much greater enrichment of the product, I put up a small, crude mill with several series of screens, so as to size the material and treat on the separator the different sizes by themselves. This gave a still better product. None but the 15-inch separator was used. We shipped from this mill 11,000 tons of concentrates in 1889, a part of which, produced from crude 50 per cent. ore, contained 65 per cent. of iron, while the remainder, produced from crude ore running 52 to 54 per cent., carried 60 per cent. iron.

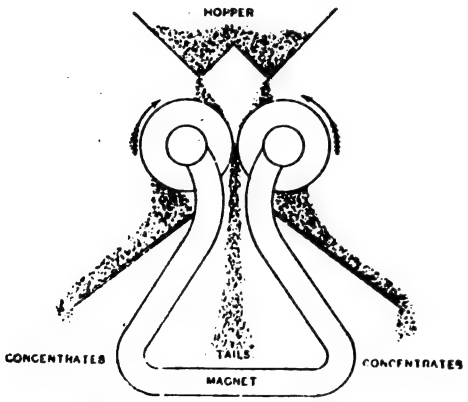


FIG. 1.—THE BUCHANAN MAGNETIC ORE SEPARATOR.

The experience at this mill shows that the fine powdered ore and the ore going through a ¼-inch screen, should never be allowed to fall directly on the separator, but should be carried near the separator by a belt on an inclined plane and attracted to the drum of the separator by the electro-magnetic force. It is almost impossible to feed this fine ore directly on to a separator in a sheet sufficiently thin to permit a satisfactory separation, because ore and rock overlying one another are bound together in the drum; but by feeding the fine ore by a belt up to the separator, the mass of material is agitated, and the ore flies to the drum and the rock falls, or remains on the belt. The greater the electric current which is carried on the separator, and the farther away from the separator the crude ore is when it enters the magnetic field, the higher will be the percentage of iron in the concentrates and the lower in the tailings. For instance, crude ore, containing 52 per cent. of iron and 0.324 of phosphorus, when treated directly on the separator, gave concentrates in one case containing 58 per cent. of iron and 0.215 of phosphorus; and in another case 60 per cent. of iron and 0.180 of phosphorus; while the same ore, treated by a belt-feed, not in contact with the separator, gave concentrates containing 67.07 per cent. of iron and 0.160 of phosphorus.

The fine ore that passes through the screen, is delivered to a swing-screen, from which it drops into several pockets, and is then fed by gravity to the Buchanan separator, Fig. 1. This separator also treats, independently of the crushed ore, all the previously-mentioned mine-screenings. These are fed to it direct from storage-pockets, without any preparatory crushing or sizing. The concentrate, or "ore," produced by the separator, is conveyed to railroad cars and loaded for shipment. The tailings are run over our Wenström separator, Fig. 2, to take out any remaining ore. The Buchanan separator is very well built; it has a much larger capacity than the small Wenström machine, and makes richer concentrates. It carries a current of 23 amperes, and is wound with heavy copper wire. The Wenström machine, on the other hand, can carry only 10 amperes, and is wound with wire of one-third the size. We keep the Wenström machine in use

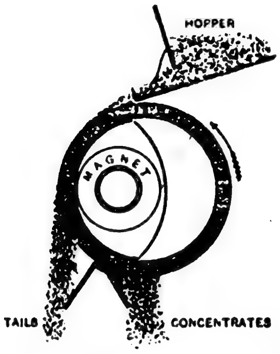

FIG. 2.—THE WENSTROM MAGNETIC ORE SEPARATOR.

only because we happen to have it. It is our original Swedish machine and is a good one—much better, in fact, than one which was built for us in this country, but which we do not use.

I consider the concentration of magnectic ores by electricity to be still in its infancy as to cost, capacity and quality. Our experience has been exclusively with separators having one or more drums, and I claim no knowledge of practice with other forms of apparatus. The many mills now in operation in the East will undoubtedly, during the present year, work out new methods for concentrating iron-ores, whereby the cost will be reduced and the output still further increased.

1. Abstract of a paper read before the Amer. Inst. of Mining Engineers, New York, Sept. 29, 1890.

THE COMPENSATION OF ALTERNATING CURRENT VOLTMETERS.[1]

BY J. SWINBURNE.

IN 1887 I had the honor of bringing before Section A several methods of compensating voltmeters and resistance-bridges for variations of temperature. Wires with different temperature coefficients were used, by which means errors from change of temperature can be avoided. Methods of compensating wattmeters for the errors inherent in them were also explained. The present communication relates to a somewhat analogous arrangement for compensating alternating voltmeters for changes of frequency.

It is much more easy to make a current indicator for alternating than direct currents, for troubles from hysteresis do not come in, and the slight tremble makes the moving part hang freely. If it is attempted, however, to use such an instrument as a voltmeter, the self-induction makes the reading far too low, and the error varies with the frequency.

To get over this trouble, a voltmeter may have a non-inductive, or nearly non-inductive, resistance put in series with its active coil. A coil with an adjustable iron core is then put in shunt to the active coil, this shunt coil having a very much larger time-constant. Though both coils have iron cores, they have open magnetic circuits, so they have practically constant coefficients of self-induction. When the frequency increases, the current through the whole instrument under a given pressure falls; but the back pressure of the shunt coil increases more rapidly than that of the active coil, so that it takes less than its share, while the active coil gets a larger share of the reduced current; the actual current, and therefore the reading, in it remaining constant. The instrument is calibrated with a direct current. An alternating current is then put on, and the core of the shunt coil regulated till the readings agree with those of the direct current.

1. Paper read before the British Association, Leeds, September, 1890.

ON WELDING BY ELECTRICITY.[1]

BY PROF. ELIHU THOMSON.

The purpose of the present paper is to call attention to some of the more prominent steps in the progress being made in the development of electric welding and metal working, it being understood that even while this present paper is in preparation, advances are taking place in the working out of details. It is not, therefore, intended to have this paper take the character of a complete statement, but rather that it shall be a brief review of some phases of the development of the art.

In this art, the foundation experiments were made about four years ago. The author had the pleasure of describing some of their results, particularly relative to electric welding, in a paper written in the latter part of the year 1886. The appearance of that paper aroused a considerable interest in the subject, which has continued from that time, and it is curious to note how it has caused the revival of early attempts to use the electric arc in metal welding or working, sometimes in conjunction with a magnet for displacing the arc and converting it into a blow-pipe of great intensity, the latter being a procedure due, it is believed, to Werdermann, in the early days of the production of electric arcs from dynamo machines.

It is not my present purpose to deal with any of these arc methods of electric metal work. Their practicability is doubtful. So far as is known to the author, there are no existing instances of the use in practice of the electric arc for welding, though numerous attempts have been made, which have failed from one cause or another.

The operations with which this paper deals are those in which the heating effect of electric currents traversing a solid metal conductor gradually brings the metal to the working temperature. This temperature is, in the case of easily fusible metals, much below a red heat, and is hence unattended with luminous effects, which, however, appear in the case of metals softened or fused with greater difficulty.

In order to distinguish this process, applied to the welding of metals, from the application of the heating effect of an electric arc for like purposes, it has been called the incandescent method of electric welding—a designation which is, in my judgment, misleading, for the reason that lead, tin, zinc, and other metals fusing far below the temperature of incandescence, are thus welded.

Electric welding occurs between pieces of all metals thus far tried, though the perfection of the joint obtained varies with the metals and with the conditions under which the work is performed. Many different metals unite each to the other, and in many cases the union is such as to possess a strength or tenacity equal to that of both, or of the weaker of the metals joined. In other cases it is not so strong, owing to wide differences in the physical nature of the metals or alloys, or in their tendencies to surface union. Perhaps the incipient alloying at the joint may affect the strength, according to the nature of the alloys possible to be thus formed.

It is proper here to correct an impression which has gained some currency—namely, that it is the extra resistance caused by the break or limited contact between the meeting portions of metal which gives rise to the heating in electric welding. While this limitation of contact surface undoubtedly hastens the heating at the joint, it is nevertheless a fact that a solid bar, joining the clamps of an electric welding machine, will be heated between those clamps to welding temperature, and may be upset by the approach of the clamps one toward the other. Indeed, this process is actually employed to upset collars on shafts, or to set or fasten in place, by a sort of riveting action, collars which have been placed as rings, more or less closely fitting, upon a bar or shaft. The real cause of the concentration of the heating effect at the joint, or between the clamps, is the relatively greater conductivity of other portions of the welding circuit, which circuit is usually composed of massive copper conductors, kept cool, in the case of large work, by circulation of water.

The present tendency in the construction of electric welding machinery is towards having its action in most respects automatic, so as to leave little to the skill or dexterity of the operator in charge.

The apparatus first used by the author consisted of an alternating current dynamo, feeding a comparatively high potential current to the primary coil of an induction coil or transformer, the secondary of which was made so large in section, and so short in length, as to supply to the work currents not exceeding two or three volts and of very large volume or rate of flow. The welding clamps were attached to the secondary terminals. This first type of apparatus has survived to the present day, and most of the apparatus is constructed on that principle, the secondary coil usually consisting of a single turn only.

The practical results are not very different, whether continuous currents or alternating currents are used, though it is to be noticed that in the discussion of Sir Frederick Bramwell's paper the actions of the two classes of currents were spoken of theoretically, to some extent, as different. It has been shown that in conductors of large section the tendency of alternating currents is to keep to the surface of the conductor or to flow in the part of it farthest away from its centre. This is undoubtedly true as a tendency, but how far this tendency will be allowed to develop itself will depend on the drop of potential in a given length of conductor, a circumstance which appears to have been overlooked in many of the discussions of this interesting question. In other words, if the fall of potential, as in welding, is, say, two volts in two inches of length of the bar welded or worked, the density of current will be great, even in the centre of the section of the bar, but of course much greater near the exterior. But the heating effect also requires to be greater near the exterior on account of radiation taking place at the outside surface. The practical result may easily be that there is really a uniform heating effect throughout the section of the bar; and without doubt the conditions could be selected to secure such a result.

In welding the ends of two bars, however, they are frequently rounded, and at the start meet only in the centre. In such cases, whether the current be alternating or continuous, the heating effect begins at the centre. A curious fact may here be mentioned. It is found that the distribution of the alternating current may easily be controlled by increase or decrease of self-induction at various parts of the section of the bar by the proximity of magnetizable iron masses. This principle has been applied in a variety of ways to govern the distribution of the heating effect, and also to effect the restriction of current to the weld in thick rings. This will be adverted to later.

The temperature resistance co-efficient is, in general, much higher in the case of simple metals than in metallic alloys. The conductivity for heat has also a decided influence on the heating, and the comparatively low heat conduction of iron assists the work materially. Brass of ordinary composition scarcely seems to become plastic at all before melting. Hence the joints made with it generally show, in part, a real fusion and not merely a softening. In cases where the pressure used is too great, the joint is obtained by the crushing up of the hot metal in a semi-granular state before fusion, but this joint is not generally so perfect as the other. Some of the bronzes, and notably the alloy called aluminum bronze, show some plasticity before fusion.

The behavior of copper in welding by the electric current may be noted. It is an example of a metal of very high conductivity for heat and for current. Naturally, to weld it electrically, the current strength required will be much greater for a given section than for metals of smaller conductivity. The heat produced escapes rapidly by conduction, and the low resistance of the metal requires a great current to be passed to cause it to heat. This is compensated for, in large part, by the fact that the copper requires a very low potential, or E. M. F.—less than a volt across the joint. The rate of energy-consumption being the product of the current used by its electromotive force, and the total energy consumed being the product of this by the time, it will be seen that if a copper weld be made, in a short time the losses by conduction and radiation from the joint can be kept down to a moderate percentage of the total energy. Copper, as is well known, becomes decidedly softened before melting, and is, therefore, often forged hot. Hence, joints may be made apparently without real fusion; or, in other cases, when a lighter pressure for forcing the pieces together is used, a real fusion of portions of the meeting ends may occur. While in the electrical welding process joints are obtainable with most metals without the use of any flux, it is not the less true that a flux is sometimes desirable for good work, particularly with those metals the oxides of which do not melt at the temperature of welding or union of the pieces. Thus a flux should be used with brass, which has a temperature of welding and union below that of the fusing points of oxide of zinc or of copper, while a flux is not an essential in the welding of copper, the melting-point of which is above that of its oxide. A peculiarity of the electric welding process, and one which renders it capable of forming joints, even where metals may be coated with oxides infusible at the temperature of fusion of the metals themselves, is the expulsive power exerted to remove metal sidewise from the joint, and thus bring unoxidized, clean surfaces into contact at fusing temperatures. It is this fact which more than any other accounts for the universal applicability of the process to metals and alloys. For example, the chief obstacle to the soldering or welding of aluminum may be the skin of alumina formed on its surface when hot, which not only protects the metal from further oxidation, but prevents its union with other pieces of metal. The alumina is only fusible at the highest temperatures, whereas the metal fuses at about a red heat. Let two pieces, however, be vigorously pushed together while softening at the joint; then the oxidized surfaces will be thrust aside outwardly from the joint, and the new metal of the interior of the pieces will come together in the cleanest possible state, and unite. The removal of the burr or excluded metal of the joint can be afterward effected with proper tools.

The uniting of iron and various grades of steel is, of course, the most important industrial use of any welding process, and

1. Abstract of a paper read before the British Iron and Steel Inst., New York, Oct. 3.

this is particularly true of an electrical one. The behavior of soft iron is particularly favorable to the welding operation. Its great plasticity before fusion renders its working and welding easy and simple. In the case of steel, for the higher grades of which, especially, the ordinary blacksmithing operation is liable to be very uncertain, the electric process is rendered easy and certain for all grades. When it is remembered that the exact conditions of current, conduction, and pressure at the joint may be made definite, and are perfectly under control, it is seen at once that, if the pieces are weldable at all, we can even establish an automatic control of the welding after these conditions have been once determined.

There are many kinds of work to which electric welding seems to be peculiarly applicable. It is now in use largely far the joining of sections of wire into one length, and its use for such a purpose is still extending. Joints are regularly made in wires, which are afterward reduced in diameter by the wire-drawing process, various metals, such as copper, iron, brass, &c., being treated in this way. In other cases the electric welding process replaces the twisted joint formerly made in galvanized telegraph and similar wires—the galvanizing operation either preceding or succeeding the making of such joints. Even the ends of wire cables are readily jointed, the resulting weld possessing a strength not much inferior to the cable itself, and probably about equal to that of any heated or annealed portion. The making of such joints requires, or course, special precautions, but the operation is quite simple otherwise. In the welding and coiling of pipe the electric method seems to be especially expeditious and useful. Coils of pipe are now made continuously, as section after section of pipe is welded on. There is no limitation to the length of pipe which may be so welded and wound as one coil.

The process seems destined to work a revolution in pipe coiling operations. A machine will soon be tested which is intended for welding sections of six-inch extra heavy pipe together endwise. The current developed in this machine may reach 70,000 amperes, though its normal work will demand somewhat less than this. Most of the details of this and the other welding apparatus thus far constructed and put to use have been devised and arranged by Mr. Hermann Lemp, to whom the greatest credit is due for the original character and effectiveness of the machinery itself. Lieut. W. B. Wood has also had in charge a number of special pieces of work in adapting the welding process to several important applications.

Somewhat akin to pipe welding is the making of armor-piercing shells (as devised by Mr. Wood) from sections of varied grades of steel and without screw joints. In the making of rings, links, bands, &c., the electric welding operation is particularly useful, and a number of machines specially designed for such work have been put into practical operation. Even rings of small diameters relatively to the weight of section of stock used, are made with facility, though at first it might be thought that the current would pass around the joint and through the solid metal of the ring, instead of the joint or cut ends pressed together. This is true in part; but the actual result is that only in very stout rings is there much heating outside of the joint, and then only enough to make the ring flexible, so that the ends of metal at the joint may be readily moved together. With the alternating currents used in electric welding, not only does the current take the path of least resistance in largest amount, but it also seeks the short path, or path of least counter induction or self induction, and therefore will not go around a ring as freely, other things being equal, as along a short, straight path through the joint at one side. Furthermore, if it be desired to check any flow around the ring still more effectively, we have only to introduce into the centre of the ring or link a magnetizable core of iron, which effects a great increase of the counter induction mentioned.

An important matter which may be mentioned in this connection is the facility with which the milder grades of steel may be manipulated in the welding by electricity. The advantage of the superior strength of the steel over puddled iron may thus be secured, which allows the use of a cheaper material, and less of it for a given strength. This remark applies forcibly to chain making, in which the substitution of low steels for iron secures the double advantage mentioned, with the other advantages of the electric process over the ordinary ways of working. Considerable attention has therefore been given to the development of machinery for chain work, and a small working apparatus has even been made, which takes a wire from a reel and turns out lengths of chain with electrically welded links; the operation being automatic throughout. A curious feature of electric welding work is that two or more welds may be simultaneously made in parallel. This fact is utilized in chain making, where two welds, one at each side of a link, are made simultaneously. There are not yet in industrial operation any chain machines using the electric process. This step, however, is reserved for the near future. A special heavy chain machine will soon be completed.

It will readily be understood that the heating effect of very heavy electric currents may be applied to other cases of metal working than welding. Thus, it may be used to heat pieces for soldering or brazing, an operation which only differs from welding in the use of a more fusible metal between the surfaces to be united. In many cases the advantages of control of temperature, quickness of heating, and convenience of holding the pieces will be found greatly in favor of the electric method. In fact, an electric brazing machine has been regularly in use for some time past for bicycle construction, while in other instances such welding takes the place of joints formerly made by brazing with the blow pipe. The application of the electric methods to many tinplate soldering operations is likely to become industrially, as it has been already experimentally, successful.

Among the operations which can be readily performed electrically is that of heating a rivet in place by current passed through it and heading it while hot. In numerous trials, it has been proved that short, straight sections may be used as rivets, and both heads formed simultaneously, either as projecting heads or as countersunk heads.

Considered in relation to automatic character, range of adaptibility, the convenience and cleanly nature of the work, the perfect control of temperature secured, and the uniformity of result, the electric welding and metal working processes are decided advances over the prior art, and seem destined to a wide application.

TESTING IRON.[1]

BY J. SWINBURNE AND W. F. BOURNE.

In practical work iron has to be tested as to its permeability and as to the loss by hysteresis. As regards permeability tests, the ordinary ballistic galvanometer method can, of course, be used; but a ballistic galvanometer is not a convenient instrument, and the method is too slow for practical use. It may, therefore, be of interest to describe the apparatus we use commercially. It is the development of a method devised in 1886. (See *Phil. Mag.*, July, 1887.)

The various samples of iron are obtained in the form of wire, and made up into rings, being wound on a former kept for the purpose, so that all the rings are alike as to dimensions. Before winding, the specific gravity of the iron is taken by weighing, and the specific resistance is measured. The ring is weighed to get the volume of iron, and is then wound with suitable primary and secondary wires.

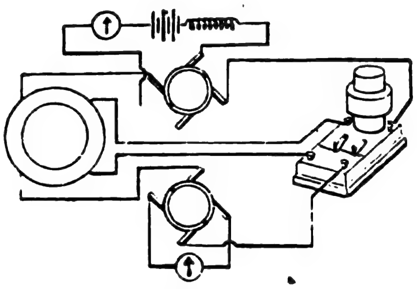

DIAGRAM OF IRON TESTING CIRCUIT.

The arrangement is shown diagrammatically in the annexed figure. The circuit from secondary cells is led through an adjustable resistance, then through an ammeter to a commutator, resembling Brillouin's, which is driven by a belt from any shafting that may be near. The circuit is led through the primary to an induction box to the ring under test, and then back to the commutator. The circuit is then led back to the cells. The induction box consists of a primary coil, standing on end, and a number of secondary coils arranged so that the mutual induction is the same for all of them. The secondary coils are led to buttons, and the switches include them by ones or tens, making the readings in steps of one per cent. of the highest. The primary of the sample ring is in series with that of the induction box. The secondaries are coupled so as to oppose each other, and arranged in circuit with a second commutator; a Varley, or, as it is more often called, a Deprez-d'Arsonval galvanometer, being inserted in the circuit. The two commutators are, of course, on the same spindle. The adjustment of the induction box was carried out as follows: The coils were roughly calculated to give a mutual induction a little in excess of a convenient round number per turn of secondary. A cylinder of a known diameter with a known number of turns per centimetre in the primary, and a known number of turns in the pilot coil, was taken, and put in the place of the sample ring, and its mutual induction measured with the induction box. To allow for the error due to the shortness of the cylinder of the standard coil, it was slipped out of the pilot coil, and moved exactly half its length in a direction along its axis, and a new reading taken. This reading gave the error due to the ends of the cylinder. A shunt was then put across the

1. Abstract of a Paper read before the British Association in Section A, Leeds, September, 1890.

primary induction box, so as to make the readings come out in microhenrys.

To test a sample of iron all that is necessary is to alter the mutual induction by steps, and to bring the galvanometer to zero for each step by means of the adjustable resistance. As the galvanometer is dead-beat, the readings can be taken in a few minutes.

We use the same rings as for the permeability test, but do not employ the secondary wires. The loss of power at various frequencies and inductions is taken with a wattmeter. It is sometimes supposed that a wattmeter cannot be made with little enough self-induction to read accurately. If there is much self-induction in the pressure or shunt circuit, the reading will be lower than that with a direct current if there is no self-induction in the circuit in which the waste of power is to be measured; but if the current is behind the pressure, as in measuring the loss in iron, the wattmeter may even read too high. We therefore designed a special instrument, which was made for us by pupils of the London College of Electrical Engineers. The current coils are fixed, and the moving coil is suspended by a fine wire, with a fine spring at the foot, to take the electricity out again. The moving coil has few turns and a little self-induction, and a large non-inductively wound resistance is in series with it. This wattmeter can be read with a mirror, if desired; but with 2,900 ohms in series with the pressure coil, it gives a torsion of 2° per watt on a non-inductive resistance. The series resistance is not wound with a looped wire as is usual in resistance boxes, because this method is not good, the insulation being apt to break down. A single wire was therefore used. When one layer was wound, the bobbin was reversed in the lathe, and the next layer wound in the opposite direction, a thin layer of insulation being put between the layers. This method secures absence of self-induction, and good insulation, as the beginning and end of the coil are kept well apart. The readings are taken by bringing the index back to zero by turning the suspension, so that the mutual induction of the coils is zero, as the coils are at right angles.

SOCIETY AND CLUB NOTES.

THE BRITISH IRON & STEEL INSTITUTE AT THE EDISON LABORATORY.

Friday last, Oct. 2, was largely given up by the mining engineers now visiting this city from Europe, to electrical matters, and a morning devoted to the discussion of electrical subjects and the inspection of various electrical plants and institutions was followed by an afternoon at the Edison Laboratory. About 200 visitors were expected, but when the party left West Twenty-third street and mustered at the Jersey City depot for the special Llewellyn Park train, it was found to muster no fewer than 500, a large proportion being ladies. The gathering included members of the British Iron and Steel Institute, the kindred French and German bodies, and the American Societies of Mining, Civil, Mechanical and Electrical Engineers. The train arrived at Llewellyn Park about 1:45, and lunch was hospitably provided by Mr. Edison in the laboratory library. Owing to the unexpected largeness of the crowd, it was impossible to serve all there at once, but good nature prevailed, and in an hour everyone had lunched and got down to the work of sightseeing. It is but truth to say that Mr. Edison himself proved far more attractive than his beautiful laboratory, and that he was surrounded all the time by clusters of ladies and gentlemen desirous of the honor of an introduction and a few words. But the various departments were not neglected, and the workshops, dynamo room, phonographs, electrical department, &c., &c., were curiously examined. During the afternoon, the ladies were given a drive in buggies through the lovely Orange Mountains. Before leaving all gathered together again in the library, where Sir John Kitson, president of the Institute, thanked Mr. Edison, in its name, for the pleasure he had given them all. After three cheers for Mr. Edison the party left the laboratory and took the return train at 5 p. m.

BROOKLYN INSTITUTE—DEPARTMENT OF ELECTRICITY.

Owing to the fire in the Institute building on September 12th, meetings of this department will for the present be held in the lecture hall of the Union for Christian Work, 67 Schermerhorn street, near Court street. A course of general lectures on the science of electricity will be given during the coming season. A course of lectures on technical electrical subjects will also be given. Eight regular meetings of the members of the department will be held for the discussion of special subjects and the demonstration of the action and use of electrical apparatus and appliances.

There will be exhibits of electrical apparatus and appliances as follows:

1. Batteries of various forms and kinds.
2. Telegraphic, telephonic, phonographic and graphophonic apparatus.
3. Electric lighting appliances.
4. Electro-motors and kindred apparatus.
5. Electro-metallurgical apparatus and processes.
6. Electrometers, galvanometers and kindred apparatus.
7. Electro-medical and electro-surgical apparatus.
8. General exhibit covering all branches of electricity.

The meetings of this department will be held on Friday instead of Saturday evenings as previously. On Thursday, October 2d, there will be an important business meeting of the members of the department. On Friday, October 10th, a lecture will be given, the subject of which is announced later. On Friday, October 24th, will be given a lecture by Schuyler S. Wheeler, Ph.D., on "Certain Applications of Electricity," with illustrations, and on Friday, October 31st, there will be an exhibit of electric batteries by members and other electricians. The phenomenal success of this department last year bids fair to be eclipsed by that of the coming season.

The next meeting of the department will be held in the Lecture Room of the Union for Christian Work, Friday, Oct. 10. At this meeting a paper will be read by Mr. C. A. Robbins on "The Engineering Difficulties Connected with the Recent Destruction by Fire of the Western Union Telegraph Company's Main Office in New York City."

As this fire completely destroyed the company's New York plant, its rapid recovery surprised the whole country, and Mr. Robbins being among those who disentangled the wires he will no doubt make the subject very interesting.

DINNER OF THE NEW YORK ELECTRIC CLUB.

In order to signalize the beginning of its winter season, the New York Electric Club gave a dinner at the Club house on Oct. 2, at 7 P. M., when about 120 gentlemen sat down to table, the whole floor occupied by the parlors and dining room being turned into a handsome banqueting hall. The dinner was served by Mazzetti in excellent manner. At the head of the table sat President Madden, supported right and left by officers and guests of the Club. During dinner much interest was taken in the music transmitted audibly to all, from the telephone exchange in Cortlandt street, the receivers being placed in the large electroliers, only the resonators showing. Enthusiasm was also evoked by the sorbet which was served in moulds like incandescent lamp bulbs and by the ice cream which took the form of a telephone set, complete and correct enough in every detail to pass as a dangerous infringement.

The hall of the Club house, it may be mentioned, was ornamented by a beautiful floral double carbon arc lamp, mounted on a base of flowers, upon which were the words "Science," "Progress," etc. This was the gift of Dr. De Lery.

The evening, after dinner, was whiled away with a programme of infinite variety. Gen. O. E. Madden, as President, first made made a brief and felicitous speech of welcome; he was followed in quick succession by ex-President Henry C. Davis, Judge Taylor, of Indiana, Grosvenor P. Lowrey, Gen. Greeley, and W. D. Sargent, president of the National Telephone Exchange Association. Then came Angus Hibbard with a song, and Mr. F. Z. Maguire with some original stanzas hitting off humorously the merits and idiosyncracies of the more modest members of the Club. Mr. Alec. Patterson also spoke with such eloquence that a quartette had to sing two or three times before equanimity was restored. Mr. E. T. Gilliland, late president of the Club, made a few earnest remarks, and to him suceeded the Hon. C. Maclaren, ex-M. P., and a nephew of John Bright, whose fervid expressions of good will and esteem were returned to him ten fold in applause and cheers. Mr. C. Dutton, Dr. Otto A. Moses, Capt. Zalinski, U. S. A., Lt. Veeder, U. S. N., and C. L. Thayer, also were required to confirm their reputations as after dinner orators.

Letters and telegrams of regret were read from Dr. L. Waldo, U. S. Senator Plumb, Abram S. Hewitt, J. I. Sabin, T. B. Doolittle and J. J. Dickey. After the regular programme, the "bars were let down," and joviality unrestrained took possession of the place until the small hours of the morning. The Club has never given a more brilliant, more successful or more perfect entertainment than this.

CONTESTING FRANKLIN'S WILL.

The bequest by which Benjamin Franklin left to each of the cities of Boston and Philadelphia, in 1790, the sum of £1000 sterling to be loaned out at 5 per cent. to deserving young married artificers is being disputed in the courts by his descendants. In Boston the fund has reached $400,000 and in Philadelphia, $100,000. The contest is based upon several grounds, the most important of which is what is known as the rule of perpetuities in common law. The law does not provide for the vesting of a legacy beyond the period of twenty-one years after the lifetime of the legatee, except funds devoted to charity. It is distinctly alleged that Franklin's plan did not contemplate charity from the fact that interest was charged on the loans. The claim is also raised that the purpose of the testator has not been fulfilled, owing to the apathy and negligence of the trustees, both in Philadelphia and Boston.

LITERATURE.

Practical Electrical Engineering: A Complete Treatise on the Construction and Management of Electrical Apparatus as Used in Electric Lighting and the Electric Transmission of Power. By W. W. Beaumont, C. H. W. Biggs (Editor), C. Capito, G. Kapp, A. Reckenzaun, P. Sellon, J. Swinburne and H. Swan. London, Biggs & Co.; New York, J. A. Penman. Published in 18 monthly parts, 10 x 13 in. Price, 75 cents per part.

THE literature of electricity has during the past ten years increased at such a rate that but few can hope to keep pace with it and this is true as well of periodical literature as of that issued in book form. But in spite of this, complaints are frequently heard of a lack of what is termed "practical information," such as will enable the student to design and carry out actual construction according to the best practice of the day, and, on the other hand, will afford the practicing engineer a ready hand-book of reference. To afford such information to the large number who are constantly demanding it is evidently a work of no mean proportions, and it must necessarily embrace departments of so varied a character that no one person will be able to write authoritatively on all the subjects connected with practical electrical engineering problems of the day. The electrical enginner at the present time is called upon as often to solve questions of mechanical and steam engineering as he is those of an electrical nature, and hence a work to be of use must include all these other branches within its scope. To fulfill this object there has recently appeared the work entitled as above, of which four parts now lie before us.

The eminence of the contributors would at the outset appear to be guarantee of its value, and a closer examination of the parts which have thus far appeared yields unmistakable indications of the value of the work. The idea which the authors have set before them, is to furnish the reader with a record of the best results of ripe experience, rather than the history of the experiments which have led up to them. For all that, however, a thorough exposé of the subject must include the principles upon which established facts are grounded, and hence it is eminently proper that the work opens with a chapter on the general engineering principles of electricity, in which the two circuits, the inductive and the magnetic, are taken up and thoroughly discussed, and the main laws upon which many calculations depend clearly set forth. The various phenomena connected with the wire carrying a current, including magnetic, heating and others most generally involved in electrical engineering apparatus, are very fully treated, and numerous tables giving the results of practical experiments are added, among them being the most recent ones of Mr. Preece and Prof. Forbes. The chemical action of the current is also given due consideration.

Next in order we find the phenomena connected with the exterior of a conductor carrying current, and with the magnetic circuit, taken up; and the interactions between a conductor carrying a current and one with no current, and two conductors both carrying currents, are discussed. A short but concise chapter on the inductive circuit, in which the relation of charged bodies to one another and their specific inductive capacity is treated furnishes what may be called the exposé of the principles; and we may remark here that, throughout, the subject is presented in an entirely original manner, differing widely from that met with in the usual text books. In some respects its dicta and dogmas vary from the popular notions now prevailing, but it is none the less clear, and to the extent of its novelty is all the more interesting.

The leading notion here employed in the explanation of the phenomena treated has been to consider that current is due to a difference of electrical pressure, and this idea will be carried out, and we believe with advantage, in the subsequent parts of the work, when the description of machines will be gone into.

In chapter V what is called Electro-graphics is taken up, which will give the student an excellent idea of the manner of representing graphically the action met with, and the results obtained in electrical tests. This is an important consideration, as to many, a table of values is not nearly so eloquent as a curve representing the action going on, as, for instance, in the construction and calculation of dynamo-electric machines.

Chapter VI takes up the central station and treats of the installation of all the parts which go to make up this important element in the distribution of electricity. After a preliminary discussion of the economic problems and conditions to be met with in the situation of a station, the manner of its construction is gone into in a very thorough manner, beginning with its foundations and passing through the entire construction. In the part before us the information on the nature of the soils and methods of building is briefly but concisely sketched and present indeed a very good resumé of this part of the subject. Part III continues the central station work, and taking up the subject of steam boilers describes very fully the construction of a variety of boilers, the designing of chimneys and the numerous details which pertain to this part of the plant. Some attention is also given to the design of boilers, the strength of the parts, etc., and the relative advantages of various methods of construction.

Part X, which has been issued in advance of the intermediate numbers, and very wisely so, takes up the subject of dynamos, alternators and transformers. Though only the mere beginning of what is to come, the contents of these forty-two pages give sufficient proof that the reader will be entertained with a literary treat on a subject as to which the demand for information is enormous, but upon which, unfortunately, but a comparatively small amount of matter is available, or rather digestible, by the majority of readers. Mr. Kapp presents in a clear manner the conditions involved in the construction of such machines, beginning with the general scope of the theory of dynamo-electric machines and passing in succession through the magnetic field, the calculation of its strength, and measurement, and he accompanies the various discussions by numerous practical examples which have unhappily been lacking in many otherwise good discussions of the subject, but which are here introduced with excellent effect and will be welcomed by many readers. This part of the work is not entirely free from formulas, nor could it be otherwise, as the subject is one which for a thorough treatment must introduce calculations of a higher order than simple arithmetic; but for all that they are of such a nature that they can be readily handled, and, indeed, the more important ones are quite simple. Here are also discussed the magnetic properties of iron, and the relations which they bear in the construction of dynamo-electric machines. The loss met with in the magnetization of iron is also taken up and the author gradually leads up to the electromotive force generated in the armature conductor on its passage through the field of a given strength and with a given velocity.

While the contents of the parts before us are exceedingly accurate in the light of the most modern research, there are one or two points which we think require notice. Thus on page 8, Prof. Matthiessen's table of conductivity of the metals is very properly given as a standard. On page 11 we find this same table referred to and expressed in a different form, but showing the conductivity of copper to be greater than that of silver, and the relative values of the other metals are also different from those of the Matthiessen table. It is evident that the second table has been constructed from data embodied in the results of the latest investigations, such as those of Benoit. It would have been well to have pointed out this discrepancy in order to avoid possible misconception on the part of the reader. In the discussion of power and work we notice an error on page 14, in which a horse power is given as equal to 42.75 thermal units. This confusing of power, that is, the *rate* of doing work, with thermal units which represent actual work or energy, seems to us to require pointing out and correction. In a subsequent part of the work, page 10, of Part X, in referring to the same question, the proper definition is given, though in a somewhat different form. In a work like this, however, slips of this sort will, of course, come in, but they do not affect the accuracy of the work as a whole and are merely pointed out for possible future revision.

The book throughout is clearly illustrated and printed in large, clear type. We shall await with pleasure the issuance of the succeeding parts of this noble work, which seems destined to place in the hands of the student and engineer what many have been looking forward to with anxiety and hope for a long time past.

JOSEPH WETZLER.

LOVE, RYAN & BURNETT.

A new law firm just formed in this city with offices in the Potter Building, Park Row, is likely to have the best wishes and cordial interest of the electrical fraternity. It is that of Love, Ryan & Burnett. Mr. H. Warren Love is a graduate of the Albany Law School and a practitioner of many years experience. Mr. James G. Burnett is a graduate of the Law School of the National University at Washington, and in his early days was a newspaper man. Under his supervision was constructed a telegraph line from the *New York Herald* office to Whitestone, L. I., and it is believed that this was the first line ever built and owned by a newspaper. Of Mr. R. W. Ryan, the other member of the firm, it is needless to say very much to electrical engineers. He is a graduate of the New York University Law School, but has only of late taken up the active practice of his profession. Being perhaps the best technical stenographer in this city, his services have been in unceasing demand for this very difficult class of work. and hence he has hardly ever had a moment to think of anything else. Not only has he been retained by nearly all the engineering bodies in New York, but he has been particularly popular with electrical men, so that he has reported the proceedings for years past of the National Electric Light Association, the American Institute of Electrical Engineers, the New York Electric Club, the National Telephone Exchange Association, and others. This peculiarily new and difficult work has been done with marvelous accuracy and the greatest intelligence. Latterly Mr. Ryan has been acting as private secretary to Police Commissioner McLean, a distinguished lawyer, and he thus arrives at the goal of a worthy ambition.

EUROPEAN CORRESPONDENCE.

LONDON.

Electric Traction in Leeds.—Electric Lighting of Small Towns.—Electric Light in Churches.—Electric Light in Madrid.—Telephones and Churches.—French vs. English Steel.—Fire Risk Rules.—London Central Station.—French Elmore Company.—Electric Car Accident.

I MENTIONED in my last letter that it was probable electric cars would be adopted on a section of line in Leeds. The proposal has now taken a more definite form. The Thomson-Houston Company, through their English agents, have offered to place six cars on the line as soon as possible. They undertake to pay the Corporation the nominal rental of 100 guineas on the understanding that the local authority erect sheds for the cars, offices, and other necessary buildings. At the end of two years, if the Corporation decide to use electricity on the other lines in the town, the rolling stock of the American company will be sold to them at a fixed valuation. This matter has to be finally settled by the Highways Committee and the County Council; if these bodies approve, the cars will be in working order by the end of the year.

Another town to be wholly lighted by electricity is a small place named Fareham, in the county of Hampshire. It is a somewhat remarkable thing that the smaller towns have shown, in regard to electric lighting, much more progress than the larger places.

Chelmsford, one of the earliest to adopt electric lighting publicly, is a comparatively small place. Fareham is an old-fashioned English country town, blending ancient rusticity and modern trade. The lighting is carried out by the Fareham Electric Light Company, a concern supported entirely by local capital. To comply with Board of Trade regulations the wires are carried on tall poles. The two chief streets with a united length of about a mile are lighted by 21 arc lamps of 1,200 candle power each, Thomson-Houston system. The smaller streets are lighted by 20 candle-power incandescent lamps, one lamp being placed where previously stood a gas lamp. Messrs. Laing, Wharton & Down, agents for Thomson-Houston, are responsible for the work. The company has entered into an engagement with the town authorities to light the town for three years for £500 per annum, to give an average of eight hours light every night all the year round. A curious feature in connection with the lighting is to see the parties arrive at night fall from the surrounding villages, who stand in little groups about the quiet streets and gaze for a considerable period at the lamps.

Church lighting by electricity is becoming fashionable, and the latest addition to light in dark places is St. John the Divine, Brixton. The plant supplies 300 incandescent lamps. A motor is also used for blowing the organ.

The Electricity Supply Co. of Spain, an English Company acting under a concession from the local authorities, has just completed a central station in Madrid, and houses are being lighted at a distance of two miles from the works.

The telephone company in Birmingham is arranging a system by which subscribers will be connected with the church presided over by a popular preacher, and will be enabled to hear the sermon with distinctness.

In my former letter it was said that Mr. Preece had found French steel much superior to English. An English firm now say that they supplied the very specimens characterized as French to M. Marchal, and have supplied him for many years past. This certainly replaces the feather in the cap of English manufacturers.

The Fire Risk Rules have been the subject for correspondence in the columns of the *Times*, which has lasted a considerable period. Prof. Silvanus Thompson and many others have taken part in a wordy warfare. The rules laid down by the Institution of Electrical Engineers and adopted by some companies have caused considerable dissatisfaction to many. Others on the contrary hold that the rules are practically safe. No matter what may be the outcome of this, few fires have been caused in London by the use of electric light.

It is stated that the Manchester Square station of the Metropolitan Company is near completion, and at present they are running one 100-unit dynamo night and day. It is probable that I shall have more to say about this later on.

The French Elmore Copper Co. has been formed to work the patents of Messrs. Elmore in France, with a capital of £200,000 in £2 shares. 66,750 shares were offered to the public at a premium of 10 s. per share. I hear on very good authority that there were three times as many applications for shares as could be supplied.

A newspaper correspondent telegraphed from Florence yesterday the news of a fatal accident which occurred on the electric tramway between that place and Fiesole. The cars ran off the track, five persons being killed on the spot and twenty others injured.

H. S.

LONDON, Sept. 24, 1890.

CORRESPONDENCE.

CHICAGO.

A Brotherhood of Telegraphers Movement.

A MEETING of railroad and commercial telegraph operators was held last week at Orpheus Hall, on La Salle street, for the purpose of effecting an affiliation between the commercial operators and the railroad operators, and was called by the Brotherhood of Telegraphers.

The organizer, Mr. A. L. Morris, explained that the Brotherhood had at the present time nine active lodges and nine others in the course of organization. In an address he said that the difficulty telegraphers were laboring under at present was want of organization between the commercial and the railroad men, and that when any trouble arose with the commercial men railroad operators could be obtained by the Western Union or Postal from the railroads, and vice versa. If the men would only organize and bring about an amalgamation of the two bodies they could maintain the rate of wages, and instead of first-class men earning $65 per month they could demand the standard pay of $80 or $90. He thought the organization of both bodies of men in one brotherhood would deter rather than promote a strike, as the mere fact of such a brotherhood existing would prevent the cutting down of wages.

Before the meeting adjourned a number of commercial and railroad operators joined the new organization. About sixty-five operators were present.

CHICAGO, Oct. 4, 1890.

BOSTON.

Lighting the Shoe and Leather Exchange.—The Boston Electric Elevated Road.

THE petition heard before the gas commissioners, Tuesday, wherein the Shoe and Leather Exchange ask that the Edison company be obliged to furnish electric lights for their building is complicated by the fact that the building has its own dynamos, and the Edison company's electricity is wanted only after the building's dynamos have stopped. The dynamo is run from about 2 o'clock to 6, and a few tenants need light later. The Exchange was represented by H. W. Chaplin and the Edison company by W. W. Gooch; Messrs. Claflin & Kimball, agents of the Mather electric system, were present in the interest of the Exchange, as they furnished the dynamos and did the wiring in the building. The Edison company claimed that the system in use in the Exchange was not suitable for the working of their plant, while the Exchange put in evidence to show that it could be operated with ease.

President Whitney, of the West End Street Railway Company, has at last unfolded his scheme for an elevated railroad in this city, and a conference between representatives of the West End Company, Mayor Hart, Corporation Counsel Richardson, and the members of the railroad committee of the Board of Aldermen was held at the West End Company's office on Wednesday. The scheme provides for a double track 4.90 miles long, extending from Roxbury post office *via* Washington street to East Dedham street, thence to Harrison avenue and Hawley street, thence *via* Water street to Devonshire street, thence to Haymarket square *via* Adams square and New Washington street, thence to Charlestown, and from thence to Charlestown Neck, the northern terminus, with a loop touching the northern depots. This route necessitates the formation of a new street from Harrison avenue to Hawley street, and also from Hawley street to Water street, the value of the property which will have to be torn down being probably about $2,500,000, though it is not yet decided whether the railway company will have to bear the whole expense.

The site of the Roxbury station has not yet been decided upon, but it will be in close proximity to the post office on Warren street. The Charlestown Neck station will be near the West End car stable there, on land now owned by the company.

The style of elevated structure to be used has not yet been decided upon. President Whitney, Vice-president Reardon, General Manager Monks and Electrical Engineer Pierson have been making extensive researches in this connection, and have examined about every elevated road system that has been invented. One conclusion they have reached is that their roadway shall not be like that of any yet built, but shall contain all the good features of such as they have seen, and some points entirely original.

They have engaged as chief engineer, Thomas C. Clarke, and he is now at work on plans. Mr. Clarke is one of the most noted engineers in the country. He had charge of the Gilbert elevated road in New York, designed the Poughkeepsie bridge and several others in this country and abroad, and was consulting engineer on the Brooklyn bridge.

All the details as to motive power have not yet been settled, and experiments are constantly being made at the works of the

company on Albany street. One thing is certain, and that is that electricity will be used, so that there can be no ground for objection to the road on account of smoke and cinders. The power will be applied to the motors by means of feed wires, as is the case with the present surface road system, but instead of being strung overhead they will be laid along the structure at, or a little below, the level of the tracks, and the current will be supplied through connections under the motors.

The opinion seems to be generally favorable to the scheme, though in event of its rejection another route may be laid out which would not necessitate the destruction of property, but which would introduce a number of dangerous curves. The new streets would be a boon to the city anyhow, as they would serve to relieve Washington street of much of its heavy traffic.

BOSTON, Mass., Oct. 4, 1890.

PITTSBURGH.

A New Electric Forging Machine.—An Electrical Oil Well Driller.—Electric Railway Work.—Municipal Electric Service.

ELECTRICITY is about to be introduced in the iron mills of Carnegie, Phipps & Company, in this city, in the manufacture of iron and steel. Two prominent officials of that firm recently received a patent for an electrical device, called an electric-forging machine, which is used for the purpose of "stoving" eye-bolts for bridge structures. The machine so far has only been used on an experimental basis, but as these experiments have been very successful, it will be generally introduced in the works very shortly. The inventors claim that by the use of this machine a greater amount of work can be performed, and there will also be a great economy in time and expense, as fuel will only be needed to furnish power for the dynamos.

Another Western Pennsylvanian is also deserving of great credit for inventing an electrical machine to be utilized in the drilling of oil wells. The apparatus is a unique affair, and if a success, the business of drilling oil wells will be entirely different to what it has been heretofore. It is a well-known fact that at present a great many heavy tools, necessary in drilling oil wells, are very cumbersome to handle. This new device, however, is to do away with them. It is an apparatus composed of a series of small motors arranged behind each other. This appliance is let down into the well and drills the hole. The rod and drill bits are projecting from the series of motors and the combined force of all acts upon the rod and the bits. Several tests have been made with the machine and all are said to have proved the apparatus to be a great success. The inventor claims that his machine will not only be a more effective driller than the appliances now used, but it will also be labor saving.

The Verner Street Electric Railway Company has been organized under a charter received a few days ago from Harrisburg. Work on the road will soon be commenced. When completed, the line is to be combined in the Pittsburgh and Manchester Electric Railroad system.

All the machinery for the new electric fire alarm office in this city will soon be in position, and Mr. Morris Mead, the superintendent of the Pittsburgh bureau of electricity, says that he will have the most complete fire alarm in this country.

In the city of Allegheny, where an electric light plant is now operated by the municipal authorities, an increase of the number of lights is soon to take place. The plant has now 3,000 incandescent and 450 arc lights, Westinghouse alternating current system, and the city intends to put up one hundred additional arc lamps.

PITTSBURGH, October 3, 1890.

ELECTRIC LIGHTING IN WASHINGTON STATE.

Mr. A. C. Balch, of the Pacific Electric Light Co., of Seattle, Wash., writes us : "In THE ELECTRICAL ENGINEER of August 20, I find an article on Central Station Statistics of the United States, in which the statement is made that in Washington there are central stations using 250 arc lights. This does not give Washington credit for quite as many as are being burned, as Tacoma has some 600, and Seattle, over 750. Port Townsend, Spokane Falls, and Walla Walla, each have quite a number, besides a great many smaller plants in other towns with from 30 to 50 each." It will be remembered that with regard to the statistics, which were not our own, we said that they would be found conservative and under the reality. Mr. Balch's interesting data shows that this is particularly true of so rapidly progressive a State as Washington.

Of the numerous forms of lamp guards now in use, many need a shade-holder, and others have so coarse a mesh as to afford but little protection. Seeing this, Mr. George Cutter has brought out a new form of expanding wire-guard which combines the good features of all the others. It has five rings surrounding the part of the bulb which most needs the protection, has sliding sleeves which adapt it to any 16 candle-power lamp, and looks much neater than the older forms. The Great Western Electric Supply Co. are pushing this guard.

REPORTS OF COMPANIES.

NORTHWESTERN TELEPHONE EXCHANGE CO.

The Northwestern Telephone Exchange Company (Erie company) has elected the following officers : President, Levi Sprague ; secretary and treasurer, Charles J. Glidden ; directors, Levi Sprague, Charles J. Glidden, A. S. Adams, C. E. Adams, W. A. Gove, J. E. Hudson, Francis Jewett, J. W. C. Pickering, A. C. Russell, Thomas Sherwin, James A. Weston and H. A. Whiting.

INTERNATIONAL PORTELECTRIC CO.

The annual meeting of the stockholders of this company will be held at its office, 254 Pearl street, Wednesday, October 8th, 1890, at 2 p. m., for the election of Trustees for the ensuing year, and any other business that may regularly be brought before the meeting. The Transfer Books will be closed at 3 p. m., October 4th, and reopened on the morning of October 9th, following.

CLEVELAND TELEPHONE CO.

The Cleveland Telephone Co. has chosen the following officers: —President, Levi Sprague ; vice-president, J. P. McKinstry ; secretary and treasurer, C. J. Glidden ; directors, Levi Sprague, J. P. McKinstry, Charles J. Glidden, C. E. Adams, J. E. Hudson, A. B. Hough, W. J. McKinnie, T. Sherwin, G. W. Short, E. P. Wright, E. P. Williams ; executive committee, Levi Sprague, Charles J. Glidden, A. S. Adams, C. E. Adams, J. E. Hudson, W. A. Gove, Francis Jewett, J. W. C. Pickering, A. C. Russell, Thomas Sherwin, James A. Weston, H. A. Whiting.

HEAVY DEALINGS IN THOMSON-HOUSTON STOCK.

At a meeting on Saturday, Sept. 27, the Thomson-Houston board of directors voted to sell Messrs. Lee, Higginson & Co. 50,000 shares of common stock at $50 per share (less a bankers' commision, presumably), and they have now voted to sell shareholders of Oct. 8, 10,000 shares of common stock at $50, payable on or before Oct. 15, and chose T. Jefferson Coolidge, Jr., president of the Old Colony Trust Company, a director of the Thomson-Houston Company. It is understood that President S. Endicott Peabody, of the American Loan & Trust Company, will also enter the Thomson-Houston board. The 50,000 shares of stock are payable Oct. 1. Speaking of this, the Boston *Herald* says : "These sales will yield the company $3,000,000, less any bankers' commission, an amount sufficient to clear off every note payable, and leave a working balance in cash. The addition of the names of Messrs. Coolidge and Peabody will introduce a strong Boston financial element to the board, and the sale through the banking house will increase the strong and wealthy element in the list of stockholders. The Thomson-Houston company has been a sort of Lynn institution, with a certain wealthy backing in Boston and New York. The large sale of preferred stock was to a considerable extent made abroad. The new issue of common goes chiefly to investors, and it compliments the bankers that they have placed this stock in a pinching money market, which they could do through their own endorsement and the exhibit which the company was able to make privately, an exhibit heretofore outlined in a general way in this column. The bankers not only bought 50,000 shares of common stock, for which they already had a market, but could place 6,000 to 7,000 more, which, perhaps, assures the taking of the 10,000 shares, if stockholders do not want them. The company still has 60,000 shares of common stock in the treasury, whose sale is authorized by vote of shareholders. It does not appear that the company has any need to sell this balance, and it would possibly help the market for outstanding shares if a resolution not to sell these shares within a stated period should be passed by the directors. The present sale in private helps the stock by cancelling the debt and by bringing strong support to the company. How much of the proceeds of the 50,000 shares, $2,500,000, payable Oct. 1, remains in Boston, and how much of it comes from Boston, is not known. The company still owes $300,000 on account of the Brush purchase, payable in equal installments in October, November and December, or all may be paid in advance. That money may go out of town, and then some notes payable are believed to be held by out of town institutions. It is quite possible that this transaction may be a factor in the money market. The Thomson-Houston Company receives, say, $3,000,000 for common stock, say, $2,500,000 for preferred stock and $1,000,000 on account of collateral trust bonds—say, $6,500,000 in all, a pretty good indication that its maturing obligations were in the vicinity of $6,000,000. The issued stock will soon stand at $6,000,000 common and $4,000,000 preferred, the latter requiring $280,000 for a year's dividend, and the latter $960,000, on the proposed basis of $4 per share, $1 quarterly. Together the dividends would call for $1,240,000 per annum, a figure far within present net earnings, as claimed."

FINANCIAL MARKET.

QUOTATIONS ON ELECTRICAL STOCKS.

Mr. F. Z. Maguire, Electrical Securities, of 18 Wall street, this city, reports the following quotations of October 4th from New York, Boston and Washington:—

A TOWER OF LIGHT AT PORTLAND, ORE.

At the Exposition now being held at Portland, Ore., a tower, very similar in construction and appearance to the one which was called the "Tower of Light" at the Lenox Lyceum last spring, has been erected, and lighted with Edison miniature lamps. This is set in a large bank of flowers. The tower and festoons contain about 3,000 lamps of 4 c. p. each. The Edison Lamp Department have received a telegram from Portland, Ore., stating that the tower was completed in time to be lighted on the opening night and was a great success, giving entire satisfaction to the management and winning much applause from the public.

LEGAL NOTES.

LEGAL METHODS OF MAKING TELEPHONE CONNECTIONS.

The United States Circuit Court at Wheeling, W. Va., Sept. 11, held that a telephone company has the right to determine the manner and mode of making connections with subscribers, and there is nothing to prevent the companies changing from time to time these modes of connection with proper notice. The case was a suit for damages because the company insisted on subscribers calling for numbers and not for names.

A DECISION AGAINST W. U. POLES AND WIRES.

A decision made by Judge Stevens in the United States Court at Grand Rapids, Mich., on Oct. 2, is very important to the entire country, as it affects the right of the Western Union Telegraph Co., to use highways for their wires. Judge Severence rendered the opinion, and it was concurred in by Circuit Judge Jackson. It is the opinion of the court that the act of Congress permitting the Western Union to use all the Government Postal routes to string their wires, is permissive only, and does not give the company the right to go into the States and use the highways and byways unless by State authority, and that the occupancy and use of the streets must be under the regulations of the police powers vested in the several States.

The court further holds that the charter gives the city authorities power to regulate the use of the public highway, and that the city authorities can exclude the wires from any street, and can designate in which streets the company can erect poles and string wires. When the injunction was dissolved last week the city authorities promptly cut down the poles, and they are still down.

ELECTRIC RAILROADING AT BUFFALO, N. Y.

The Park electric system of the Buffalo Street Railroad Company has been doing some remarkable work this summer. Four cars are running on this branch, a distance of about one and three-quarter miles. The traffic on pleasant Sundays is extremely heavy, and each car is required to draw two trailers for a large portion of the day. Under these circumstances the following figures will be of interest:

July 16th, the road carried 17,000 passengers.
July 20th, " " " 8,000 "
July 27th, " " " 11,000 "
Aug. 3d, " " " 5,000 "
Aug. 10th, " " " 9,000 "
Aug. 17th, " " " 3,000 "
Aug. 25th, " " " 10,000 "

On August 3d the day was cold and disagreeable; on August 17th the weather was cold and rainy, which accounts for the small number of passengers carried.

This road is equipped upon the Edison system and has been in operation now for about fifteen months with remarkable results, the repair bills having been merely nominal, although the service called for has been excessive, particularly in the summer. The largest load ever carried was a little over twenty thousand, the occasion being a picnic, and the time being two days after the road commenced operation in July, 1889. But three motor cars were in service on that day, and this remains the greatest record ever made by that number of cars.

OBITUARY.—COL. A. D. BULLOCK.

Col. Anthony D. Bullock, of Cincinnati, president of the City and Suburban Telegraph Association and of the Bell Telephone Exchange, a prominent and wealthy capitalist and a highly esteemed citizen, died of apoplexy at his home in Mount Auburn, Friday evening, Oct. 3. He has two sons, one in Williamsrown, Mass., and one in Cincinnati. No man in Cincinnati was better known or more highly esteemed.

TRADE NOTES AND NOVELTIES

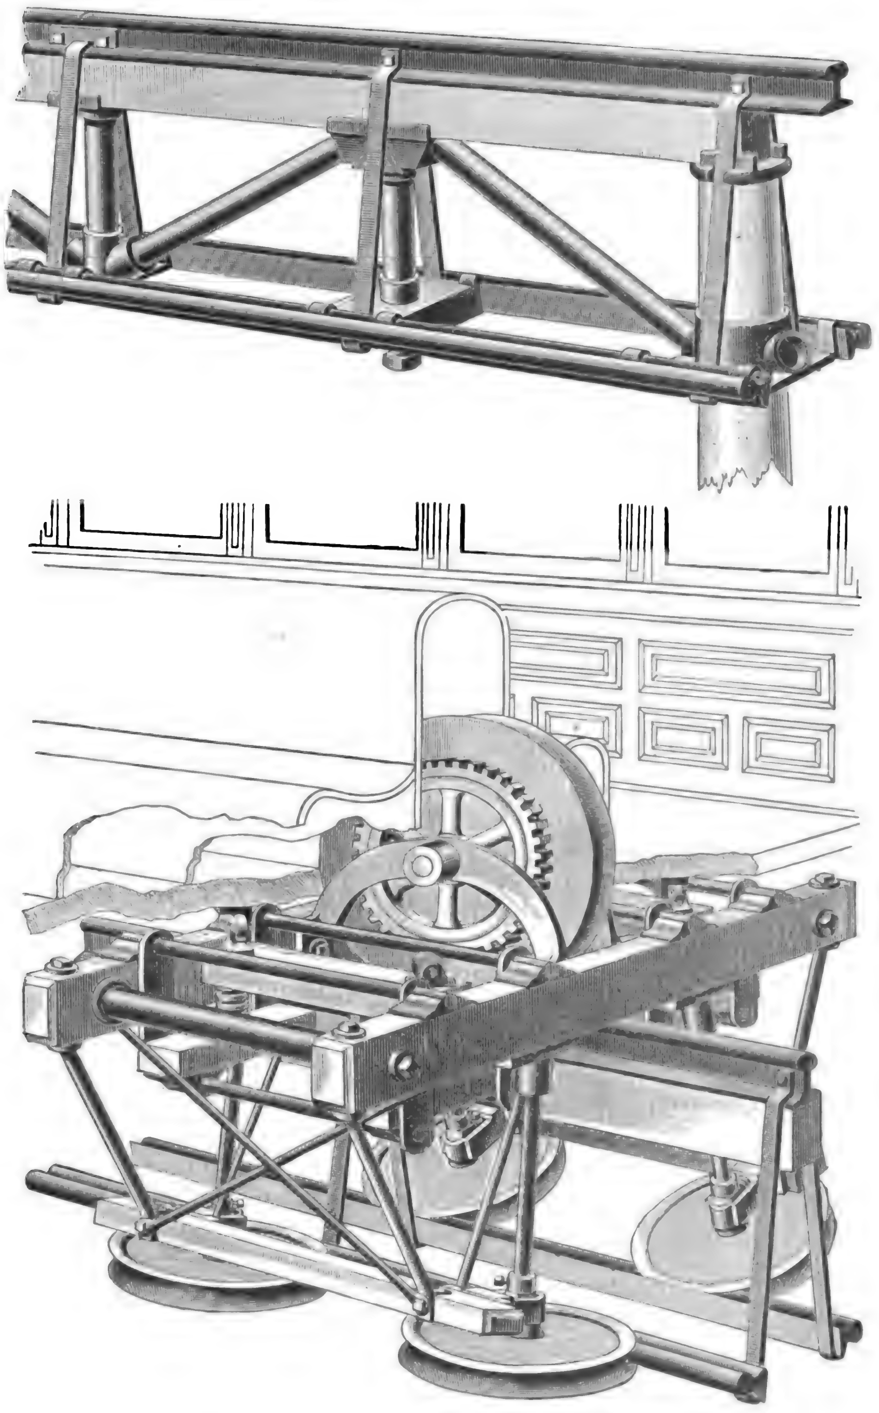
AND MECHANICAL DEPARTMENT.

THE UNICYCLE RAILWAY AT THE ST. LOUIS EXPOSITION.

The Turner system, which is known as the Unicycle Railroad, is shown in actual operation in the north end of the casement, at the St. Louis Electrical Exposition. A small Unicycle car, having a seating capacity for a motorman and two passengers, runs backward and forward on a single rail elevated track 120 feet in length. A 1 h. p. Sprague motor supplies the motive power. The system by its novelty attracts widespread interest, and hundreds of passengers are carried over it daily.

The inventor has sought to devise a simple elevated structure composed of few parts and easily constructed. Fig. 1 shows one section of a span. The main beam and rail are supported by posts which are well anchored into the earth. Side straps are bolted to the main rail, and, extending downward, have hooked ends which hold up the guide rails. Gauge pieces are placed between the guide rails, resting on the upper flange of same by two hooks on each side. These gauge pieces serve as rests for the lower ends of angle and upright braces. The centre gauge piece of each section serves as a nut for a tension screw for tightening up the section.

Fig. 2 shows a truck without the electric motor. The main double flange wheel runs on the main rail, revolving in bearings on two yokes from which are suspended the truck and car. The truck is provided with braces and beams which carry four small double flanged guide wheels. The guide wheels engage closely with the guide rails, and thereby keep the car upright, and also lock the truck firmly to the main rail.



FIGS 1 AND 2.—THE TURNER UNICYCLE RAILWAY.

The truck has a swivel motion. Anti-friction rollers play between the car bottom and truck frame working in a flanged ring on the bottom of the car, thus permitting the car to turn a short curve with ease and safety. The beams which carry the anti-friction rollers are mounted on springs, thus enabling the car to ride easily.

The electric motor is geared to the spur wheel on the main

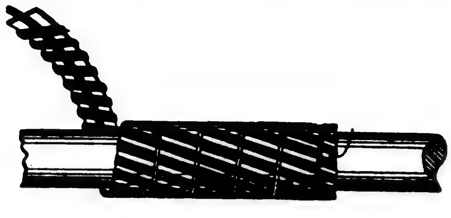
axle. The trolley wire is supported on one side of the main beam.

There is an automatic device not shown in the figure for equalizing the weight on the centre of the car and thus taking off all unnecessary friction.

The system is preferably constructed as a double-line road, the two sets of tracks running parallel. The two lines can be braced together, and thus made more substantial.

A NOVELTY IN INSULATION.

Mr. Charles F. Splitdorf, of this city, has recently patented an interesting novelty, in the line of insulated wire, by which high insulation and fire-proof qualities are obtained. This is effected by covering the conductor with thin and narrow strips of mica,



NEW SPLITDORF INSULATION.

first protecting and strengthening the mica strips by wrapping them round with silk, cotton, paper or other pliable and non-conducting material. The illustration herewith shows Mr. Splitdorf's method of insulation. The high insulating property of mica would indicate that wire covered by this new method would be very useful in cases of severe strain upon the insulation, such as is frequently met with in electric railway motors.

A NOVEL BILL OF FARE.

A report gained currency last week that the distinguished inventor of jokes and pleasantries, Bill Nye, had been secured by the new firm of Alexander, Barney & Chapin as an expert. While willing to believe anything evincing enterprise on the part of the new house, the electrical public thought that in this instance there must be a mistake. The appearance during the week of a highly original "menu," confirms the report, however, and Mr. Nye is to be congratulated on his venture as an electrical humorist. Surely none but he would have thought of blue vitriol for soup; turtle gong as an entrée; insulated joints under the head of roasts; automatic drops for dessert; and coffee in porous cups, with no grounds. We print the menu in full as a curiosity:

OYSTERS.

(no grounds).

CIGARS.

Electric Club.

October 6, 1890.

This tempting menu was sent all over the country to friends and future patrons of the house, and Monday, 6th, saw the beginning of the influx, the store at 20 Cortlandt street being opened on that day for the first time for regular business. Lunch was served to three or four hundred visitors, among whom were the officials of all the leading electrical concerns in the city. There was also an excellent display of electrical supplies of all kinds.

ACTIVITY OF THE WESTINGHOUSE ELECTRIC AND MANUFACTURING CO.

It is a fact, which experience in the electrical business has always manifested, that during the summer months, the industry is less active than during the remainder of the year. It is in the summer that the largest electric companies get an opportunity to catch up in filling those orders with which they are behind; or else they have a chance for working ahead and getting ready for the time when the heavy fall trade begins. Reports from all over the country show that this year is the greatest the electrical industry has ever known, and one of the largest companies is already so stocked with contracts for the equipment of electric lighting central station plants, for isolated plants, for electric railway equipment, etc., that the works are now being operated at their utmost capacity day and night, with every prospect of having to continue in that way for the entire winter. This company is the Westinghouse Electric and Manufacturing Company.

Since the company entered the field of constructing electric railway motors, especially, it has been obliged to increase its facilities very extensively. The many advantages of the company's railway motor have made it already familiar among most of the electric railway people in the country and the result is an influx of many contracts for street railway equipment.

The total amount of orders for alternating current incandescent lighting apparatus received during the month of September, aggregate 28,250 lights, which is over a thousand lights for each working day. Besides this, the demand for Westinghouse alternating current arc lighting apparatus has been unusually heavy and the company is far behind with its orders in that department. In the electrical railway department it is the same. The company has orders for the equipment of forty roads, calling for machinery valued at almost one million dollars and still the demand is increasing. The noiseless motor of the company on the Pleasant Valley Electric line, in Pittsburgh, continues to attract attention. To give an idea of the silent manner in which the motor operates it is only necessary to remark that the officers of the street car line have been requested by residents along the route to place a small bell on the axle of the car in order to make known to the people its approach and thus prevent accidents to children.

Among the new central station plants of alternating current lighting, the Westinghouse company has obtained contracts from Owensboro, Ind., 750 lights; Akron, O., 1500; Bedford, Ind., 750 lights; Norwalk, O., 1000 lights; Lykens, Pa., 750 lights; Penn Yan, N. Y., 750 lights.

In addition a number of the older central station plants have increased their capacity considerably. Among those having contracted with the company for an increase during the month of September are: Englewood, a suburb of Chicago, Ill., for 3000 lights; Bay City, Mich., 3000 lights; Duluth, Minn., 750 lights and Youngstown, O., 750 lights. It is remarkable in the latter case, that this plant in Youngstown is not yet in operation at all. After the company was organized, the management contracted with the Westinghouse Electric Co. for alternating current apparatus of a capacity of 2250 lights; but even before this machinery had been installed the management realized that the demand was greater than it had been at first anticipated and therefore this increase was ordered.

W. R. FLEMING & CO.

The firm of W. R. Fleming & Co., 174 Fulton St., this city, have been very busily engaged in the installation of numerous electric light plants. Representing the Ide and Ideal Engines, manufactured by the Foundry and Machine Dep't, H'b'g., Pa., and having consequently both centre and side crank engines of the same merit and make to present to purchasers, they have found some advantage, as their business record shows, over their past position in the sale of side crank engines only. Probably one of the showiest plants in New York city is being installed by them for running an Edison incandescent plant for the Hotel Marlborough, at 36th St. and Broadway. Two 80 h. p. self-oiling "Ideal" automatic engines will be the present engine equipment there.

Contracts have just been made for engines of this style for the following well-known concerns: Ferry-boat "New Brunswick," 40 h. p.; Fleischman & Co., New York, 30 h. p.; Browning, King & Co., New York, two 50 h. p. (6th order); Edison Ill. Co., New York, one 50 h. p.; Penn. R. R. Co., one 40 h. p.; Standard Oil Co., Jersey City, one 70 h. p.; C. H. Blanchard, New York, two 80 h. p.; Johns-Pratt Co., Hartford, Conn., one 70 h. p.

A number of large boiler plants have also been installed in the following towns: Providence, R. I., Martinsburg, W. Va., New York city, Fort. Worth, Texas, Cordele, Ga., and Montgomery, Ala.

SCHIEREN BELTINGS IN ELECTRICAL PLANTS.

About six months ago, Chas. A. Schieren & Co., of Ferry and Cliff streets, received an order from the Louisiana Electric Light Co., of New Orleans, for 160 feet, 72 inch, double leather belt, and 550 feet, 48 inch. This 72 inch belt, which is said to be the largest and heaviest leather belt in the world, has just been put on, and the firm have received a contract for a duplicate 72 inch belt. This will make two such huge belts in that single plant, besides about 600 feet of the 48 inch double. Chas. A. Schieren & Co., have lately extended their operations into the electric railway field, where they are already enjoying excellent success with their "Perforated" electric belting. The perforations prevent air cushions from forming under the belt, and hence the leather retains a firmer grip on the pulleys without slipping. The perforated belts will run with greater slack without slipping than any unperforated belt, consequently there is less strain on the bearings and the belts adapt themselves to the uneven strain of railway work, which is a peculiar strain, viz: the load is all thrown on at once, and all thrown off very suddenly. They have sold perforated electric belts to a great many electric railways, among which are the following: Utica, N. Y., Belt Line R. R. Co.; Seashore Electric Railway Co., Asbury Park, N. J.; Pennsylvania Motor Co., Easton, Pa.; Binghamton, N. Y., St. Railway Co.; Daft Electric Co., Philadelphia, Pa.; Omaha, Neb., Street Railway Co.; Edison Elec. Ill. Co., Brockton, Mass.; Edison Elec. Ill. Co., Newport, R. I.; Bangor, Me., Elec. Light & Power Co.; San Antonio, Tex., Street Railway Co.; Joliet, Ill., Street Railway Co.; Greenwood & Greenlawn R. R. Co., Columbus, O.; Naumkeag Street Railway Co., Salem, Mass.; Metropolitan Street Railway Co., Toronto, Ont.

The Belt.

Making the Belt.

A NEW DINING-ROOM PUSH.

It would seem that so simple a thing as a push-button leaves little room for improvement or change, but this is not wholly true. In the case of pushes used in connection with a wall or floor connection and a flexible cord, the extension part of the floor-push is now considered quite essential. Still the push button which is in use may be on the table, or on the lap of the hostess, or very likely on the floor, unless special pains are taken to look after it. But this is to be so no longer, for Mr. Chas. G. Armstrong has designed an attachment which holds the push in any desired place. It is evident from the cut that the new push

The Armstrong Dining-Room Push.

can readily be slipped on to the edge of the table, or on one of the side panels, or even on a chair. Whether the push is uppermost, or is concealed by being turned downward, it is always just where you put it. Any style of push-button can be furnished with this improvement, and the Great Western Electric Supply Co. will undoubtedly find a great demand for it.

NEW ENGLAND TRADE NOTES.

The Tripp Manufacturing Company, of Boston, will be represented at the Street Railway Convention, to be held at Buffalo, this month, and will have on exhibition a large model of their standard electric trucks, which are meeting with such favor with the street railway companies. The model will be equipped with the Tripp Anti-Friction Journal Bearings.

The Bryant Electric Company, of Bridgeport, Conn., have issued a neat little pamphlet, illustrating their specialties in switches, sockets, cut-outs, etc., with prices of same. These goods are having a large sale and the Bryant Company are already making arrangements to double their capacity.

E. S. Ritchie & Sons, of Brookline, Mass., have issued a complete catalogue of electrical testing instruments suitable for factory and laboratory use. The quality of these instruments, both in material and workmanship, is of a high standard, and are much more reasonable in price than those of foreign manufacture. Messrs. Ritchie & Sons supply the schools and colleges with these instruments, and are prepared also to build any special instruments which may be desired. A perusal of the catalogue will repay the reader, and they are useful to have at hand for reference at all times.

The Robinson Radial Car Company have received an order from the West End Street Railway Company, for 35 more horse cars, fitted with the Robinson Radial truck.

The Tropical American Telephone Company has secured the exclusive right to a new long distance telephone set, capable of transmitting 500 miles, for export purposes to the countries controlled by them.

The Thomson Electric Welding Company has leased three complete machines to Mr. Edison for use at his Schenectady works in welding copper wire from No. 20 to one-half inch. They will be delivered within 30 days, and are expected to make 3000 welds per day.

WESTERN TRADE NOTES.

The Sperry Electric Company are pushed to their utmost capacity filling orders for their arc light apparatus, and the demand for the new triple carbon arc lamp is increasing all the time.

J. Lang & Co., 44 Michigan street, Chicago, are very busy manufacturing the well known Lang & Andrews main line switches. They are largely used all over the country, especially for heavy currents, on account of their extreme simplicity and reliability. The new switches recently placed upon the market for alternating current work are also giving the greatest satisfaction.

Wm. Baragwanath & Son, 56 W. Division street, Chicago, have just completed a monster heater ordered a short while ago by the Chicago Edison Company, which weighs about 11 tons. Their shop is well filled with work on heaters of all sizes, and the large numbers which they have placed are spoken of in the highest terms of commendation by their users.

The Western Power Construction Company are meeting with the greatest success in building and equipping power plants. The McIntosh-Seymour engines, for which they are the exclusive Western agents, are giving the best of satisfaction wherever they have been installed, and are specially noticeable by reason of their noiseless running, regulation under variable loads, and high efficiency.

Mr. W. J. Floyd, who has recently joined the forces of the Sperry Electric Company as sales agent, is meeting with good success in pushing the apparatus of this well known company, and has already closed several large deals. Both the Sperry Company and Mr. Floyd are to be congratulated on the connection.

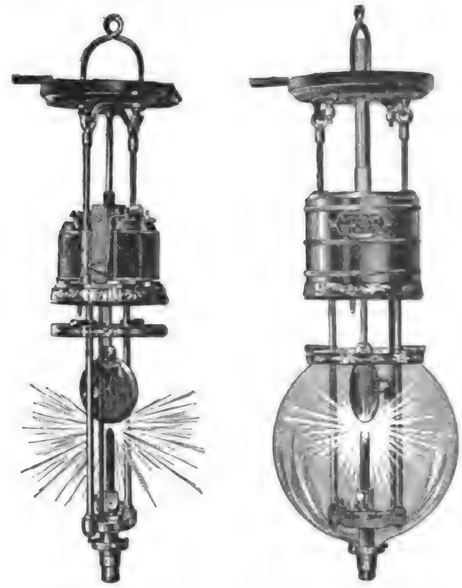
The Electrical Supply Co., 171 Randolph street, are as usual receiving orders from all parts of the country for their many specialties. They are continually adding new and valuable devices to their large line of supplies. They are doing a very large business in Habirshaw wire, for which they are the Western agents. The high insulating properties and toughness of this insulation are known from one end of the country to the other, and a vast quantity of it is in use in places where a high grade wire is called for.

The Pumpelly Storage Battery Company are making a large quantity of cells with their new method of sealing recently introduced by them. Their batteries are remarkable for the heavy discharge they will stand without buckling of the plates, and the general rough usage to which they can be subjected without injury or deterioration. The company are paying special attention to traction work, and manufacturing a very durable and compact cell specially adapted for this use.

THE RUSSELL ARC LAMP AT THE ST. LOUIS EXPOSITION.

THE Russell Electric Lamp Co., of 85 Water street, Boston, exhibit their 7 and 10 ampere arc lamps in operation. The new lamps attracts a great deal of attention among both electric light people and users of arc lights.

The novel feature of this lamp consists in substituting a carbon disc in place of the upper carbon rod. The upper carbon holder is controlled by a simple clutch device precisely as in the ordinary single carbon lamp. The carbon disc is attached to an axis by a very simple device and the axis is pressed into bearings in the ends of a yoke pin carried by the upper carbon holder. The axis carries a small pinion which engages with a rack. The rack is stationary and has no movement. By the movement of the upper carbon holder, the pinion—being engaged with the stationary rack—is caused to rotate and thus a rotary motion is



FIGS. 1 AND 2.—RUSSELL ARC LAMP.

given to the carbon disc. A fresh and unburned portion of the carbon disc is, therefore, steadily being brought into the arc. The disc of course has a slight vertical motion by reason of the feeding action of the clutch, but the rotary motion caused by the rack and pinion is the greatest and the one on which the perfection of regulation depends.

In the 10 ampere lamp the disc is about 4¼ inches in diameter, and the lower carbon, which is of the ordinary pencil form, is from 9 to 15 inches in length according to requirements. The 12 hour lamps are 33 inches in length and consume 9 inches of carbon, while the 24 hour lamps are 50 inches in length and consume 16 inches of carbon. Some of the advantages claimed for the lamp are that no light is wasted. The carbon disc being slightly thicker than the lower carbon, the rays are thrown out horizontally. There being less carbon resistance, less electric energy is required to produce a given light; and there is less cost for carbons per hour of lighting. Being shorter, it is specially suitable for inside use; and being of simple mechanical construction without complicated small parts, it is not liable to get out of order or to require delicate adjustment.

ORDERS FOR FITCHBURG ENGINES.

The Fitchburg Steam Engine Co. have recently received through their Philadelphia representative, Mr. G. H. Conner, Builders Exchange, the following orders:—Complete steam plant for the Suburban Electric Light Co., Tacony, Pa., for two 400 h. p. compound condensing slow speed engines, boilers, pumps &c. Also plant for the Powelton Electric Co., Philadelphia, for two 250 h. p. compound condensing slow speed engines, pumps, &c. Also one 250 h. p. engine for the Frog Moor Mills, Frankford, Pa. Also engine, &c., for Jacob Miller Sons & Co., Bordentown, N. J. Also two engines, boilers, bleach, &c., for the paper mill of T. S. Marshall & Son, Yorklyn, Del. They are also building a large compound condensing engine for the Quincy Market Cold Storage Co., Boston. Also for Clinton (Mass.) Electric Light Co.; Morgan Envelope Co., Springfield, Mass.; Farley Paper Co., Erving, Mass.; Boston Rubber Shoe Co.; Meriden Britannia Co., Meriden, Ct.; C. Parker Co., Meriden, Ct.; Crosby Steam Gauge Co., Boston. Also complete plant for a large brick company in Georgia. They are just starting engine for the Princeton (N. J.) Electric Light Co. They have also orders through their Chicago agents, Messrs. Kimball & Teal, 100 h. p. 80 h. p., and 75 h. p. engines for Chicago. Also 100 h. p. engine for Geneseo (Ill.) Electric Light Co., and are also building fourth engine for the large paper mill of P. H. Glatfelter, Spring Grove, Pa. This company have just completed a large plant for the U. S. Government at the Watervliet Arsenal, Troy, N. Y.

THE VAN NUIS "AJAX" SWITCHES.

Mr. C. S. Van Nuis, of 74 Cortlandt street, who has for some time past been devoting himself very successfully to the designing and manufacture of switches for heavy currents, will be present at the Buffalo Street Railway Convention with a full line of "Ajax" switches for street railway purposes. As is well known, the currents required in railway work are of heavy amperage, and Mr. Van Nuis has shown most creditable ingenuity in meeting the problems of the case.

THE RIVER AND RAIL STORAGE BATTERY.

The River and Rail Storage Battery Co. are about to issue a neat and tasteful catalogue of their storage batteries for various purposes, including medical use, phonograph work, domestic uses, etc. The company are receiving very flattering notices from those who have bought their batteries, and this new catalogue will serve to describe the merits of the cell to such as have not yet tried it.

THE "NATIONAL" SYSTEM AT JENKINTOWN, PA.

Mr. L. N. Cox, the agent of the National system at Washington, D. C., received recently the following letter from Mr. J. W. Ridpath, secretary of the Jenkintown, Pa., Light Co.: "We have a 1,000-light National machine running in a temporary plant, with a 25 h. p. engine, and furnishing 500 lights. With all the disadvantages under which we are laboring, the light is good, strong and steady."

THE WHITE "DAISY" RAIL CHAIRS.

Mr. R. T. White, the well-known inventor of the "Daisy" chair, etc., will be in attendance at the Buffalo convention next week with a model of his elevated railroad, cable road and conduit, "Daisy" chairs and girder rails, "Eureka" or channel iron form of street railway construction, and other novelties. This display of important novelties will prove very attractive.

THE WAINWRIGHT HEATERS, CONDENSERS, ETC.

The Wainwright Manufacturing Co., of Massachusetts, report a very large business for August and September in their improved corrugated tube feed water heaters, surface condenser and expansion joints. In these two months they sold 94 heaters and condensers, aggregating 11,095 h. p., and 44 large expansion joints, 8″, 12″, 14″, 16″, 18″ and 20″.

The following large concerns were among their customers for heaters, condensers and expansion joints, in the above period: Clinton Electric Light Co., Mass., 300 h. p.; New Bedford Gas Light Co., New Bedford, 700 h. p.; Fitchburg Steam Engine Co., Mass., 5 heaters, 800 h. p.; City of Easton Electric Light Department, Pa., 400 h. p.; Waltham Gas and Electric Light Co., Mass., 300 h. p.; Plymouth Electric Light Co., Mass., 250 h. p.

Many of the orders for heaters and condensers were made up in sizes from 20 h. p. to 150 h. p., inclusive, shipped to the following places: Mexico, South Carolina, Massachusetts, Maine, Connecticut, Illinois, Ohio, Pennsylvania, New Jersey, Minnesota, New York, Wisconsin, Long Island, West Virginia, Kentucky and Rhode Island. Among the orders for expansion joints were: West End Street Railway Co., Boston, 14, and Narragansett Electric Light Co., Providence, R. I., 2.

This company's business since their organization in 1889 has increased to a very great extent; and they now have the chief works in their line of goods in the country. They own exclusively all patents previously controlled by the Wainwright Manufacturing Co., besides many valuable patents granted since their organization.

The direct cause of their success is the great efficiency of their specialties, the prices of which are lower than for the ordinary manufactures.

Besides the above specialties this company does a good business in automatic gauge valves, corrugated copper baskets and Barnard's separators.

AN AUTOMATIC CUT-OUT CLOCK IN A BROADWAY STORE.

Jackson's mourning store people, No. 777 Broadway, are lighting their show windows with 10 incandescent lamps. The United States Electric Light Co. has put in an automatic clock and cut-out, which extinguishes the lights at midnight (or as soon before as necessary), thus saving the expense to the consumer of using the lights later than necessary and also saving the cost and trouble of a man to extinguish them at the desired hour. This is a case where the purchaser was looking for just such a device, before adopting electricity for illuminating purposes at night. The number of show windows throughout the country which are wired and fitted for electricity, but which are not used on account of the aforesaid expense, is very large. To such, the automatic clock and cut-out is a boon, as well as a profit to the electric light companies. W. H. Gordon & Co., 115 Broadway, N. Y., have taken the general agency for this automatic clock and cut-out.

THE

Electrical Engineer.

VOL. X. OCTOBER 15, 1890. No. 128.

WORK ON THE WEST END STATION, THE LARGEST ELECTRIC POWER HOUSE IN THE WORLD.

BY A. C. SHAW.

IN view of the interest which naturally tends towards the application of electricity to street car propulsion, at this time, owing to the meeting of the Street Ra lway companies in Buffalo, I have thought there would be many persons glad to see the two engravings herewith showing the state of piling that was necessary must be borne in mind. Fig. 1 represents a view looking through the boiler house, and shows the style of the girder roof and the extent of the area required for the boilers. Fig. 2 is a view looking down on the foundation work for the large Corliss engines, and gives an excellent idea of the magnitude of the work. The foundation work is now all completed, about 8,000 piles having been driven, and about 35,000 tons of concrete and masonry used in its construction. The boiler house has been built for the full capacity of the steam power

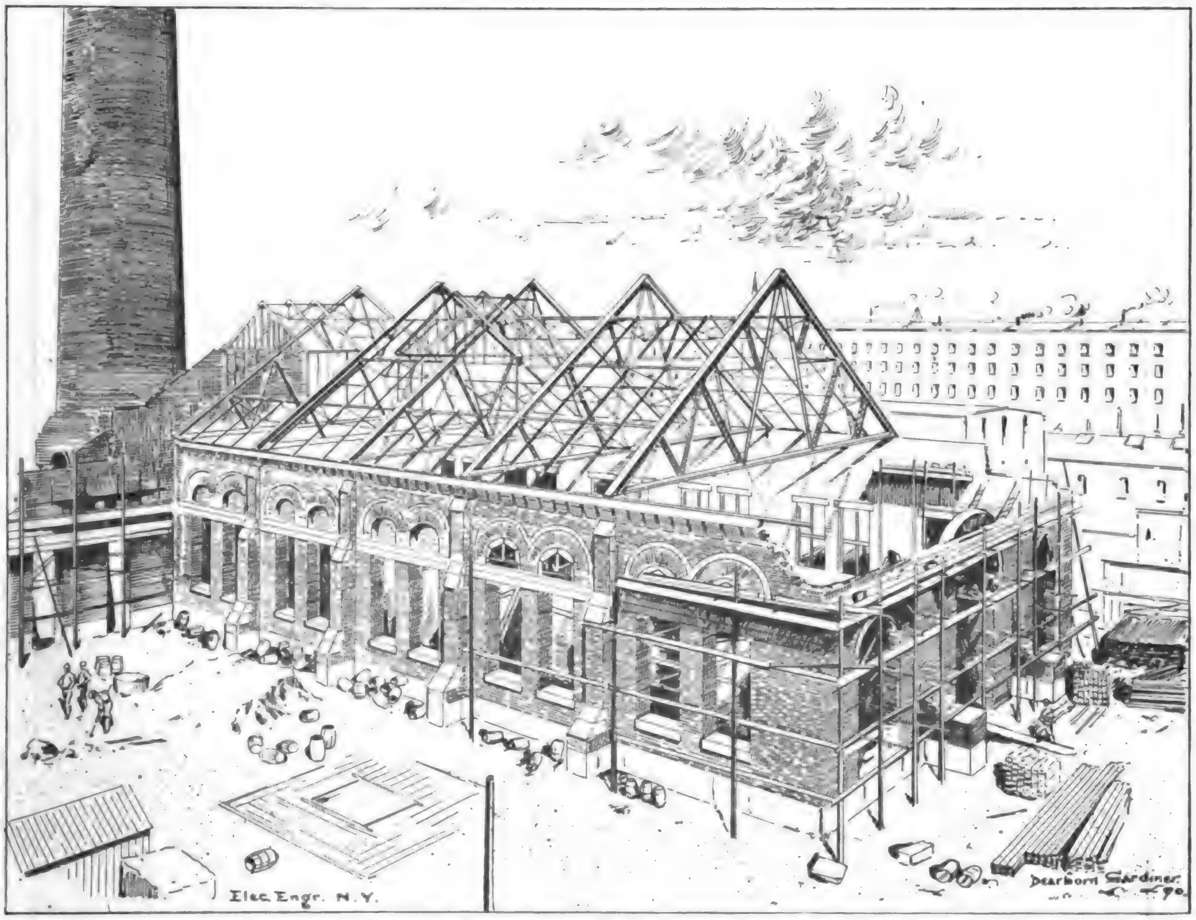


FIG. 1.—BOILER HOUSE, ELECTRIC POWER STATION, WEST END RAILWAY, BOSTON, MASS.

the buildings for the reception of the largest electric power plant in the world, in process of construction for the West End Street Railway Company, of Boston. The buildings are at present in a very unfinished condition, as shown by the engravings, yet so much interest is taken in the progress of this station, that I believe the pictures will attract some attention. The work on the foundations was begun about the first of October, 1889, so that one year has already elapsed, and, though apparently it is a long time, the nature of the ground and the immense amount of required, namely, 6,500 horse-power, though there will be steam enough for engine capacity of 13,000 horse-power. The dimensions of the house are 158 feet by 79 feet 6 inches, and six batteries of Babcock & Wilcox boilers of 500 horse-power each will be put in at present. The walls are of brick 33 feet high, and the girders of the double Fink truss type, built by the Boston Bridge Works, are all in position as shown. They are five in number, and have a span of 85 feet 10 inches. The chimney rests on a base 56 feet square, tapering to 30 feet at the top of the

foundation. It is now up 192 feet, measuring about 19 feet in diameter where it is now, and is 26 feet 8 inches in diameter at its base. It will ultimately have a height of 252 feet. Adjacent to the chimney and between the boiler house and the power house are the economizer rooms, pump room, toilet room and feeder rooms. The power house has foundations for six 1000 h. p. engines, now being built by E. P. Allis & Company, of Milwaukee, Wis., three being ranged on each side with the fly-wheels facing one another. The engine foundations are about 60 feet by 14 feet at the bottom, and 45 feet by 9 feet at the top. There is 12 feet of solid masonry, 9 feet of brick work, and a 20-inch stone slab on top for the engine to rest on.

The power house measures about 176 feet in width by about 150 feet long, and there will be a temporary wall built on the Harrison Avenue side, that is, the side furthest from the boiler house, as it is the ultimate intention to put in seven other similar engines, though the increase will probably not be made for two or three years. The engraving shows the Fink truss, of which there are three, for the roof of the central part of the power house, covering the countershafting and dynamo floor. The trusses for the roof over the engines will be similar in design, and will rest one side on the middle trusses, and the other on the walls of the building, which are not yet completed. The roof will probably be completed by December 1st, when

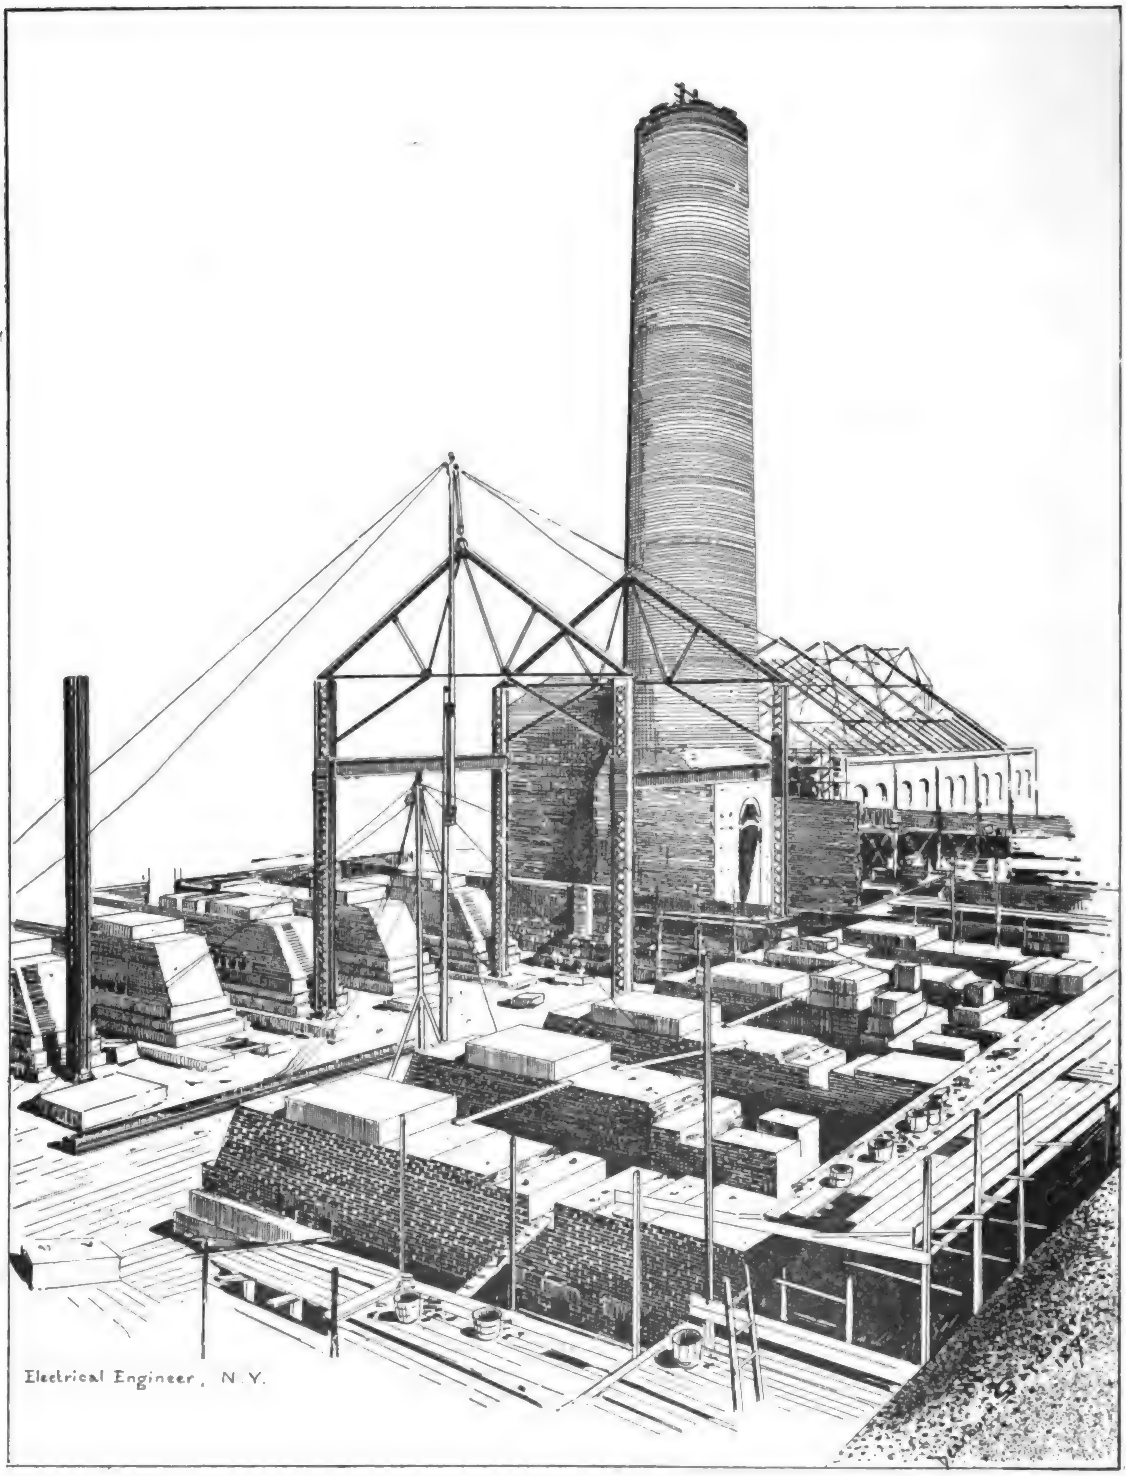

FIG. 2.—ENGINE AND DYNAMO HOUSE, ELECTRIC POWER STATION, WEST END RAILWAY, BOSTON, MASS.

the active setting of the engines and boilers will commence, and it is expected by May, 1891, to have some of the engines ready for work. The work is being rapidly carried on, and is attracting great attention on the part of visitors from all parts of the world.

THE RAE ELECTRIC RAILWAY SYSTEM.

As our readers may be aware, one of the first electric railways put into operation was the Highland Park Electric Railway, which was started in 1884, and is still in successful operation. This road was built by the Detroit Electrical Works, who some time ago put their railway and motor department in charge of Mr. Frank B. Rae, as electrical engineer, who has developed the system so that it represents to-day a whole, complete in every detail. As a complete description of the Rae system has not yet appeared, we present such an one to readers, from which it will be evident that Mr. Rea has struck out on a new line in more than one direction.

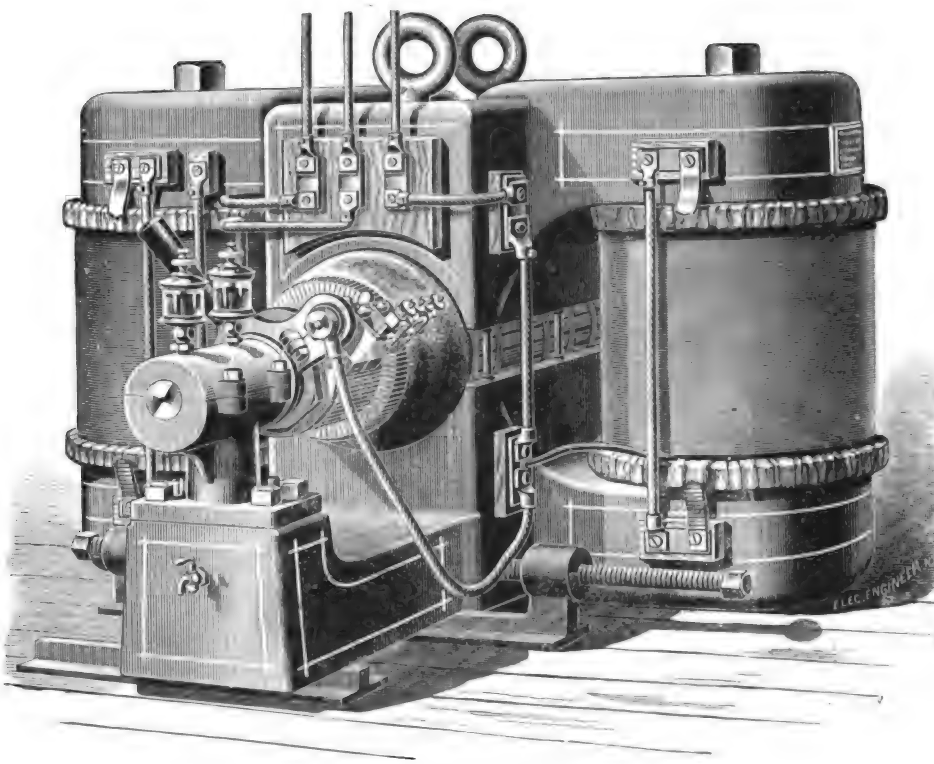

FIG. 1.—THE RAE RAILWAY POWER GENERATOR.

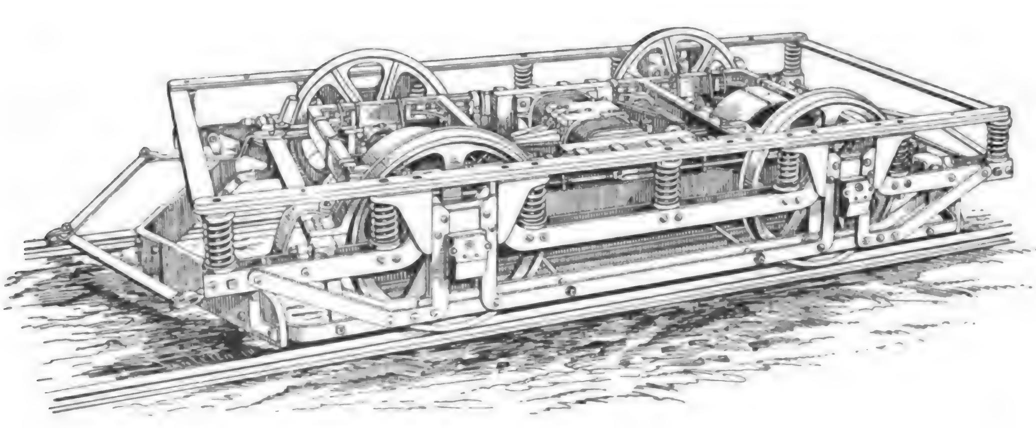

FIG. 2.—SINGLE MOTOR TRUCK, RAE ELECTRIC RAILWAY SYSTEM.

Beginning with the main source of power, the electric generator, we would call attention to a number of novel features entering into the construction of the Rae railway power generator. This machine, which is illustrated in the accompanying engraving, Fig. 1, is built in sizes of 40,000, 65,000, and 80,000 watts. The standard E. M. F. of 550 volts is maintained throughout the Rae system, and in order to avoid variation in potential on the line, with its consequent ill effects, the generators are compound wound. The field magnets, in order to obtain the highest magnetic effects, are made with wrought iron cores, and so that the magnetic strength may remain equal throughout the circuit, the cast iron employed for the yoke pieces is made of a section equivalent in magnetic capacity to that of the wrought iron.

Experiment has shown that the influence of the compound winding is enhanced by placing that winding as close to the armature as practicable. This has been carried out in the present instance by placing the winding on the cast iron yokes at the end of the cores. The compound winding, it will be noticed, consists of a flat ribbon of

copper, which is made equal in section to that of the armature conductors.

The Siemens armature, which is employed, is encircled by pole pieces, which are made equal in length to that of the armature by being extended at right angles to the main yoke pieces. The armature is built up of soft iron discs .007 inch in diameter, covered with shellaced tissue paper, and at every 20 discs a layer of shellaced cloth is interposed in order to thoroughly provide against the generation of Foucault currents. These discs are mounted on four brass splines, let into the shaft, and so arranged that an air space is left between the shaft and the inner diameter of the discs. By this construction it will be seen that no magnetic lines pass into the shaft, being prevented from doing so by the intervening air space ; and thus practically entirely avoiding leakage and straying of lines from the shaft and bearings. The commutators of all the machines have 80 sections, and the following are the electrical dimensions of the 65,000 watt machine : Armature wire, 1,000 feet of No. 4 B. & S., resistance, .061 ohm. Shunt winding, No. 17 B. & S., resistance, 250 ohms. The series coil, as above stated, has a carrying capacity equivalent to that of the armature, and consists of 60 turns complete, 15 in each coil.

Particular care has been taken with the connections of the machine, which are all permanently made before being sent from the works. These connections are all composed of copper bars, corded and covered with insulating paint, which is afterwards polished to resemble hard rubber. The shafts and bearings of the machine are extra heavy to withstand the sudden strains which are frequently experienced in railway work.

We come now to what is probably the most important element of an electric railway system, and that is, the motor and truck upon which it is mounted. Much has been said and written in the past on the method of gearing employed, and the relative advantages and disadvantages of each. In accordance with the tendency which seems to be gaining ground in more than one quarter among electric railway engineers, Mr. Rae employs but a single motor on his car, gearing it to both axles. The reduction of the source of power to a single machine brings with it advantages which cannot be denied ; involving, as it does, the equal distribution of power, irrespective of the load on the axles, and reduction in the number of gears and frictional surfaces, and the possibility of employing larger diameters of gears and pinions, with larger wearing surfaces. The general design of the Rae truck is shown in the accompanying engraving, Fig. 2, and Fig. 3 shows the same in plan. The motor has fields and poles of solid wrought iron forged, with the end yokes only of cast iron. From the sides of the pole pieces extend brass arms, which support the armature. A pinion at one end of the armature shaft gears directly with the gear of a counter shaft, which transmits the motion to both main axles by a bevel gear at each end. By this arrangement the speed of the motor does not exceed 900 revolutions at the full speed of the car.

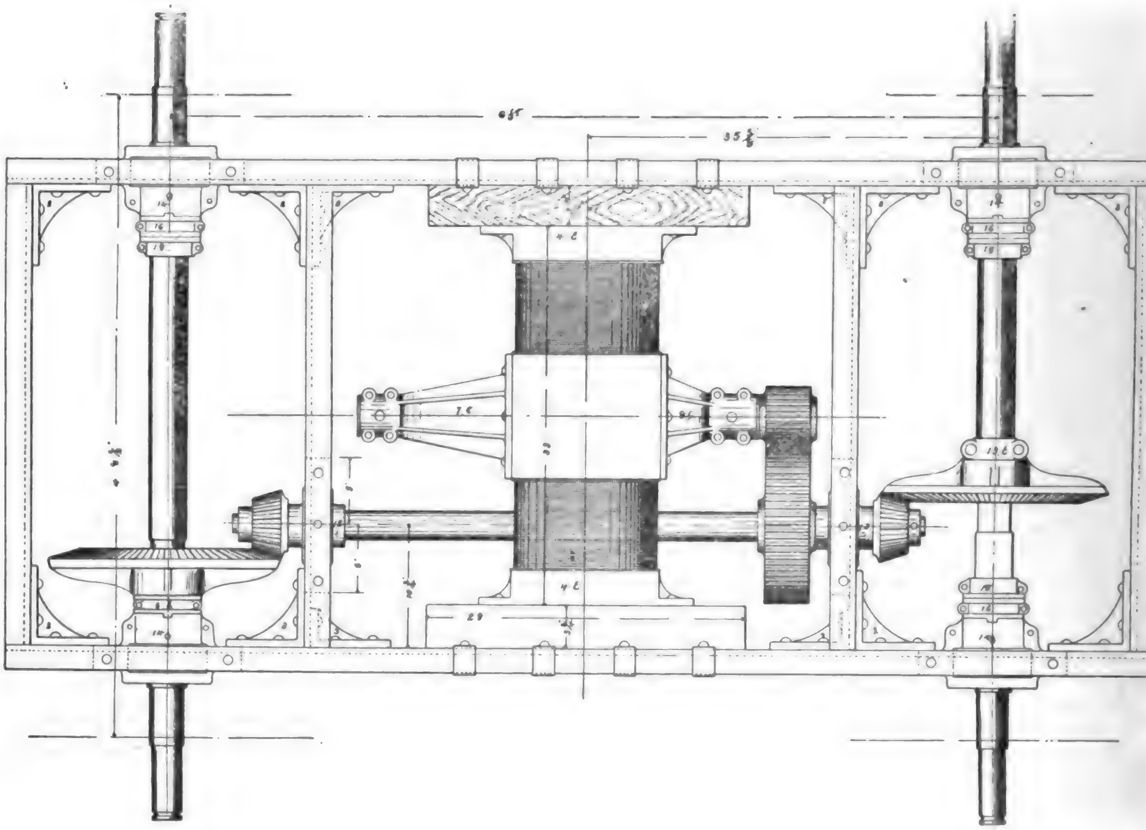

FIG. 3—PLAN VIEW OF TRUCK, RAE ELECTRIC RAILWAY SYSTEM.

The frame on which the motor and gears are mounted is made of channel iron bars with carefully leveled joints, planed square and true, put together with hot rivets, and finally tested for spring. The frame is absolutely rigid, in contradistinction to the usual practice of flexible construction of the motor support. To that end the axles are mounted in rigid bearings and side motion prevented by the use of graphite friction collars, which can be taken up when they wear. This avoids all back lash of the gear and consequent noise. The bevel gears are thoroughly encased in dust-proof boxes and run in oil. The motor is entirely insulated, being supported at the sides, as shown, by $2\frac{1}{2}$ inch oak pieces saturated in asphalt, and in addition by the raw hide or leatheroid pinions employed. The motor is of 30 h. p., and in the 16-foot car type a 6-foot wheel base is employed.

Special attention has been paid by Mr. Rae to the question of lubrication, and for that purpose all the bearings are bushed with graphite, doing away, practically, with oil,

and thus avoiding the dirt and other inconviences attendant on its use.

The motor employed on the car is series wound, and the means employed for its regulation by the motorman on the platform are exceedingly simple. The arrangement for that purpose is shown in the accompanying engraving, Fig. 4. The regulation of speed is effected by the interposition of four resistances through the medium of a very simple switch. These resistances are successively connected with the circuit in parallel, and finally short-circuited. The switch and rheostat containing these resistances is placed under the car, entirely out of the way, and on the platform of the car the single handle illustrated in Fig. 4 is placed. This is moved in one direction, or the other, for going ahead, or reversing. At the centre point a stop is provided, shown below the plate, to prevent accidental reversal of the motor by the motorman throwing the switch handle over beyond the middle point. By pulling out the stop, however, the handle can be reversed. The space occupied on the platform by this arrangement is very small and does not interfere with the occupancy of the platform by passengers.

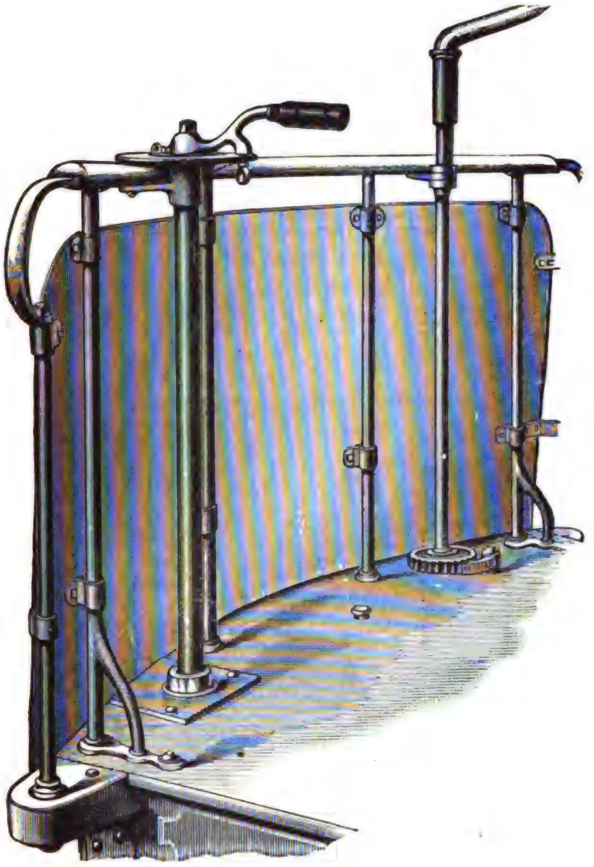

Fig. 4.—Switch-Handle on Platform.

A number of other details of this system relating to the overhead construction will also interest our readers. Among these are the trolley and trolley stand. These are illustrated in the engravings, Figs. 5 and 6. The trolley wheel, it will be noticed, is mounted upon a tubular steel pole, made in one piece, and drawn to three reductions, being ½ inch in diameter at the top and one inch at the bottom. This makes an exceedingly light and strong pole, and thus avoids considerable strain on the trolley stand mounted on the top of the car. The stand, shown in Fig. 6, is of special construction, and so designed that the tension on the springs is equalized throughout the range of motion of the pole. This is accomplished by an arrangement which changes the leverage between the spring and the stub end of the pole.

The trolley wheel itself, mounted on the top of the pole, has a bearing centre of phosphor bronze, the flanged sides which maintain the wheel in contact with the wire being of steel. In order to avoid oiling of the trolley wheel, graphite bearings are employed; the metal of the pole is also used as a conductor leading from the line wire to the motor.

Fig. 5.—Trolley Wheel and Pole.

Mr. Rae has also designed a special trolley line hanger and insulator. This consists of a bell-shaped, porcelain or lava insulator, Fig. 7, with a groove in its head, in which is inserted a brass clamp provided with yokes. A brass bolt is let through the insulator and secured by a nut at the top. This nut fits into a square socket, which is then filled up with insulating material. The clamp to which the line wire is attached is swiveled so as to give full play to the wire. These clamps are of brass. After being hooked on to the span wires the hooks are closed at the lower ends, which firmly secures the insulator in position.

In all Mr. Rae's overhead work the use of solder for connecting the various parts has been entirely avoided, as experience has shown that the heat required to sweat the parts together softens the copper, and when, later on, the slack is taken up, the copper draws at the point where the heat has been applied. To avoid this, therefore, screw clamps are employed throughout. Thus, as just pointed out in the case of the insulator, the wire is clamped to the swiveled suspension and the lower edges of the clamps brought down to a knife edge, so that the trolley passes under the insulator smoothly and without jumping.

This idea has also been carried out in the strain plates employed. These plates are put in at distances of about 1,000 feet, to take the strain off the line, and are also employed at curves, being so arranged as to pull the trolley wire towards the curve and thus to relieve the poles at the curve of all strain. The pull-off used by Mr. Rae embodies this same clamp feature. It is made of a wooden spindle saturated in paraffin and having brass ferrules at each end. The goose neck is made of steel and the whole is painted with insulating paint.

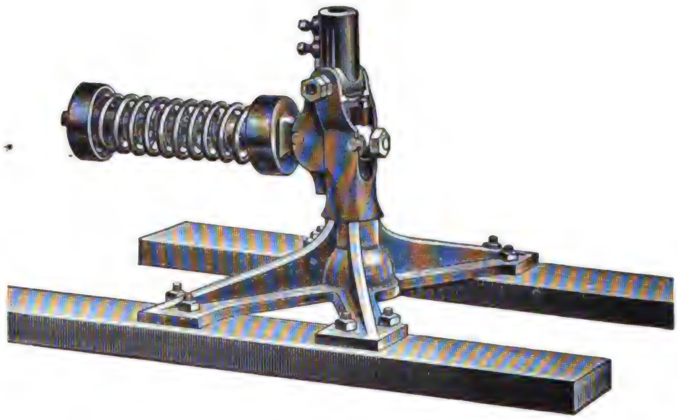

Fig. 6.—Trolley Stand on Top of Car.

Among the various station details employed in connection with the Rae system, space permits our drawing attention to only two; these are, the ammeter and the main switch. The former, which is shown in the engraving,

FIG. 7—TROLLEY LINE HANGER AND INSULATOR.

Fig. 8, is what is known as the Rae horn ammeter, taking its name from the shape of the iron core employed. The divisions are practically equidistant over the full range of the scale.

The compound station switch has three pairs of contacts so arranged that the attendant, of necessity, closes the proper contacts at the proper time, and, vice versa, opens them in their proper order. Thus, the uppermost of the

FIG. 9.—SAGINAW UNION STREET RAILWAY, RAE SYSTEM.

three switches is connected to the trolley wire bus, the central one to the neutral bus and the lower to the ground. In this way the proper connections and disconnections are made automatically.

These constitute the main features of the Rae system, which is now in successful operation in various cities, among them Detroit, Mich., Elkhart, Ind., Fort Worth,

FIG. 8—RAE HORN AMMETER.

Tex., Saginaw, Mich., and other places. The accompanying illustration, Fig. 9, shows a view of one of these roads. It has been remarked that the ease of riding and freedom from noise in the operation of these cars are noteworthy, and the employment of a single motor in place of the customary two is also a feature which the operators of electric railways will appreciate.

BUILDING MOTORS FOR THE SHORT ELECTRIC RAILWAY SYSTEM.

To an electrical engineer few topics are more vital than those which pertain to the design and construction of the apparatus he has to handle in lighting and power. We believe, therefore, that a large number of our readers will be interested in the illustrations and data here given with regard to the apparatus employed for the Short system of electric railways. As the electrical public is aware, this apparatus is built at the extensive works of the Brush Electric Co., in Cleveland. Our admirable contemporay, the *Street Railway Journal*, of whose special field electricity has now taken possession in so remarkable a manner, devotes in its October issue several pages to an illustrated description of the works and their motor product, and has done the thing so well, for its readers, that we are happy to reproduce and abstract some of the matter in the article, for our own.

It will be remembered probably, that in the Short railway system, the familiar Brush machine, that has done so much yeoman and pioneer service as a generator, is employed as a motor. It has, however, been modified in various particulars by Mr. S. H. Short, and now embodies the experience that years of up hill work have given him. As built for railway work, the material for the armature and generator core is thin sheet iron which comes in strips eight feet long and nine inches wide for the generator and five and three-eighths inches wide for the motor. These strips are first rivetted together end to end and wound on a temporary spool, forming a ribbon 920 ft. long for the generator armature and 320 ft. for that of the motor. The spool is then mounted on a shaft and the thin iron ribbon is wound very tightly upon a foundation ring placed in a lathe, as show in Fig. 1, and each concentric ring of the metal is separated or insulated from the other by a strip of manilla paper of the same width, wound off a spool placed on the opposite side of the machine. Two workmen attend to the winding, and as the spool slowly revolves one of them hammers the layers firmly together. As the splice comes in, the machine is stopped for a moment and a small hole is cut in the layer that comes just over the rivetted section so that there is no enlargement of the roll at this point. The ring of the generator when wound weighs 520 lbs. and that of the motor 109 lbs. The object of making the armature cores of laminated instead of solid iron is of course to prevent the generation of eddy currents

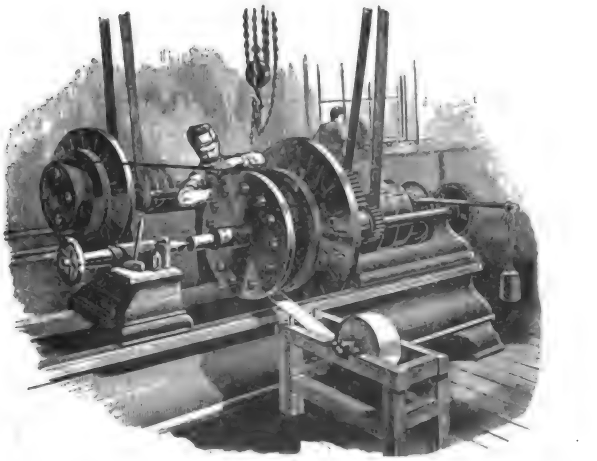

FIG. 1.—WINDING IRON CORE OF SHORT RAILWAY MOTOR.

which would cause the core to heat. The next operation is to drill through the rim of the ring in the direction of the centre, and then rivet the layers and foundation ring firmly together. The rings are then taken to the milling machines, of which there are six for this purpose and one of which is shown in Fig. 2, and pockets or slots are milled in each edge of the rim as shown. In the generator ring forty-eight slots are milled. These are spaced at irregular intervals, but are usually about an inch apart, one-half inch

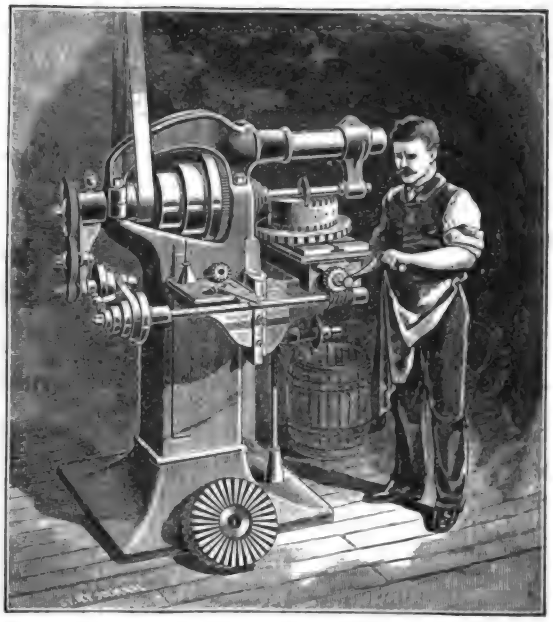

FIG. 2.—MILLING SLOTS IN ARMATURE CORE.

wide and nearly two inches deep. In the motor ring are thirty-two slots.

After leaving the milling machines the slots are smoothed up with a file, the corners of the base are rounded off and the ring is ready for the winding.

Fig. 3 illustrates the method of winding the armatures. Three men work together on the large one, which is about two feet in diameter, and one on the motor armature which is one foot in diameter. The winding consists in placing a number of coils of insulated wire around the rim within the slots, and when wound the wire in each slot is called a "bobbin" The wire for the generator is first cut in sections of suitable length, the ends are coiled up for convenience in handling and in the middle a portion of the insulation is removed and a thin metal strip is soldered to the wire. These strips come directly between the slots on the inside of the ring and are provided for connecting the bobbins together. Before winding, the walls of the slot and both surfaces of the ring are carefully covered with insulating material, consisting of asbestos ribbon, rubber cloth and fibrous material having plates of mica between its layers. As the winding proceeds, strips of canvas are placed between the different coils of wire, the wires are tied firmly together, and painted over with shellac varnish. About fifty feet of $\frac{8}{100}$ of an inch wire are required for winding each bobbin on the motor armature, and there are in all thirty-two bobbins. For each of the forty-eight bobbins of the generator fifty-one feet of $\frac{18}{100}$ of an inch wire are required, which is wound in eight coils. It takes one man four days to wind the armature of the motor, and three men six days to wind that of the generator. When finished the ring is baked for about twelve hours in an oven kept at a high temperature by steam heat, for the purpose of drying the shellac. The ends of the wire composing each bobbin are left in a coil of sufficient length, as shown in the figure, to which a small cable is attached for connecting each with the segments of the commutator.

The process of making the commutator is an interesting one. The bars of copper are cast or forged in peculiar shape, usually two inches wide and ten inches long, wedge shaped through their breadth and with fillets near the ends

which are drilled to receive the wires that connect them with the bobbins. The ends of each bobbin are connected with a bar, so that there are as many bars in a commutator

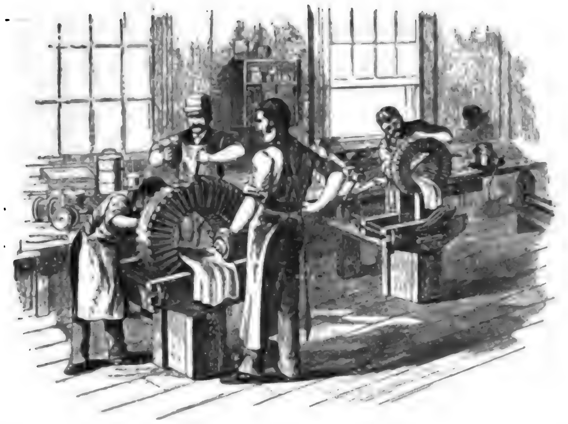

FIG. 3.—WINDING ARMATURE OF SHORT RAILWAY MOTOR.

as there are bobbins. The bars are first set up separated from each other by mica sheets inside of a cast-iron cylinder having numerous threaded bolts through the shell. When all are arranged the bolts are turned up and the bars are brought firmly together and held by shellac and other cementing material. The mica for this work is the best imported India, and is prepared with great care. It is carefully split and inspected, and in making up a plate, which is about one-sixteenth of an inch in thickness, several sheets from different blocks are placed together so as to prevent the possibility of forming a short circuit between any two bars by means of any bit of iron ore that might be in the mica. Each sheet is covered with shellac and the plates are baked to harden the varnish before using.

When completed in the above manner the surface is turned off and polished till it is very smooth and true, and the separate bars are drilled at their ends for receiving the connecting cables.

At another table in the machine shop is witnessed the operation of placing the hub or bearing in the armature. The hub is made of German silver and consists of a sleeve or thimble having four short thin spokes, the outer edges of which are designed to fit in narrow grooves cut on the inner surface of the foundation rings. These are then keyed in and the armature and commutator are ready for mounting on their shafts.

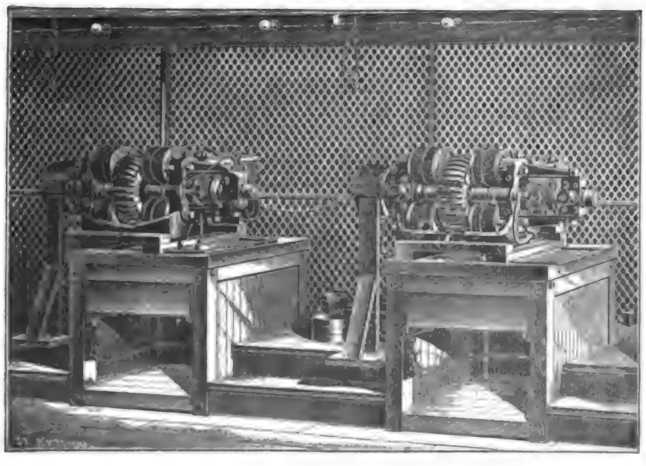

FIG. 4.—STAND FOR TESTING MOTORS.

While we have been watching the above operation a number of men and machines have been at work turning up the generator and motor shafts. Seven lathes are required for this work, and there are three machines making collars and nuts for the shafts. The shaft with its armature and commutator now goes to the connecting room, where the bobbins are connected with the bars of the commutator. Here are a number of young men at work; some are soldering the connecting cables to the coils of the bobbins; others are rivetting the other ends to the commutator bars. The connecting cables are about two feet long, one-eighth of an inch in diameter, and are made of eighty-four exceedingly fine copper wires—No. 50, almost as fine as horse hair.

In an adjoining room—the "kindergarten department" it is called—are a dozen small boys making up these cables. The wire comes braided into a large cable, nearly an inch in diameter, and the boys count out the number for each connection, twist them into a rope and cover it with rubber cloth.

The connections being made, the connecting cables are bound firmly to the shaft and covered with canvas and wire, and with water-proof material. Formerly it was the custom to drill the shaft and lead the connecting wires through the bore to the commutator, but now the bearing is placed outside the armature and the wires are led along the shaft as above.

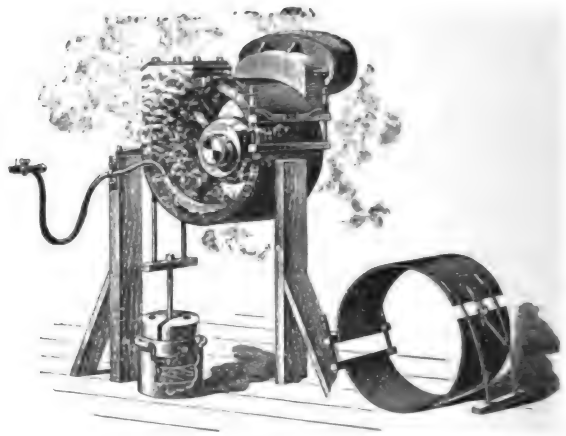

FIG. 5.—TESTING MOTORS BY BRAKE METHOD.

The testing department is next visited, and here provision is made for testing three armatures at a time. The shaft is mounted in its frame with the armature in position between the field magnets, and is connected to a circuit which is fed from a generator running in another part of the building. Fig. 4 illustrates these machines, but shows only two of the three in the room. Here all the conditions of actual work are imposed upon the motor. To the end of the shaft a hollow pulley about one foot in diameter is keyed, and this is embraced by a band or ring of thin metal having clamps, by means of which this band may be tightened to cause it to act as a brake. Attached to this ring is a suspended rod upon which weights may be placed, Fig. 5. Upon a table near by are volt and ampere meters, from which frequent readings are taken. A rheostat is also provided, the same as those placed upon the car. The current being turned on, the motor is allowed to run idle for a time and the speed or number of revolutions per minute is recorded, as are also the meter readings.

Then a fifty-pound weight is added to the brake and another reading is taken. Then fifty pounds more, and still another fifty before the test is ended. The brake is clamped just tight enough to cause it to hold suspended 150 lbs. A hose is provided as shown, by means of which a small stream of water is fed within the hollow pulley, to cool off the parts which otherwise would become very hot from the friction of the band upon the pulley. The period

of test for each motor is one hour, and none are passed that do not show an output of over fifteen h. p.

This brake and means of testing a motor or generator was the invention of Mr. Brush and is most simple and effective.

The wooden web gear wheels, a specialty in these motors, render their operation almost noiseless and also assist in the insulation. These wheels consist of a steel ring about eighteen inches in diameter, having a wooden web, instead of spokes, to which the hub is bolted, and which is strengthened by circular plates bolted through the web and made to embrace the inner fillet of the ring. The web is made from thoroughly seasoned oak boards about one inch thick, cut into triangular shaped pieces, carefully fitted and glued together and turned down to a wheel of suitable diameter. Two of these are then placed together face to face so as to break joints, thoroughly soaked in oil and carefully finished and polished. These are then fitted to the steel ring, drilled for the bolts, and the hub and sustaining plates are bolted on. The last gear wheel in the train, or the one that is mounted on the car axle, is "split" and provided with ears and bolts for holding the two halves together and for securing them firmly to the axle.

The webs having been fitted, the blanks are taken to a second machine shop on the first floor of the "Cathedral" building, where the gear teeth or cogs are cut or milled out. Here are six specially designed automatic gear cutters or milling machines for cutting the teeth on the gears and steel pinions. Four separate cuts are required to finish a tooth.

So thoroughly are these machines designed that when a blank gear or pinion is set they will cut all the teeth without further attention and ring a bell when the last cut is made. On some of the machines two blanks are placed face to face and the tool cuts across the face of both. The small six inch wheels which are mounted on the armature shaft and the intermediate shaft are called pinions. These are of solid steel or rawhide and are to be distinguished from the intermediate wooden web gear.

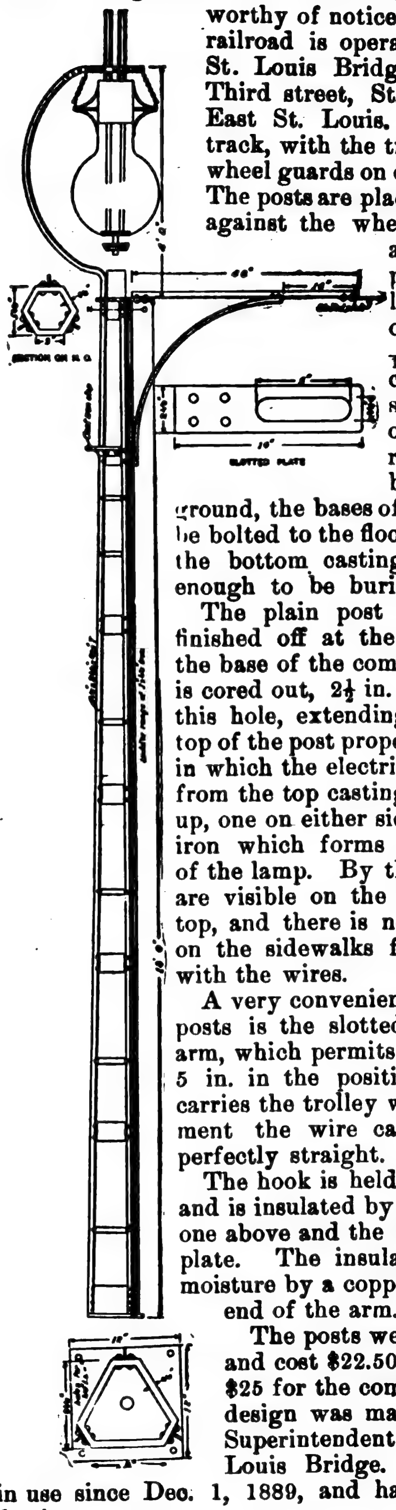
The field magnets of the generator and motor next claim attention. As before stated, there are four of these to each machine, and they are so mounted that the poles are presented to the sides of the armature instead of to the face. The core is of soft cast iron of peculiar shape, the pole shoe being widened out in the form of a crescent. The opposite faces of the field magnets are planed smooth and parallel on specially designed milling machines. Three or four magnets are placed in line on the bed of the machine and are passed between the faces of two revolving circular tools.

After being planed the magnets are taken to the winding room, but before winding each field is covered with a closely fitting thimble or shield of copper. This shield is designed to prevent the inductive spark piercing the fields, and is a special feature in the Brush machine. The fields of the generator are compound wound. The shunt coil consists of 225 lbs. of .072 wire wound in a coil of eighty-three turns of seventeen layers. The series coil requires fifty-eight pounds of .180 wire, and it is wound in eighty-three turns of forty-four layers. The winding completed, the coils are covered with shellac varnish and canvas, and the fields are placed in a hot oven until the varnish is thoroughly dried. When wound ready for service each of the generator fields weighs about 2,692 lbs. and the motor fields about 1,820 lbs. each.

The motor frames are carefully designed and are another special feature of the Short system. The frame is cast in two parts, and the parts are held together by means of wooden blocks about six inches square and eighteen inches long, fitting the sockets to which each part is firmly bolted. The wood renders the frame very rigid and serves to insulate the motor proper from the car axle.

COMBINED ELECTRIC RAILWAY AND LAMP POST.[1]

The St. Louis & East St. Louis Electric Railway, operating the Thomson-Houston system, employ a type of pole which has given considerable satisfaction, and is therefore worthy of notice. The above mentioned railroad is operated at present over the St. Louis Bridge and approaches from Third street, St. Louis, to Broadway, East St. Louis. The road is a double track, with the tracks laid alongside the wheel guards on either side of the bridge. The posts are placed on the sidewalk close against the wheel guard, 125 ft. apart, and about every fourth post carries an electric light. Each post is made of three $1\frac{1}{2}$ in. x $2\frac{1}{2}$ in. x $\frac{5}{16}$ in. T irons riveted to cast-iron blocks of the shapes and sizes shown on the drawing. As the road is entirely on the bridge and not on the ground, the bases of the posts were made to be bolted to the floor; for use on the ground the bottom castings could be made long enough to be buried in the earth.



The plain post (carrying no light) is finished off at the top by an acorn. In the base of the combined lamp post a hole is cored out, $2\frac{1}{2}$ in. in diameter. Through this hole, extending from the base to the top of the post proper, is carried an iron pipe in which the electric light wires are strung; from the top casting the wires are carried up, one on either side of the stem of the T iron which forms the bracket, to the top of the lamp. By this means no light wires are visible on the pole except at the very top, and there is no danger to passengers on the sidewalks from accidental contact with the wires.

A very convenient arrangement on these posts is the slotted plate at the end of the arm, which permits a lateral movement of 5 in. in the position of the hook which carries the trolley wires. By this arrangement the wire can be readily lined up perfectly straight.

The hook is held in place by jam nuts, and is insulated by two hard rubber plates, one above and the other below the slotted plate. The insulation is protected from moisture by a copper shield rivetted to the end of the arm.

The posts weigh about 300 lbs. each, and cost \$22.50 for the plain posts and \$25 for the combined lamp posts. The design was made in the office of the Superintendent of Structure of the St. Louis Bridge. The posts have been in use since Dec. 1, 1889, and have given perfect satisfaction.

Gutta Percha.—According to a report just made to the French Academy from an expert in the Malay Peninsula, there may be a serious falling off in the gutta percha supply owing to the reckless destruction of even the youngest trees by the natives. Protective and prohibitive measures are advocated.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. X. NEW YORK, OCTOBER 15, 1890. No. 128

A definite object in view, and a well-directed perseverance in overcoming the difficulties by which the path is usually obstructed—these are indeed the conditions of successful invention.—Lord Rayleigh.

THE DRIFT OF ELECTRIC RAILWAY WORK.

THIS week at Buffalo the street railway people of the country are gathered together for their annual convention, and the meeting will be one of great importance. Not only is Buffalo, at this very minute, the scene of new electric railway construction of the first magnitude, involving the outlay of hundreds of thousands of dollars, but the leading topic of the occasion is electricity in its application to street railways.

To those who are familiar with the condition and tendency of things, this attitude of the street railway men is no cause for wonder. Already more than 30 per cent. of the street railways of the United States are definitely committed to electric traction, and the rate of growth is continually more rapid as the new companies give in their adhesion. Thanks to the superior economy and efficiency of the electric systems, roads are now being established by the score that were previously hopeless. Many old roads that were failures with horses have entered upon a prosperous career with motors. Any number of instances can be named where the introduction of a new electric road has built up desirable new suburbs for crowded city dwellers, and has more than paid for itself out of the immediate appreciation in value of meadow land and plowed fields. Already the operation by electricity of the steam service in the "commuting" districts around our large cities is being discussed, figured over and negotiated with the most serious intent.

With the coming of the electric cars there has been seen a most notable advance in the comfort and convenience of the service. The big horse stables, with their "area of smell," have been banished to make room for steam plants, in which will be found examples of the very latest and finest products of mechanical engineering, solid, clean and sightly, employing higher-paid skill and intelligence. The cars themselves are improved. A great many are lighted electrically; not a few are warmed electrically; nearly all run smoothly on new road-beds, and several of them, when made up in trains, are vestibuled. A leading citizen in a Western town a few weeks ago, took a ride on the starting up of the new electric road. He was not a stockholder, but he owned property in the place and was interested in its welfare. So pleased was he with the ride and the luxury of the car, as well as with the evident effect for good on the locality, that he took out his check-book, drew a check for $100 and turned it in as his fare.

All this, however, is but the beginning, and as the new work goes on improvements will be seen in quick succession. Our present issue shows how great are the strides now being made in the lessening of noise, the lightening of apparatus, the perfecting of overhead trolley appliances, and the control of car mechanism. The resort to aluminum, now brought within reach by its lower price, promises an enormous economy in the long run by the smaller demand that will be made on the power house or storage cell for current.

Nor is it to be believed that the overhead system will maintain its present excessive proportion of the work. That it will long prevail, even in the larger cities, is quite likely; but the drift is decidedly away from it and towards systems of conduit or storage operation. As some figures, cited elsewhere in our columns, show, there are practically as many storage cars running to-day as there were of the overhead system only two short years ago; and there will be more. In such a city as New Orleans, for example, the storage system is the only substitute for horses, and there it will achieve one of its greatest triumphs. And then it is not to be supposed that the conduit systems will remain untried, especially such an one as we described a week or two ago, in which every section but that the car is traveling over is cut out and remains "dead" till energized by the next car.

The evidence collected by one of the Boston daily papers from cities in which electric roads are running proves beyond a shadow of doubt the immense popularity of the new system, as well as its great freedom from danger and causes of annoyance to the public. This ready appreciation serves as a stimulus in the work of improvement yet to be carried out. Electricity should brighten, beautify and better everything that it touches, and in no field will it do this to greater admiration of all than in that of street railway traction. Meanwhile, as we have hinted, electrical engineers are learning lessons and gathering strength for the kindred work that they have already been called upon to take up, namely, the operation not merely of local roads, but of roads running from point to point a distance of thirty or forty miles, or even more.

THE CENTRAL STATION OF THE FUTURE.

The history of the changes and transitions which have taken place in the last ten years in the distribution of current for all purposes, point in no uncertain manner to the status which the industry will occupy in the future, and the methods of management which will be adopted in its conduct. Arc lighting, which was the first to occupy the field, had become fairly well established as an industry when the incandescent light was brought forward as a direct competitor with gas, but it required several years to convince the majority of the operators of central station arc plants to recognize the incandescent light field as one desirable to cultivate, and, as a consequence, it devolved upon newcomers to undertake this part of the work. The success which was soon met with, however, convinced the former scoffers of their error, and as a result we find, in numerous instances, central stations combining both methods of illumination in their work. The advent of the electric motor added another chapter to the history of development, a chapter in many respects similar to that of the incandescent light, beginning with a period of doubt and hesitation and now rapidly ending to conviction, due to results which have been demonstrated beyond peradventure. Now that the electric railway has entered the field as a consumer of current, it seems proper to inquire, if, with the experience of the past as a guide, the methods in vogue at present are the best or are likely to endure? With but few exceptions the roads now running are equipped with power plants of their own, notwithstanding the fact that in many cases electric central stations are in operation in the same towns having a large, if not their entire, power equipment idle during the day time. This state of affairs is one which it seems hard to reconcile with the principle of economy. The benefits to be derived from concentrating the sources of electric current for all purposes of distribution under one roof and one management have, we believe, been recognized but in few instances; but we know that the success attained has been, as it was easy to foresee, phenomenal. Indeed, the matter is one of simple calculation, and we believe that the time is not far distant when, at least in the smaller towns and cities, the supply of current for lighting and power of every description will be distributed from one point for each district, and with marked economy.

CO-OPERATION IN ELECTRIC WORK.

The recent fire in the Western Union Building in this city and the quick recovery from practical extinction of the service to full operation has justly been commented on and praised by experts as an excellent piece of work, demonstrating the ability and energy of those upon whose shoulders the burden rested. The manner in which the frightful confusion was, in a few days, converted into an orderly arrangement, is very graphically described by Mr. A. C. Robbins, in the paper read before the Electrical Section of the Brooklyn Institute, which we print elsewhere. The wiping out of this great central station, notwithstanding its situation in what was considered a fireproof building, naturally leads to the thought that a similar accident may occur in other places, with equally disastrous consequences. This truth applies generally to all telegraph stations. Few may have stopped to consider, however, what would be the consequences of the complete destruction of one of our large costly telephone exchanges, such as are now in operation in several important cities, and connecting with thousands of subscribers. In the case of the Western Union fire it took but a few weeks to connect the few hundreds of circuits to the proper instruments; but even those little acquainted with multiple switch board work must realize that the connection and cross-connections required for two or three thousand subscribers would require months of labor. The inconvenience created by an interruption of such a long duration would seem to make it worth while to guard in every possible way against such an occurrence. Evidently the main feature of the exchange is the switch board, and to wait for its construction, not to mention the time required for setting up and connecting it, would be adding another and fatal loss of time. With these facts before us, it seems proper to suggest that much time and annoyance might be saved by the maintenance in reserve of switch boards, thoroughly equipped, which could be set up at a moment's notice and be ready for work by the mere connection of the line circuits to the proper terminals. It might be argued, however, that while the plan is a good one, the great cost of a switch board capable of accommodating several thousand subscribers, and aggregating over $100,000 in cost would make the scheme financially impracticable. But we think that there is a very simple way in which the plan could be worked on the co-operative basis. To that end it would only be necessary for the numerous telephone companies to combine and together contribute to the construction of such reserve boards. The sections of such a board could be distributed at various points so as to be readily accessible to exchanges in any particular district, while, on the other hand, they could be quickly concentrated at any one point, if required. The plan, if carried out on this basis, would be a new form of mutual insurance which could be obtained with comparatively small cost to each individual company. Thus the chances of interruption of service will be reduced to a minimum.

Novel Uses for Incandescent Lamps.

Not only are incandescent lamps now being used by the million in public buildings and in private houses, as well as in such structural decorative effects as "towers of light" and triumphal arches, but they invite the ingenious inventor and engineer to a variety of novel experiments. Thus, in this issue mention is made of the use of the flashing of incandescent lamps, by the automatic opening and closing of the circuit, to record visually the number of sheets printed by newspaper presses. Another striking novelty is that which will adorn the new marble building of the Penn Mutual Life Company in Philadelphia. The huge clock on the tower, instead of having an illuminated dial with dark hands, will have a dark face with enormous pointers of light. These pointers will be made of glass over an iron frame and be rendered plainly visible for miles, by incandescent lights, which will give them the appearance of slender white rods of fire.

THE WEUSTE TELEMETER.

THERE are many situations in which it is desirable to have an indication or obtain a record of the condition of apparatus situated at a distance, and for this purpose the variety of instruments has been designed in the past. The favorite method for obtaining such indications at a distance, and indeed the most convenient, is evidently by means of electricity; the apparatus required being simply an instrument which shall be affected by the varying conditions of which it is desired to have a record, and at the other end of the line a receiving instrument or indicator actuated by the impulses transmitted from the first station.

Among the apparatus recently brought out for this purpose, such as the indication of the height of water in reservoirs or of gas tanks or the position of elevators, and the like, is one due to Mr. Chr. Weuste, of Muelheim, Germany, and which has been patented in this country.

The object of the inventor has been to make the apparatus as simple and absolute in its action as possible. The manner in which this has been carried out is shown in the accompanying engraving, Fig. 1, which shows the appar-

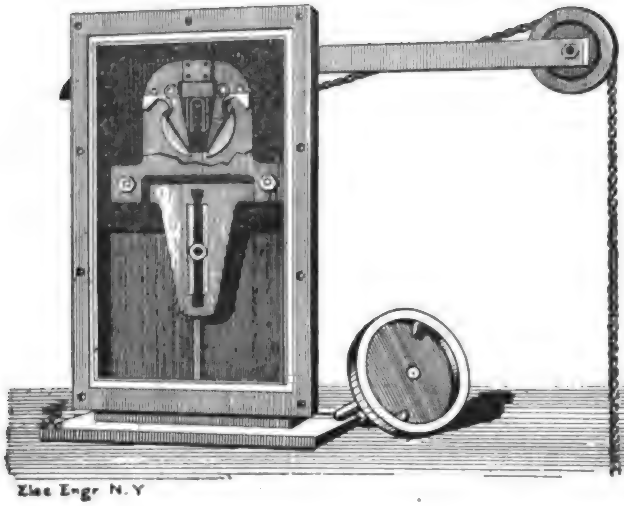

FIG. 1.—THE WEUSTE TELEMETER.

atus in perspective, and Figs. 2 and 3 illustrate the principal working parts in detail. The apparatus consists of a short cup-shaped cylinder, *a*, mounted horizontally on the shaft; and suspended from its lower end by means of a pin, *b*, is a rod, *c*, which carries a weight at its lower end, which tends constantly to pull the rod downwards. The cup-shaped cylinder, *a*, is provided with two lugs, *d d*, placed opposite each other, and between the loosely pivoted rods, *h*, are situated the contact points, *f* and *g*.

In the case of a reservoir, for instance, the shaft, *d*, upon which the short cylinder, *a*, is mounted, is wound about with a flexible cord or chain connected with a float. As the water rises or falls it necessarily acts through the cord to turn the cylinder, *a*, and in doing so the lugs, *d*, come in contact with the pin, *b*, and carry the weighted rod, *c*, along with it. This is guided in its upward motion between the cheek pieces, *e*, until the lug reaches the position shown in the diagram, Fig. 2. A slight motion beyond that point allows the weighted lever, *c*, free motion to be drawn down, and it falls in between the cheek piece, *e*, and the loosely pivoted lever, *h*. In doing so it presses the lever, *h*, inwardly and closes the circuit through the contact, *f* or *g*, depending upon the direction in which the cylinder, *a*, was turned. The closing of the contact sends an impulse over the line, which, acting upon the indicating instrument at the other end, makes known the change which has taken place. By means of this arrangement all delicate parts are avoided and the apparatus gives a positive rubbing contact.

It is evident that the fineness of indication can be made as small as desired by diminishing the diameter of the shaft, *d*, upon which the cylinder, *a*, is mounted, so that a

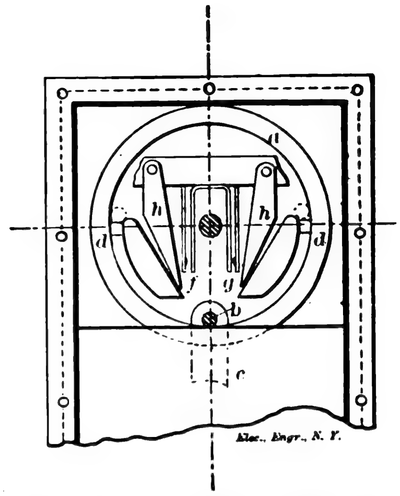

FIG. 2.—THE WEUSTE TELEMETER.

rise or fall of a fraction of an inch may be indicated. A revolution of 90° of the cylinder is all that is required to take the lever, *c*, from its lowest extremity half way up either side. By the addition of an air or glycerine dash-pot the motion of the rod, *c*, can be made as easy as desired. One of the special merits of the apparatus is that a

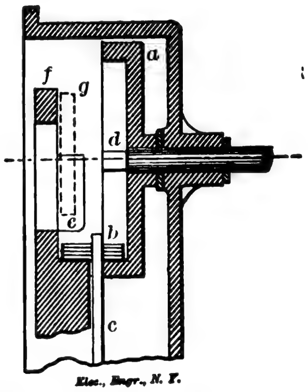

FIG. 3.—THE WEUSTE TELEMETER.

large variation in the level of a reservoir, for instance, in no way affects the proper working of the apparatus, while, as stated above, the fineness of the indication can be made as small as desired.

ELECTRIC LIGHTING AT CHARLESTON, S. C.

Some important changes are contemplated at Charleston, S. C., in the electric light plant of the Charleston Light and Power Co. President Geo. B. Edwards writes us: "Electricity is spreading so fast in the South that this would be a fine location for any manufacturer of electrical supplies. Labor and living are very cheap in this city, and any good manufacturing would pay. This point has also great advantages in freight rates. We are now desirous of selling our present electric light station, either with its whole steam plant of 300 h. p. or with only 100 h. p., as a purchaser may prefer; we moving the other 200 h. p. to the new site. There we intend to erect a 700 h. p. plant, but so constructed as to permit of extensions, without interference with the operating plant." The Charleston Co. has been three years in operation, and it has a capital stock of $50,000. The plant is Thomson-Houston arc and incandescent, run by Putnam engines. Mr. P. P. Toale is secretary and treasurer, and Mr. F. P. Upson, superintendent.

THE WESTINGHOUSE ELECTRIC RAILWAY SYSTEM.

When it was announced a few months ago that the Westinghouse Electric and Mfg. Co. had decided to enter the field of electric railroading much curiosity was evinced as to the type of motor and truck arrangement it was proposed to adopt. Since that time various roads have gone into operation equipped on the Westinghouse system, as for instance at Lansing, Mich., and quite a number of others are in course of construction or under contract. During a recent visit to the works of the company at Pittsburgh, we were afforded an opportunity of inspecting the manufacture of the electric car equipment in every detail and the new features embodied in the apparatus will not fail to interest our readers.

We may say at the outset that, following out the usual practice of the Westinghouse Co., as much care has been bestowed upon the mechanical as upon the electrical part of the apparatus, it being fully recognized that electric railway apparatus, to insure success, must be built in the most substantial manner. With this idea constantly in view there has been developed a combination of elements which together go to make up an exceedingly interesting whole.

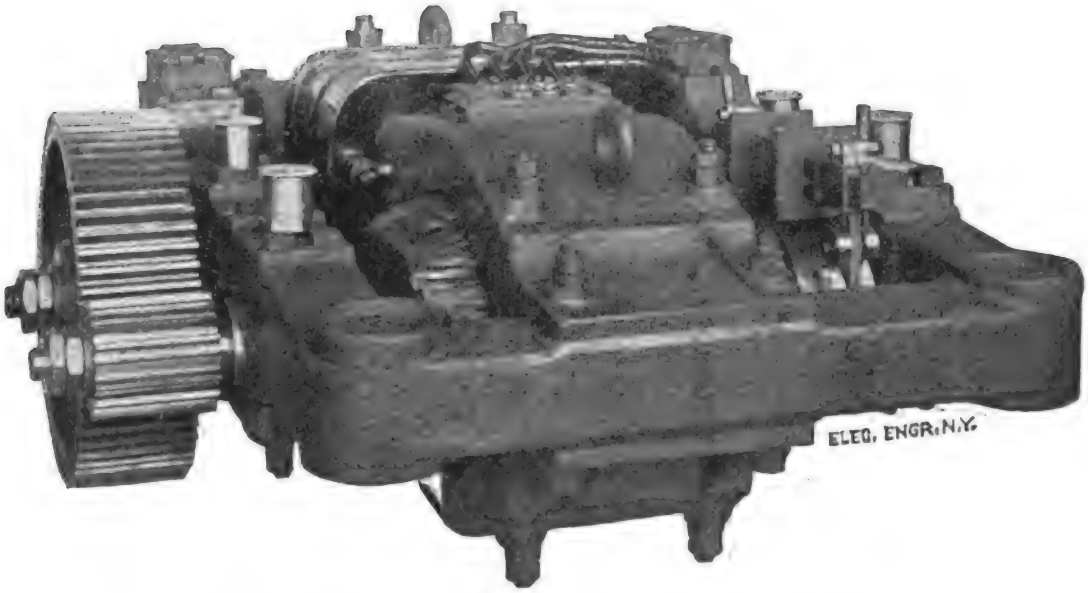

Fig. 3.—Westinghouse Electric Railway Motor and Frame.

The general arrangement adopted is well shown in the plan and elevation of the car truck, as shown in Figs. 1 and 2. Following the now general practice, two 15 h. p. motors are employed, mounted, as shown, with intermediate reducing gear.

One of the most distinguishing features of the new arrangement will at once be recognized in the frame within which the motor is mounted. This will be still more evident by an inspection of Fig. 3, which shows the motor and frame removed from the truck; and by Fig. 4, which shows the iron frame and magnetic circuit of the motor. As will be seen, the frame is carried entirely around the motor, giving a strong mounting and perfect rigidity between the parts of the motor, which are so essential in the street car motor. The gear wheels are placed so as to equally distribute the strains which the motor is called upon to endure, and as will be noticed, the gearing is mounted closely to the frame so as to eliminate the objectionable buckling and tendency to loosening of parts. The gears are incased in a dust-proof box partially filled with oil, which reduces the objectionable noise to a minimum and increases enormously the life of the gears. The oil boxes which are used for lubricating the car axle are filled with waste, and a thick grade of oil is used here, the same as in the car boxes of the truck. A hinged cap is placed over this box, thereby rendering the same dust-proof. The oiling of the other two bearings is done by means of a thick grease, and the grease-box is sunk down under the castings so that there is no part to project or to be injured by rough handling.

It will also be noticed in this frame, that the armature, and the intermediate shaft are taken out from below. The reason of this will be evident when it is considered that the car body is always placed over the truck, and whenever any changes are to be made from accidents or for general inspection and repairs, the car is run over a pit, the working parts being then usually removed from below the frame instead of above.

This frame is suspended at the two corners, upon springs, which give it a flexible support. This flexibility is not considered to be at all essential; at the same time, it is supposed that the motor rides somewhat easier on account of the springs.

Special machinery has been devised for boring out the castings on the side of the frame where the three shafts pass through it. This machinery is so devised that any frame is interchangeable with any other. The advantage of this is obvious when repairs become necessary. The ridges, of which four will be noticed on the top of the frame, are arranged to hold the heads of the bolts, to prevent the same from turning and thereby becoming loose.

We now come to the magnetic part of the frame, which is clearly shown in Fig. 4. The field castings, it will be seen, are made of one piece and hinged at the rear end upon the yoke or keeper. The fields are loosely hinged for ready removal, but when put together are bolted tightly and make intimate contact with the keeper which is planed to receive them, the joint having a surface of 40 square inches. The fields are made with very little curve at the pole-pieces, so that the coils, which are wound separately, can be easily slipped on. Separating the pole-pieces is a suspension piece of brass which breaks the continuity of the magnetic circuit and causes the magnetic lines to follow through the armature. Thus it will be seen that but five castings are employed to make up the frame, keeper, fields and suspension piece, of which two are alike.

Among the other advantages gained by this construction is the great ease with which all parts, especially the heavy ones, can be gotten at for inspection and repairs, and in virtue of which it is never necessary to remove from the

car axle any of the heavy parts in the case of repairing the armature, field coils, or the replacing of bearings or gears. Thus, if it should be necessary to remove one of the field coils from the upper field casting, all that is necessary is to remove the trap door from the floor of the car, loosen the bolts which hold the field casting down, raise the forward end upon its hinge, and slide off the field coil. The lower field coils can be removed by allowing the lower field casting to swing down into the pit where they can be removed over the casting. The manner in which this is done is indicated in Fig. 5, which shows the pole-pieces swung out of the way, exposing the armature. A sling can be placed about the armature, and that can be lowered into the pit; and the same method of removal is also true of the intermediate shaft and gears and boxes.

The armature employed is of the Siemens type and special precautions have been taken to avoid every possible trouble at the commutator. For this purpose it is constructed entirely of brass and fibre so that no unequal expansion with change of temperature can take place. Each segment besides being insulated from the next segment by mica plates, has underneath a bearing surface for its entire length, so that it cannot bend down, or move out of place. The commutator bars are cast by a special process, the cast bars being preferred on account of the hard granular structure produced.

The motor, which is series wound, has two sets of coils on each field magnet, and the speed is varied by these in connection with a rheostat, or current "diverter," as it is called. This is composed of three separate coils, but, unlike the German silver or iron coils usually employed, they are wound of copper wire, cotton covered. The wire is wound on these insulating cylinders, separated from each other by an air space, and is thoroughly insulated and made practically water-proof. The employment of copper wire as a resistance coil might at first sight appear anomalous, but experiments undertaken by the company have shown that the necessarily increased length of wire required also affords a far greater surface for radiation, so that the elevation of temperature is greatly diminished as compared with German silver or iron. Again, the variation in resistance due to this change of temperature is, in consequence,

Fig. 4.—Magnetic Circuit and Frame, Westinghouse Railway System.

also kept down to a minimum, thus avoiding irregular action in the rheostat due to changing resistance. Above all, however, practical experience has shown that the "diverter" requires so little labor in its construction, and weighs so much less, that it can be built at a lower cost.

The arrangement adopted for the brush holders has also been very neatly worked out. It consists of a square oak holder attached to the side of the frame and carrying brush holders which are clamped so that they can be readily adjusted. The carbon brushes are placed in a sliding frame and are pressed against the commutator by a pair of springs which can be released by a pressure of the finger, and the carbon slipped out for replacement when worn. The mechanical details of the running gear also deserve notice. Thus, the main axle gears are made with solid webs instead of spokes. All care possible is taken that every

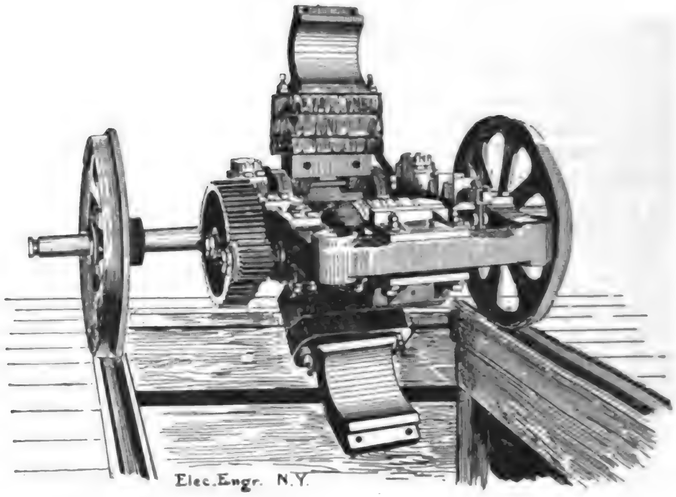

Fig. 5.—Westinghouse Railway Truck over Pit.

gear is free from flaws, and is cut with the utmost precision. The hole is tapered, and a jig is inserted in each gear before it is sent out to make sure that it will fit perfectly upon the car axle. In addition to this, a circular jig has been sent to the principal truck builders with the request that they make their car axle to conform with this jig. This is done to insure a perfect fit.

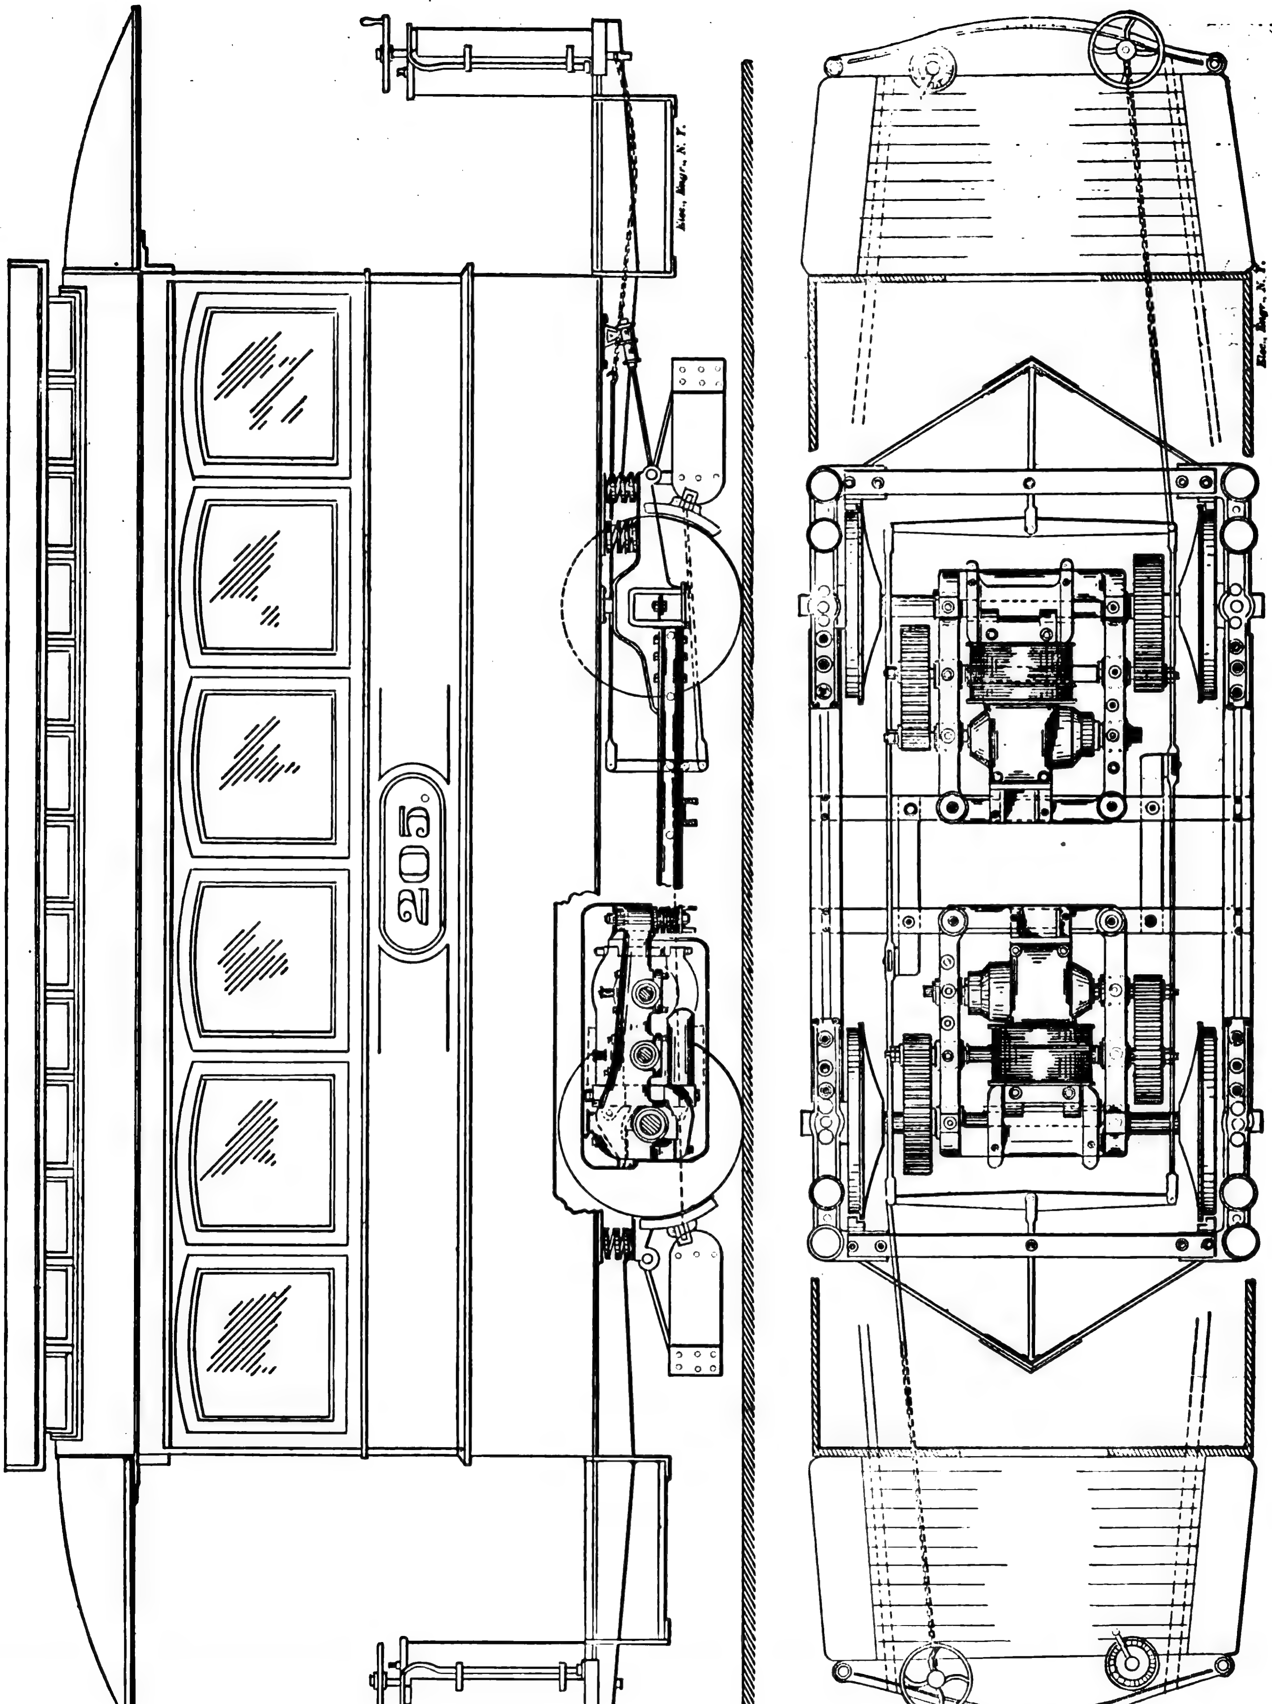
The armature pinions are made of solid steel forgings which are carefully cut and tested before being sent out. With this combination of material and running in oil, encased in a dust-proof box, the life of the gears ought to be considerable. Another interesting method of construction is that adopted for the bearing of the pinions on the motor shaft.

One of the difficulties encountered in railroad work has been the heating of the pinion and consequent expansion and loosening on the shaft which causes a rattling of the gears. To overcome this, the end of the shaft is tapered and provided with a feather, then a spring washer, two nuts and a split pin or cotter, placed at the end of the shaft. If the pinion, which is cut with a taper hole, becomes heated on this tapered shaft, the lock-washer forces it along the taper, thereby always making a perfect fit and bearing. Another great advantage of this taper, is the ease with which a pinion can be removed from the end of the shaft without the difficulty experienced with a straight bearing.

It would lead us too far to enter into the smaller details of construction embodied in the system, but during our visit to the Works, we were impressed with the thoroughness of construction adopted in all the work, and the care which is given to the insuring of good contacts and insulation.

INSPECTING SIGNAL SERVICE STATIONS.

Second Lieut. Frederick R. Day, Signal Corps, now on duty at St. Louis, Mo., has been ordered to proceed to the following named points and make a thorough inspection of the Signal Service stations located thereat, in accordance with such special instructions as he may receive from the Chief Signal Officer, and having completed the inspection at the point last named, will return to his proper station and resume his duties: At Cairo, Ill.; Memphis, Tenn.; University, and Vicksburg, Miss.; Shreveport, La.; Palestine, Galveston, Corpus Christi, Brownsville, Rio Grande City, San Antonio, and Abilene, Texas; Fort Sill, Oklahoma Territory, and Fort Smith, Arkansas. Lieut. Day is authorized to inspect and to condemn and destroy, if found worthless, such unserviceable Signal Service property at the stations visited (for which he is not responsible) as may need the action of an inspector.



Figs. 1 and 2.—Westinghouse Electric Street Car.—Plan and Elevation.

THE COEFFICIENT OF MUTUAL INDUCTION OF TWO PARALLEL WIRES.

BY DR. CARY T. HUTCHINSON.

CONSIDER two wires running parallel for a distance, l, and at a distance, d, apart. Then, neglecting the effect of the return circuits, it can easily be shown that the coefficient of mutual induction—

$$M \propto \left[l \log_e \frac{l+\sqrt{l^2+d^2}}{d} - \sqrt{l^2+d^2} + d \right] \quad (1)$$

Assume, further, that $\frac{d}{l}$ is a negligibly small quantity in comparison with 5 per cent. which is the limit beyond which I do not go ; then this reduces to

$$M \propto l \left[\log_e \frac{2\,l}{d} - 1 \right]$$

or

$$M \propto l \left[2.3 \log_{10} \frac{2\,l}{d} - 1 \right]. \quad (2)$$

This expression would represent, in the simplest conceivable case, the dependence of the disturbing effect of a telegraph or trolley line upon the geometrical constants of the circuits. In applying it to actual cases, the effect of the various telephone wires upon each other and the effect of electrostatic induction, are the most important factors neglected ; the latter, indeed, has been shown experimentally to be the dominant factor in some cases ; yet it is probable that in the actual case the general form of the expression for M would be similar to the above.

The equation shows that the effect varies directly as the distance of parallelism only when the ratio of this distance to the distance apart is kept constant ; that is, if the distance of parallelism is doubled, the distance apart being kept constant, the effect will be considerably more than doubled ; but if the distance apart be doubled at the same time, then the effect, always to the degree of approximation mentioned, will be doubled.

A simple consideration shows this to be true. The coefficient of mutual induction is proportional to the number of lines of force linked with both circuits ; if then the distance of parallelism and the distance apart be increased in the same ratio, the proportion of lines linked to total lines in one circuit, will be approximately the same, but the absolute number of lines, upon which M depends, will be doubled. In no case does the effect vary inversely as the distance apart.

The following numerical table shows all this clearly ; it is calculated from (2), the numbers given for M being only proportional, not absolute values :

TABLE.

No.	l (feet).	d (feet).	l/d	$M \propto$
1	10,000	20	500	200
2	5,000	20	250	88
3	2,500	20	125	38
4	1,000	20	50	12
5	500	20	25	5
6	5,000	10	500	100
7	5,000	20	250	88
8	5,000	30	167	81
9	5,000	40	125	77
10	5,000	50	100	73
11	5,000	100	50	61

Comparing Nos. 1 and 5 shows that increasing the distance 20-fold increases the effect 40-fold ; Nos. 2 and 5 show that increasing the distance 10-fold increases the effect 17-fold, when the distance apart is constant. When the length of parallelism is constant, Nos. 6 and 11 show that increasing the distance apart 10-fold diminishes the effect only to .61, and not to .1. This makes the case for telephones very bad, and shows the necessity for metallic circuits—for the telephones, of course.

SIMPLE SAFEGUARDS ON ELECTRIC RAILWAYS.

BY M. C. SULLIVAN.

JUST at this juncture, when so much attention is rivetted upon the subject of electric railroads, a plain word or two from one who is in circulation all the time and has many opportunities of observation, may not be out of place if it help toward needed changes and improvements. The exploiters of electrical novelties and inventions must always be ready to justify and increase the confidence of the public by hastening to remove all possible sources of annoyance and inconvenience.

Let us take, for instance, the subject of overhead trolley wires, which are often so strenuously objected to, yet which have proved such a boon by the increase of traveling facilities they have brought, with concurrent advantages. These wires are generally strongly set up, but owing to their peculiar construction they often act as a catch net for the vagrant wires of other electric services. The current of a street railway circuit, while not dangerous to life, is of necessity not very pleasant, and a "dead" wire dropping across the trolley wire at once becomes very much alive. In this condition it dangles in the air, or trails along the ground to all appearances a harmless relic, until some generous person volunteers to remove it, and then there is usually trouble. Nor does it help matters to have one excited citizen after another receive severe shocks in their efforts to clear away the obstruction, until after, may be, hours of delay the "expert" comes along arrayed in all the glory of his rubber gloves. Then he fondles the wire as though it were indeed dead, seeking at the same time to make the ceremony very awful and impressive. The newspapers will come out next day in inch full-face head lines announcing "The Deadly Wire Again," "Volts on the Rampage," etc., until the people are led to believe that the wires which have proved such a blessing are disguised messengers of death, and that travel by means of electric railways is bald-headed suicide.

It is of little use, however, to complain of the exaggeration and sensationalism of the papers. That is what they are here for. The source of annoyance does exist, and it is for us to remedy it if possible. The question of how this can best be accomplished, is answered by the necessities of the case, namely, the removal of the offending wire. To do this with the bare hands is not to be considered, for it is well known that a person cannot stand a railway shock for any length of time. He could, however, if his hands were protected by the best known insulation for the purpose, rubber gloves. Each car on a well equipped and well operated road should be supplied with these simple, but very valuable adjuncts. Their use will save annoyance, and heavy electric shocks, and at the same time save the company a great deal of wasted time and adverse criticism. A pair of insulated pliers and nippers should also be considered as a part of the car's equipment. The gloves especially should be kept in sight of the passengers, in the same manner that wrecking tools are carried on our railway trains, and that fire extinguishers are kept at convenient points in office buildings. Nobody avoids the trains or buildings on their account. A small placard indicating that these appliances are to be used in the handling of an electric wire should be placed in full view. It seldom, if ever, happens that there is not among a carload of passengers one or more who know enough of electricity to safely remove an obstruction of the kind I have named if they have the right protection. Besides the drivers and conductors are there.

This may seem a trivial matter when we consider how slight is the remedy required, but it is of as much consequence viewed from the standpoint of the people whose servants we are and whom we wish to please. If an accident occurs along our lines, the pessimists, who look with disfavor on all steps of progress, open their vials of wrath upon us; while the newspapers, glad of the opportunity of getting hold of a small incident that may be magnified a thousand times, and about which hangs an air of mystery, will energetically endeavor to make the most of the occasion.

In a word, I would suggest the supplying to each car operated by the electric current a pair of rubber gloves, insulated pliers and nippers, and suitable inscriptions nearby to indicate their use.

LEFFEL TURBINES WITH HORIZONTAL SHAFT.

In view of the great interest that is now being taken everywhere by electrical engineers in the utilization of water powers, we are glad to be able to publish the accompanying illustrations, Figs. 1 and 2. They show a type of wheel now being made by James Leffel & Co., of this city and Springfield, O., the object of which is to dispense entirely with gearing. The connection is made direct to a pulley on the main horizontal, or intermediate, shaft by belting from one or more pulleys on the horizontal shaft of the water wheel.

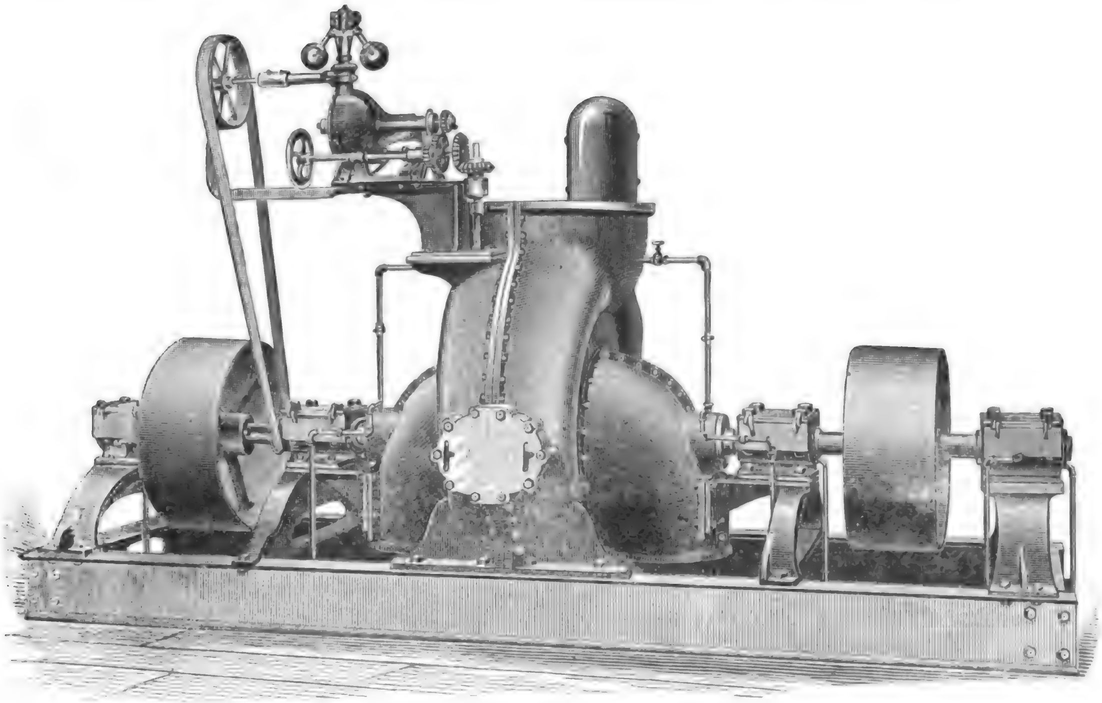


FIG. 1.—DUPLEX DOUBLE DISCHARGE LEFFEL TURBINE.

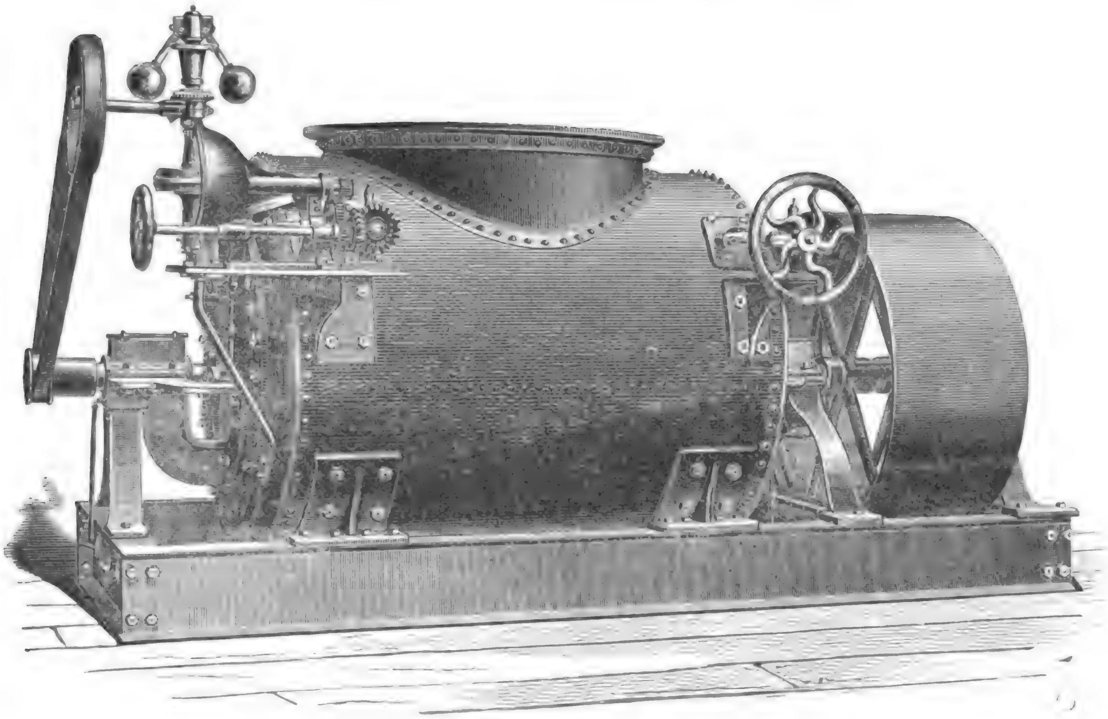

FIG. 2.—TWIN COMBINATION LEFFEL TURBINE.

The application of these wheels occurs most frequently where high heads and small quantities of water, and where very large powers with ordinary high head, are to be utilized. They are very often applied to electric light and

power plants, under both the foregoing named conditions; and are also employed for mining purposes, as the mining industry is usually carried on in mountainous countries where high heads frequently occur.

The illustrations, published by permission of Messrs. James Leffel & Co., represent two styles or varieties of this type of wheel, of which the company manufacture more than twenty modifications. The journals or bearings of these wheels are entirely out of water, and outside of the casing, enabling them to be run in oil, and to be inspected at any time.

Fig. 1 exhibits the exterior casing, enclosing the Leffel wheel modified from the ordinary standard make. The principal feature of this duplex combination is its double discharge; the water, dividing equally at the centre and passing laterally and parallel with the shaft in opposite directions, discharges downwards on each side of the wheel through curved pipes, which are attached to draft tubes. The exterior casing is made strong and substantial, but as narrow through the central portion as possible for the purpose of obtaining the shortest distance between the journals, bringing them as near to the wheel as the discharge space will admit, with the object of securing a solid and substantial arrangement in the most condensed form. This style admits of a pulley on each side of the wheel, or on opposite ends of the shaft, or one side only, as the situation requires.

Fig. 2 illustrates the twin combination, consisting of two regularly built James Leffel wheels, placed within a large cylindrical wrought iron casing with cast iron heads. The wheels discharge towards each other, the water uniting and passing downward, through a single draft tube of sufficient capacity for the two wheels. The illustration shows but one pulley attached, but this can be modified to receive two pulleys, one on each end of the shaft similar to Fig. 1, by merely extending the shaft at the opposite end to which the pulley is now secured. These forms also easily admit of attaching the head pipe at any angle from horizontal to perpendicular.

These general styles can be used with, or without, a governor, and may be variously modified to suit any combination of circumstances; but it is necessary for the company to understand the conditions fully, that the best possible adaptation and most harmonious arrangement may be secured.

WORK WITH THE LONG DISTANCE TELEPHONE.

An interesting, well written and appreciative article appeared in the *New York Times* on Oct. 9, describing many of the features connected with the long distance telephone system. It concludes as follows:

"Ithaca and New Haven are now connected, and Mr. A. S. Hibbard has in mind a novel test exhibit for this winter. He will try to have the Cornell and Yale Glee Clubs give simultaneous concerts in Ithaca and New Haven. The two concert halls will be connected by telephone, and then the Yale Club will sing, and both the Ithaca and New Haven audiences will hear the music simultaneously. Then the Cornell Club will sing in Ithaca and the New Haven audiences will hear it as well as the one 400 miles away when the singing is taking place. Spice would be added to the entertainment if a joint debate between the Yale and Cornell navies could be arranged on the Yale-Cornell boating difficulties.

"Mr. Hibbard, at his home in Morristown, received reports by telephone from New London during the last Yale-Harvard race. For the benefit of his guests he rigged up a couple of tin shells, each with its eight oarsmen, and by changing the relative positions of the boats at each report he kept his friends in high excitement for twenty-three minutes. At the end of the race the cheers for Yale from the spectators on the banks of the Thames could be distinctly heard in Morristown."

THE RAE RAILWAY SYSTEM AT NASHVILLE AND CHICAGO.

A contract has just been closed by the Detroit Electrical Works for the full electrical equipment of a street railway in Nashville, Tenn., (Rae system). The Calumet Electric Street Railway, of Chicago, equipped throughout with the Rae system, was successfully opened to the public on Saturday, Oct. 4th. This is Chicago's first electric road and it is received with so much favor that extensions are already being arranged for.

STEVENS' POSITIVE GRAVITY SWITCH.

The accompanying illustrations show the new switch just put on the market by the Electric Merchandise Co., of Chicago. This switch has been christened the "Only" overhead switch. Fig. 1 shows the switch as it appears

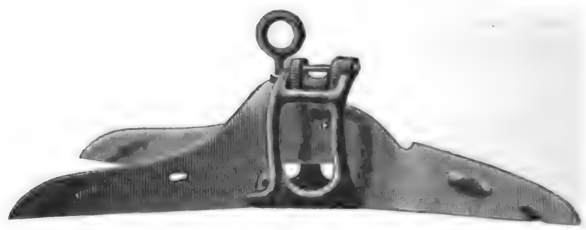

Fig. 1.—The "Only" Positive Gravity Switch.

on the line. It will be noticed that the face of the switch where the trolley wheel runs is level with the trolley wire, having no depressions to wear the wheel. Fig. 2 shows the openings through which the wheel passes. Whichever way the car is going, the wheel itself opens a space wide enough to allow the wheel to pass through. That opening closes immediately as the car passes and is ready for another car or for a car coming in an opposite direction.

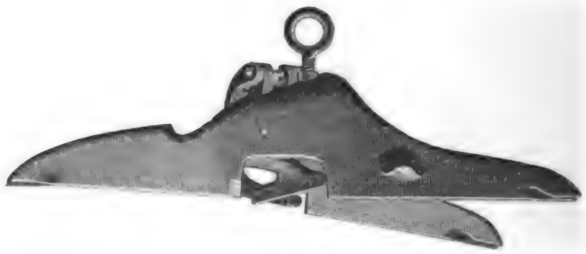

Fig. 2.—The "Only" Positive Gravity Switch.

It matters not at what speed the car is going, it is an impossibility for the wheel to leave the trolley wire. The switch is but 18 inches in length and is said to be by far the smallest overhead switch in the market. It is made for both right and left hand turn-outs.

TO INVESTIGATE GAS AND ELECTRICITY.

State Senator George Z. Erwin has been in New York City for a few days. He is chairman of the committee to which the duty was given of investigating electric and gas lighting. Considerable testimony was taken by the committee last spring. The adjournment of the Legislature prevented the passage of any measures on this subject, but a bill will be presented at the opening of the coming session. The committee will probably meet some time this fall to take further testimony.

COUNTING PRINTED SHEETS BY LAMP FLASHES.

A new use for electricity has been found at the Cook publishing house, according to the Elgin, Ill., *Daily News*. In the office of the superintendent ten electric lamps are arranged in separate compartments of a frame or box, somewhat similar in appearance to the annunciators seen in hotel offices. The lamps are concealed from view, apertures in front of the compartments being covered with colored glass, each having its distinguishing color. The lamps are connected by means of wires with the automatic counting machines on the ten large printing presses located in an adjoining building. When the presses are in operation the circuit is opened and closed by the working of the counting machines, causing quick flashes of light in the lamps. Thus every sheet of paper printed in the establishment telegraphs its record to the office, where the operation of each machine can be seen and its speed, or delays, noted.

In this connection it may be interesting to note that the speed of the large perfecting press is so great that it was found necessary to record each two sheets printed instead of single sheets, and even then the flashes of its lamp are almost continuous in appearance, showing that while the press is not quite as quick as lightning, it is too fast for the eye to follow. It is believed that this is the first application of electricity to purposes of this kind, and it may serve as a valuable hint to managers of large establishments who wish to be enabled to see the operation of their machinery while working at their desks.

SOME OF THE ENGINEERING PROBLEMS CONNECTED WITH THE RE-ESTABLISHMENT OF THE WESTERN UNION TELEGRAPH COMPANY, AFTER ITS RECENT FIRE IN NEW YORK CITY.[1]

BY A. C. ROBBINS.

On the morning of the 18th of July last, occurred the most disastrous fire in the history of the electric telegraph. The General Operating Department of the Western Union Telegraph Co., at New York, was completely destroyed. The general operating room occupied the entire seventh floor of the Western Union Building, with a frontage on Broadway of 75 feet, and on Dey street of 150 feet, and furnishes employment to upwards of one thousand people, operators, clerks and messengers. The height of the room was about 21 feet. A gallery extended across the Broadway end of the room and was occupied by the Commercial News Bureau.

The room contained a main line switch having a capacity of about 700 wires; a city line switch with about 250 wires; a loop switch of 200 loops; 40 sets of quadruplex instruments; 40 sets of duplex instruments; about 700 simplex instruments; the pneumatic tube system; 3 sets of the Hughes-Phelps printing telegraph apparatus; a rapid transit distributing system; and offices of the management and staff.

The battery room was located on the sixth floor, and contained about 20,000 cells, principally of the zinc-copper, gravity form. The coat and toilet rooms were also on this floor.

The eighth floor was occupied by the Associated Press operating department, and the Western Union book-keeping department and the employees' lunch room.

The ninth floor contained the kitchen, and lodging rooms of the lunch room employees. The tenth floor was used as store-rooms for records, and other miscellaneous matter.

The wires entered the building at the cellar, and were 2,000 in number, conveyed to the operating room in cables containing from 50 to 100 wires each, through flues in the central partition wall of the building.

How the fire originated is something of a mystery, and probably will ever remain so. It was discovered by various people on the sixth and seventh floors simultaneously at about 7 o'clock, and spread with such rapidity that several who tarried a few moments in vain endeavor to extinguish it, found the stairways a seething mass of flame, and their only means of escape to be through the windows, from which they were in various ways rescued by gallant firemen, happily without loss of life or accident; as was the case with some half dozen employees who were rescued from the roof by the life-saving corps of the fire department.

While the engines were yet playing upon the building, operators were detailed to Jersey City, Brooklyn, Weehawken, Hoboken, Harlem, and all possibly available suburban offices in all directions, there to tap the wires, and handle the vast business as best they could.

Almost before the fire was entirely extinguished a part of the engineering staff repaired to the former operating-room of the defunct Baltimore and Ohio Telegraph Company, on the fifth floor of No. 415 Broadway, where, with only a room destitute of all furniture, an electric light dynamo in the cellar, and a permit from the authorities to string a few temporary aerial wires, they proceeded to open up communication with the outside world.

Cables were strung to, and connected with, the trunk line cables on the Sixth Avenue Elevated Railway structure, the dynamo in the cellar was put in operation, and at seven o'clock in the evening, after seven hours' labor, they were working their first wires. By Saturday morning they were working 20 wires; and on Saturday evening electric lights, furnished with current from the dynamo in the cellar, replaced the candles and lanterns of the previous night. On Sunday morning a second dynamo for furnishing current of opposite polarity to that of the first one, was in operation, and 12 duplex systems were started. Monday morning found this energetic party operating 15 duplex and 25 simplex circuits to the North, East and South.

The fire occurred on the regular weekly pay-day of the employees, and the systematic and business-like methods of this company is finely illustrated in the fact that every employee who presented his voucher to the cashier on that day received his salary. One employee humorously remarked that while the engines were pouring water into one window he received his money from out another.

The scene inside the building, after the fire, beggars description. It was enough to discourage the stoutest heart. Everything burnable above the fifth floor was entirely consumed. In the operating room, the largest piece of combustible material left was the leg of a table.

The once magnificent switch-board was reduced to a mass of melted brass, and twisted beams, and to trace the identity of a single wire from out the tangled mass would be as difficult as tracing a thread in the broken web of a spider.

Water flowed from the building in rivers, and for days afterward dripped from the ceilings of every floor. This dripping was the source of great annoyance in the work of reconstruction, and in many instances, during the first few days, instruments and wires had to be covered with tarpaulin to protect them from the water.

On the morning succeeding the fire new life was inaugurated amidst the ruins. The fifth and a part of the fourth floors were to be converted temporarily to the uses of the operating department.

The occupants of these rooms were busy removing to other quarters; an army of workmen were engaged in erecting switches, building tables, setting up instruments, and running wires.

The conduit from the cellar was opened in the hall on the fourth floor, and the work of testing out and identifying each one of the 2,000 wires therein was commenced. The pneumatic tubes were opened up in, and business with their terminals conducted from, the cellar.

Day and night the work progressed, until, one by one, as fast as wires were provided, the entire force was brought back. On the following Saturday, eight days after the fire, nearly all of the wrecked wires had been re-connected in working order at the general operating department, and the temporary quarters at 415 Broadway were abandoned.

Gradually the business resumed its former, and well organized routine, until to-day, as for several weeks past, with rude pine benches for desks, and wires strung promiscuously around the ceilings, an unusual delay to a *single* message, and the cause therefor, is instantly known to the management.

One of the worst difficulties encountered in this re-establishment was a lack of proper apparatus, and at times the engineering staff were severely taxed in substituting for apparatus not in stock, and which was needed immediately; for instance, the dynamo duplex and quadruplex systems require pole reversing transmitters different from the ordinary in that they require only two points of contact in place of four where a battery is used.

The dynamo quadruplex system also requires resistances of 600, 900 and 1,200 ohms respectively, in proportioning its currents, and it also requires a set of battery and ground switches of peculiar construction.

Of this apparatus, and much more, only samples are kept in stock, and considerable time is necessary to construct when required. In substituting for the pole reversing transmitters the battery style (of which, fortunately, there was a good supply) was used by the insertion of ivory insulation on two of its contact points. For the quadruplex proportional resistances, incandescent lamps were used until the proper resistance coils could be obtained. While the lamps, as a makeshift, answered fairly well, I cannot say that I consider them a decided success, as they are too sensitive to changes of temperature. The proper equilibrium of the apparatus at the distant station, to a very considerable extent, depends upon the joint resistance of the 900 and 1,200 ohm resistances, equalizing that of the independent 600 ohm resistance; and, again the outgoing current is regulated in proportion as is the 900 to the 1,200 ohm resistance, so that a quadruplex circuit working nicely for a part of the day, is liable to become unsteady, or variable later on by a change in the wind, or draughts of air from an open window, which may cause one set of resistance to vary considerably more than the others. Constant watching, however, partly overcame this difficulty. For 9 point combination dynamo and ground switches, 3 point switches were connected in substitution.

Another difficulty experienced was the want of battery room. No room was available for this purpose, except some shelves in the halls, and boxes under the desks. This was overcome by using the Edison-Lalande caustic soda battery, which, while of low pressure, furnishes quantity sufficient for from 8 to 10 circuits from one battery.

There are 5 local circuits on each set of quadruplex instruments; these circuits ordinarily require 10 cells of gravity battery; 4 cells of the caustic soda battery has been found ample to work the local circuits of 2 sets of quadruplex, a saving of 16 cells, or 80 per cent. in battery room. The same percentage was secured in saving of battery room for the local batteries of the multiplex city loops, several loops being supplied from one battery.

The 20,000 cells of battery used previous to the fire have been replaced by 1,750 cells; and, in a few weeks, perhaps days, not a single cell of chemical battery will be used for telegraph purposes in the general operating department.

For several years past the dynamo has provided current for the main circuits from New York. A potential of 70 volts, regulated by a system of joint resistance, multiple supply, has been applied for supplying the loop locals. For intermediate batteries special apparatus is required for each battery. A one-eighth horse power motor is by current from the building incandescent lamp circuit, run at a speed of about 2,200 revolutions per minute. This motor in its turn operates a generator of equal size and at about the same rate of speed, from which is obtained a current potential of about 100 volts—sufficient for all intermediate battery

1. Paper read before the Electrical Department of the Brooklyn Institute, October 10th, 1890.

purposes. The saving in room is 40 square feet for each intermediate battery. About 50 intermediate batteries were formerly used, but the number will probably be reduced somewhat.

Another question of space was presented when incandescent lamp room was considered. Each battery lead before reaching its wires has a resistance inserted in form of from one to four incandescent lamps for the prevention of damage in cases of accidental short-circuiting. 5,000 of these lamps are necessary for use on the main line switches, and as each lamp requires a space of 3 square inches, or a total of 104 square feet, the problem was an important one.

This was happily solved by placing the lamps on a frame work over the switch. In so doing two results are obtained, viz: Space otherwise useless is utilized; and, secondly, yet of still greater importance, the wire chief is enabled, by watching his lamps to note grounds and crosses on his wires, and by prompt action from such observation prevent destruction by overheating of the instruments in circuit. For the multiplex currents, spaces on the framework of the doors and windows have been utilized, and the lamps thereon serve as monitors for those in charge of the apparatus.

Previous to this arrangement, the burning out of magnets by accidents to heavily charged circuits was a frequent occurrence. Since this improvement, I have yet to hear of the destruction of a single coil in this manner.

The building stood the heat wonderfully well; heat which caused the granite trimmings of the doors and windows to flake and crumble, and glass to melt, had no effect whatever upon the massive walls.

The operating room, which, when first occupied some seventeen years ago, was generally supposed to be adequate to the requirements of the department for all time to come, has for years been entirely too small for the rapidly increasing business.

Particularly during the past five years have these quarters become crowded, and the stern necessity of utilizing every inch of available space been forced upon the management.

Just previous to the fire a prominent official of the department remarked that he did not see how they could work through the coming busy summer season without more room, and that to do so a year hence would certainly be an impossibility. This is only one of many indications of the rapid growth of the telegraph business in recent years. With this experience, it has been decided to rebuild the structure from the fifth floor up, and to extend the building 25 feet on Dey street; and it is confidently predicted that when completed it will be the finest and most complete telegraph office in the world.

The remodelled building will be nine stories high, and the old mansard will be replaced by a flat roof. The sixth floor will be used for offices for various departments; the seventh and eighth floors for operating rooms, and the ninth floor will be occupied by wardrobe and lunch rooms, kitchen, etc.

The operating rooms on the seventh and eighth floors will each have a frontage on Broadway of seventy-five feet, and on Dey street of one hundred and seventy-five feet—considerably more than double the space occupied before the fire, and will be furnished with every facility that can be procured to secure perfection of operation. There will be used twelve dynamos in series of four each for the main line batteries, two only being in use at any one time, and the third series being kept in reserve in case of accident to either of the others. Two dynamos of low voltage will furnish the current for instrument local circuits, one being used and the other held in reserve. Two dynamos will be devoted to supplying current for city multiplex loop, local circuits, one of them as a reserve; and as many sets of the one-eighth horse power motors and generators will be used as there may be intermediate batteries required. The chemical battery will have no place in this model telegraph equipment, its day of usefulness having passed.

To the telegraph engineer it is a pleasing one. It marks an advance of the telegraph, in keeping with the progress of electrical science up to the present time, and we can feel assured that the results will be such as to induce the management to apply the improvements to all the principal offices of the company in the near future.

There is great need of improvements in insulating material. An insulation for wires is needed that will be cheap, light, flexible, and durable; one that dampness will not decay, nor the heat of an electric arc dissolve or burn. A fire extinguishing liquid is also to be desired which will be a non-conductor of electricity. When these have been obtained, and not until then ,can the large telegraph offices be absolutely assured of protection from fire.

Please consider this matter. The one who succeeds in obtaining these results, will, I am sure, be richly rewarded for his trouble. Nearly all of the employees lost personal property in the fire, of greater or less value. Some of the losses were memoranda of experiments never to be repeated, or the gift of some departed friend, and can never be replaced. To some of the employés their losses were, to them, a much more serious matter than was to the company its more formidable calamity; yet from these employees are heard no complaints or lamentations; and, with sad regrets for their misfortune, all turned with eager hands to lend their aid to the restoration of public service.

This disaster has demonstrated that there is to-day between the Western Union Telegraph Company, and its employés in New York City, a combination of capital, labor and harmony. Capital for dividend on its investment; labor for the love of science, and advancement of its chosen profession, and both harmonizing in successful endeavor to make the now largest telegraph office, the most perfect one in the world.

A BRIEF SKETCH OF STORAGE TRACTION DEVELOPMENT.

THE time is certainly ripe for at least a brief review of storage battery traction. It was first attempted at the Paris Exposition of 1881. Two cars were run from the Place de la Concorde to the Palais de l'Industrie. This was shortly after Faure and Julien had begun to introduce the storage battery in Europe. The experiment began and ended there and was resumed in 1883 by Julien, who put a storage battery car in service in Brussels. After a year or so of service, this car was exhibited in service at the Antwerp International Exposition of 1885. It attracted so much notice there and did its work apparently so well, that it was awarded the First Prize as the best and most economical method of street railway traction then known. Succeeding this favorable report, and no doubt actuated by what had been done at Antwerp, The Electric Power Storage Company constructed and put in service one or more storage battery cars at their works at Millwall, England. In the early part of 1885, Mr. Bauer, now of the Pullman Co., made some experiments with a storage battery car in Baltimore with varying degrees of success. In October, 1886, storage battery traction was brought prominently before the attention of engineers in this country by a Julien car which was put in service on 8th avenue, New York city. That car was afterwards transferred to the 4th and Madison avenue line, and was, by degrees, followed up by more cars, until in 1889, the largest installation of storage battery cars that had ever been attempted (to wit, ten in all), was put in actual service on the 4th and Madison avenue line, in New York city. They have continued in service up to the present time with the exception of an intermission brought about by adverse litigation. Following the example of the Julien people in this country, The Electrical Construction Company, Limited, of England, have made an installation of twelve storage battery cars at Birmingham, England. They have built a large station there expressly for storage battery service and Mr. Pritchard, the engineer in charge, reports the road as now in successful operation. Within the last year or so, storage battery traction has been receiving considerable attention in various quarters. Mr. Wharton has now five or six cars in actual service on Lehigh avenue, Philadelphia; that line is run exclusively by the aid of storage batteries. Another company is running four cars at Beverly, Mass., and has been doing so for over a year with considerable success.

The Electric Traction and Manufacturing Company, in New Orleans, have now two storage battery cars in actual service, and have ten additional cars which they expect to have in service by the 1st of November, while a number of additional cars are being constructed for New Orleans.

Two Julien cars are in passenger service at Indianapolis, Indiana; it is said with great success.

A storage battery car equipped by the Daft Electric Company (now the United Electric Traction Company) is and has been for several months past in service in Toledo and with great success. It has carried as many as 1,100 passengers in one day.

One or two cars have for some time been in service on the Metropolitan Street Railway in Washington, D. C.

We understand that four storage battery cars are now in Paris and that arrangements are being made to enlarge the number.

In addition to the twelve storage battery cars in service at Birmingham, there are about eight other cars in service here and there throughout England, so that there are in actual passenger service, 20 cars in England; 10 cars in New York; 4 cars at Beverly, Mass.; 5 cars on Lehigh avenue, Philadelphia; 2 cars in Washington, D. C.; 2 cars at Indianapolis, Indiana; 1 car at Toledo; 4 cars at Paris; 12 cars at New Orleans, and about 6 additional cars here and there on the continent, making in all 66 cars. This would about represent the number of electric cars run by the overhead system sowewhat less than three years ago; the storage battery cars, however, it is claimed, run much better to-day, than the overhead cars did, two and one-half years ago. One of the chief obstacles in the way of storage battery traction has been the uncertainty arising from conflicting litigation as to the ownership of storage battery patents. Considerable allowance for delay must also be attributed to the fact that storage battery traction is more difficult to attain than any other practical system of traction. It has taken longer time, from the very nature of things, to overcome the difficulties encountered in storage battery traction than those to be met with in the overhead system. There now seems to be left but one question as to the final outcome of storage battery traction and its relative position with other systems. That question is its relative economy. The

only element entering into the question of economy is that of the duration of the battery. The battery, as is pretty generally known, is composed of about an equal number of positive and negative plates. The negative plates as now manufactured might last indefinitely. It is fair to say that they will last ten years. It was once thought that they would not last over two or three years. The only question, therefore, is the life of the positive plates. If they can be made to last six months, there is no reason to doubt that storage battery traction is as cheap as horse traction where ten or twenty cars are in service, and cheaper than horse traction, where the number of cars in service exceeds twenty. All the mechanical difficulties heretofore encountered in storage battery traction, have been substantially overcome. They have been overcome as fully as the mechanical difficulties of the overhead system. The car goes and is as reliable in service as a steam car or an overhead car—probably more so. It shifts its batteries in a sufficiently short period of time to admit of that method of traction, no matter what the headway may be on the most crowded line, and by ingenious arrangements the batteries can be shifted economically and can be stored within a small space. The motors, gears and switches are substantially the same as those used by the overhead system, and are, of course, equally reliable. The sole question then is as to the life of the positive plates or one-half the battery. They cost at present for a car about $600; they can be furnished for a much less figure than this when used in large quantities. They ought to last for one year; that would mean $2 a day or two cents a car mile for 100 days' run. They will last longer, running 100 miles a day, than if they should run 50 miles a day. One gratifying point about a storage battery is that the more continuous the service, the better its condition remains. There is nothing more harmful to a storage battery than disuse. Almost all the difficulties encountered on Fourth and Madison avenues, due to the storage batteries, arise, it is stated, on Monday, and are to be attributed to the fact that the batteries have been idle, as the cars do not run on Sundays.

From all that can be learned three cents a car mile for storage batteries is a conservative estimate. This leaves from six to seven cents a car mile for steam power and the maintenance of the motors and gears. Conservative estimates by electrical engineers place the cost of motive power for these items as follows:

Electrical energy delivered at the terminals of the battery or generated on the overhead system	2 cts. a car mile.
Maintenance of motors and gears	2 " " "
Maintenance of batteries	3 " " "
Sundries	1 " " "
Total	8 " " "

or eight cents per car mile by the storage battery system.

Cost of motive power in horse traction in large cities is 10 cents per car mile; leaving in favor of storage battery traction two cents per car mile. Add to this the superior service obtained, and the advantages are unquestioned.

ELECTRIC RAILROADING AT NEWARK, N. J.

Newark, N. J., celebrated on Saturday Oct. 4th, the opening of the first electric road operated within the corporate limits of the city. It is called the Market Street and Springfield Avenue Road, runs through the most crowded district, and is of the overhead single-trolley type. The equipment consists of twenty eight-wheel cars, each 32 feet long, which are driven by two 20 h. p. Thomson-Houston motors. The current is generated by Thomson-Houston dynamos, driven by Straight-Line compound tandem engines of 500 h. p. The complete installation was made by the Field Engineering Company, of this city.

All day the cars were loaded to their full capacity and ran without a delay of any kind, although the line has a number of heavy grades. The system is to be extended to nearly all the lines in the city, and the Field Engineering Company is now prepared to erect a 4,000 h. p. central station. It selected the location last week.

ELECTRIC RAILROADS AT ROCK ISLAND, ILL.

The Tri-cities—Rock Island, Moline and Davenport—will soon have a complete electric railway system in operation. The Thomson-Houston Electric Company, of Boston, through Mr. F. W. Horne, who represents its railway department, has, as lately noted in these columns, closed a contract with Mr. C. B. Holmes, John J. Mitchell and E. Buckingham and the Davenport & Rock Island Railway Company for the construction and equipment of such an electric railway. The contract represents the sum of $350,000. There will be twenty miles of single track and five miles of double track, containing more than sixty curves; and 2,100 feet of track will be on bridges, including 1,500 over the government bridge. The overhead system will be employed and the wires will be carried over the bridges on towers. The contract calls for fifty passenger cars, seven 100 h. p. generators, two 350 h. p. Corliss engines and three 300 h. p. Hazelton boilers. It is expected that the whole will be completed in something less than 80 days.

The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.

In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.

Sketches and drawings for illustrations should be on separate pieces of paper.

All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

A CURIOUS BREAK IN A CONVERTER PRIMARY.

[141.]—I would call the attention of your readers to a sample of wire taken from the primary coil of a converter, which shows an apparently unaccountable break. The ends of the break are fused, while the insulation has not been charred except close to the break. There was nothing to show that this was caused by any cross with the secondary coil, or by any escape to ground. It is accepted by some people as being a freak of lightning, and has come to be such a common occurrence as to amount to a very serious trouble. I would like to inquire whether others have noticed this difficulty and whether there is any good explanation to give except a fault in the copper finally resulting in a break.

C. W.

CHICAGO, Ill., Sept. 27, 1890.

OFFICIAL REPORT ON THE KEMMLER EXECUTION.

Dr. Carlos F. Macdonald, president of the State Commission in Lunacy, has furnished Governor Hill an official account of the recent death of William Kemmler at Auburn Penitentiary by electricity. He admits the bungling, torture, and uncertainty and says in contradictory conclusion:

Compared with hanging, in which death is frequently produced by strangulation, with every indication of conscious suffering for an appreciable time on the part of the victim, execution by electricity is infinitely preferable, both as regards the suddenness with which death is effected and the expedition with which all the immediate preliminary details may be arranged. By the latter method the fatal stroke renders its victim unconscious in an infinitesimal fraction of a second, so small as to be beyond the power of the human mind to estimate, while, at the same time, it disintegrates the nerve tissues and blood to an extent which insures an absoluteness of death in a shorter space of time than is possible by any other known method. In other words, it is the surest, quickest, most efficient and least painful method that has yet been devised.

The execution of Kemmler, from the time he entered the room until the second contact was interrupted, occupied not more than eight minutes; whereas executions by hanging usually require from fifteen to thirty minutes. In fact, it not unfrequently happens that the heart continues to beat for that length of time after the fall of the fatal drop. Then, too, far more time is consumed in placing the prisoner on the gallows, pinioning his limbs, putting on the black cap, placing the noose about his neck and carefully adjusting the knot under his left ear (from whence it sometimes slips at the critical moment, resulting in strangulation instead of a broken neck), than would be required for arranging the preliminary details of an electrical execution. During the preparation of this report the Associated Press dispatches contained an account of a hanging in which the criminal's head was almost completely torn from the body.

Dr. Macdonald makes the following recommendations:

First.—The statute providing for the execution of criminals by electricity should be amended so as to provide for but one plant, to be located in the central part of the State, in a building especially constructed for the purpose. The building should contain the necessary electrical apparatus, an engine, execution-room, solitary cells and quarters for the guards and other necessary officials, the apparatus to be in charge of and operated by a competent, accredited electrician.

Second.—The engine and dynamo should be especially constructed for the purpose, and should be capable of generating an electromotive force of at least 3,000 volts, in order to insure the maximum voltage that would be necessary and at the same time cause no injustice to any electrical lighting company, such as is likely to be the case so long as commercial dynamos are used in executing criminals.

Third.—The volt-meter should be located in the execution-room, and a competent and responsible official should be detailed to take the readings of the meter before and at the instant the current is applied. The voltage should not be less than 1,500, nor more than 2,000, and should be a matter of official record. The prisoner's resistance should also be taken immediately before bringing him into the execution-room.

Fourth.—The statute should require an official report of each execution to be made to the Governor within ten days after the execution takes place.

EUROPEAN CORRESPONDENCE.

LONDON.

London and Manchester Connected by Telephone.—The Postmaster-General's Report.—The Vaughan-Sherrin Battery.—Church and Telephony.—Electric Light at Godalming.—Another Elmore Copper Company.

COMMUNICATION by telephone has just been opened by the National Telephone Company between London and Manchester. The route is via Macclesfield, Birmingham and Coventry, the distance being 219 miles. The line was used on Monday night for the first time at a semi-private gathering by members of the Manchester Field Naturalists Society, who conversed with Prof. Meldola, F. R .S., Sir Philip Magnus and others, of London. The wire employed, 11½ B. W. G., is of hard drawn copper, 200 lbs .to the mile, and has cost £13,000. Blake's transmitters as used in ordinary exchange work were employed, and the Bell receiver. The voices were distinctly heard in London and easily recognizable. Connection was afterwards made with the Savoy Theatre, London, when the music of the Gondoliers was heard over the wires with great effect.

The Postmaster-General's report shows a remarkable increase in the year's telegraphic business. During the twelve months 62,408,399 telegrams were sent over the wires, which is several millions above the previous year's figures. In the period under review, 263 post offices and 58 railway offices were opened for telegraphic business, making a total number of 5,673 offices. On September 2nd, 1889, the issue of telegraphic money orders between London and 17 large towns was begun as an experiment. Between that date and Feb. 28, 2,088 orders of the value of £8,674 1s. 3d were issued, and on March 1, the system was extended to all head and branch post-offices in the United Kingdom, with the result that in one week 573 telegraphic orders were issued, representing a sum of £1,968. In the month 1,769 orders were issued, amounting to £6,262.

A company has been formed to acquire the patents of the Vaughan-Sherrin which consists of a special kind of primary battery and motor. Tests were made yesterday of their motive power in combination with a tricycle, bath chair, and electric launches. The battery is a two fluid one with sheet zinc and carbon. In each cell there are three fixed carbons and two replaceable zincs. The outer cells are made of gutta percha and in them are placed the porous cells which surround the zincs. The liquid used in the inner cells is water, whilst that placed in the outer cells is a depolarizing liquid of special composition, supposed to be produced at a low figure. The E. M. F. is nearly two volts. The motor is a two pole Gramme machine with the field magnets arranged in a peculiar way. Prof. Silvanus P. Thompson has tested the battery and concludes his report as follows:

"Considering the size and weight of the motor, and comparing its efficiency with that of the best motors of equal weight or power in the best motor in the market, I consider the performance of Mr. Sherrin's motor very satisfactory. For so small a motor the power is high, being at the rate of one horse-power for only 62 lbs. of dead weight. The electrically-propelled bath chair is fitted with a small motor and driven by current from ten of his cells. In a short run which I took in it on unfavorable roads, it ran about six miles per hour on the level. It was perfectly easy to manage, and the batteries gave no trouble either from spilling or fuming. I consider the electrical chair a thoroughly practical and successful vehicle."

The cost of current is estimated by the Professor at from *9d.* to *10d.* per Board of Trade Unit. It is claimed that the tricycle will travel at eight miles an hour.

The experiments of connecting telephones to Christ Church, Birmingham, which I mentioned would take place, was a distinct success. When the morning service began there was quite a clamor to be put in connection. The morning prayer was interrupted by irreverent cries of "Hallo there," "Are you there," "No, I don't want the church." These and other interruptions drowned for a time the voice of the minister, but when quiet was obtained, there was an unbroken connection which allowed of the service being heard.

Connection was also made with London, Manchester and other large towns, the service being heard with ease.

The electric light committee of Godalming, after visiting the electric light works at Bath, recommended the adoption of electricity for public and private lighting. As the committee is practically the Town Council, it is probable that work may be expected shortly.

Another Elmore Copper Company has been added to the list under the title of the Elmore Austria-Hungary Patent Copper Depositing Co. It will acquire the patents for operating in that country for £50,000 in cash, £50,000 in shares and the premium of 10 s. each on 75,000 shares, making a possible purchase price of £137,500. It is a curious thing how anything relating to Elmore is snapped up by the British public, although not a single definite figure is given as to work done. H. S.

LONDON, Oct. 1st, 1890.

CORRESPONDENCE.

CHICAGO.

Calumet Electric Road Opened.

THE Calumet Electric Street Railway, the first in Chicago to adopt electricity as the motive power, was formally opened to the public last week.

At 3.30 p. m. a car left the northern end of the line, carrying on board C. E. Loss, the contractor; Columbus R. Cummings, N. K. Fairbank, S. E. Gross, W. V. Jacobs, the representatives of the press and a few others. After a lunch at the power house and a short speech by Mr. Loss, the party returned to the city. Many were the expressions of satisfaction at the smoothness of the road-bed, the comfort and elegance of the car, and the high speed attained.

The new line is only the commencement of an extensive system to connect the various manufacturing and residence suburbs which now lack proper communication with each other. It extends at present from the South Chicago Rolling Mills by way of 89th street, Mackinaw avenue, Harbor avenue, 93rd street and Long Island avenue, to 95th street. The Rae system of electric traction is employed, overhead construction being used, and each car is equipped with a single motor, and the cars are very strongly built and with their equipment weigh about 5 tons each, and attain a speed of from 15 to 20 miles with perfect ease and safety. The curves and switches are guarded against accident by an automatic device, of which Mr. Loss is the inventor.

The power house is equipped in the most complete manner with Armington-Sims engines of 125 horse-power, boilers, etc., and the power plant was constructed by the well known Pond Engineering Co., who have an enviable reputation for the excellence of their work. The present power capacity is capable of supplying the line opened last week, and another already built from Pullman to Cottage Grove avenue and 87th street. By December 1, a connecting line will be opened from South Chicago to the Pullman line at Cottage Grove avenue and 104th street. As soon as practicable, the system will be extended to 115th street, through 115th street, Michigan avenue, 111th street and Vincennes Road around Washington Heights and Morgan Park. Further extensions will probably follow.

Mr. S. S. Breman is now engaged in getting out plans for a two-story repair shop 500 feet square at an estimated cost of $250,000, to be built at Pullman for the Pullman Palace Car Co. It will accommodate 100 cars at a time, and have electric light, steam heat and all the latest improvements.

N. E. Swartout, of Chicago, foreman of the Postal Telegraph Company, is busily engaged at Terre Haute, Ind., in securing a right of way through that city for the projected extension of his line from Indianapolis to St. Louis. The company has secured the right of way on the National road and through all other cities along the route. The new line will be in working order by the first of the year.

CHICAGO, Oct. 9, 1890.

BOSTON.

West End Railway Work.—The Portelectric System.

MAYOR HART has received and transmitted a petition from the West End Street Railway Company to the Board of Street Commissioners, begging the city to extend Harrison avenue of its present width to Avon street, and from Avon street to Summer street, on lines to connect with Hawley street; also to extend Hawley street of its present width to Water street and to widen Water street by including therein that portion of Spring Lane and the buildings situated between Spring Lane, Water street and Devonshire street, easterly of said proposed extension of Hawley street.

The West End Company are continuing the good work of laying substantial T rails, and have this week completed a most important improvement at the corner of Boylston and Tremont streets, the entire location of the tracks and curves having been changed and relaid.

The New England Portelectric Company are making excellent progress with their demonstrative section at Dorchester, and have given several exhibitions of the working of the system. They do not claim that these exhibitions are to show the speed that can be developed, but merely to demonstrate to the doubting that progress is being made in the right direction. As the principle involved is absolutely new, an immense amount of purely new experimental work has to be done, and improvements are being made every day. The track is 2,784 feet long, and coils about 11 inches in diameter and nine inches broad, are set along the whole length of the track at intervals of six feet. The car is cigar shaped, pointed at both ends, measures 12 feet in length and is 10 inches in diameter, weighing 350 pounds. Severe grades and curves have been introduced in the track, the worst being a 5% grade on a 280 feet radius curve. The best speed that has yet been developed has been 1½ minutes for the whole course, but this does not represent in any way the ultimate speed when the

system is perfected, merely showing that the scheme is feasible, and possesses great possibilities of success. Mr. Williams, the inventor, is perfectly confident that he will be able to treble or quadruple this speed when he gets the electrical details thoroughly perfected. At present the system is using about 200 volts and an average of 30 amperes, though owing to the construction of the truck and rails, one of the rails being a conductor, there is a great amount of breakage and consequently lost energy.

BOSTON, MASS., Oct. 11, 1890.

REPORTS OF COMPANIES.

ANNUAL REPORT OF THE WESTERN UNION TELEGRAPH COMPANY.

Net earnings amounting to $7,312,725 were shown in the report for the fiscal year 1890 submitted at the annual meeting of the stockholders of the Western Union Telegraph Company yesterday. This is an increase of more than one million dollars over the net earnings of the previous year. After paying interest and dividends, the Western Union will have a surplus, according to the Treasurer's report, of $1,441,582. The aggregate dividends paid for the year amounted to $4,956,000.

In President Green's report to the stockholders he shows that the capital stock of the Western Union now amounts to $86,199,852, of which $26,243.93 is in the company's treasury. The bonded indebtedness of the company is $14,779,500. Of the increased earnings the land lines yielded $1,362,925 and the cable lines $240,000. There was about $43,000 increase in the amount realized from leased wires. The figures show that the company now has a total surplus of $10,052,900.

In the course of the year 55,878,762 messages were sent over 678,997 miles of wire on 183,915 miles of poles. The average toll per message was 32.4 cents, against 31.2 cents in the previous year. No increase in the message rates has been made anywhere, and Dr. Green says that the increased rate per message is attributable to the fact that the greater part of the increased business consisted of long distance messages, which paid the highest rates.

The expenses of the company for the year were as follows: Operating and general expenses, $10,863,063; rentals of leased lines, $1,637,125; maintenance and reconstruction of lines, $1,988,652; taxes, $310,297; equipment of offices and wires, $275,164; total expenses, $15,074,803. The report says:

"The additions to plant during the year were 5,163 miles of line and cables, 31,300 miles of wire, and 912 new offices, at a cost of $1,778,314, paid for out of the surplus earnings. There was expended for the purchase of stock of telegraph companies $138,868, making the total cash expenditure for new property $1,917,182. It has been the effort of the management to keep the expenditure for new property down to about $1,000,000 per year, but the cost of the ocean cables, each about 850 miles long, has swelled the account this year. There has been expended in cash out of surplus earnings for new property since July, 1866, $27,653,357; in 24 years the expenditures have been $65,181,357. Of the $27,653,357 cash investments in new property $15,526,590 was capitalized in 1881, and $1,200,000 in 1887, leaving nearly $11,000,000 of surplus earnings invested in the property and not capitalized."

Of the securities owned by the Western Union Company there is an increase of $1,943,800 in the Gold and Stock Telegraph Company, about $1,750,000 in the Inter-Ocean Telegraph, and $1,000,000 in the Metropolitan Telephone Company.

The old Board of Directors was re-elected, with the exception that Charles F. Mayer, President of the Baltimore & Ohio Railroad, was chosen to succeed John Jacob Astor.

WANAMAKER ON WESTERN UNION FINANCES.

Postmaster-General Wanamaker has written a letter to Gen. H. H. Bingham, chairman of the House Committee on Post Offices and Post Roads, renewing his advocacy of the limited postal telegraph scheme. In the course of it, he says: "According to uncontroverted statements made before your honorable committee, the capital stock of the Western Union Telegraph Company in 1858 was $358,700. The stock dividends declared between 1858 and 1866 amounted to $17,810,146, and the stock issued for new lines was $1,937,950; so that the capital stock on July 1, 1886, was $20,133,800. In 1866 new stock was created to the amount of $20,450,500, so that the total capital of the Western Union on July 1, 1867, was $40,568,300. The largest dividend declared by the company up to 1874 was 414 per cent. The largest amount of stock ever divided at one time was $10,000,000, and for a period of seven years the dividends were about 100 per cent. a year on its average capital. It was by adding dividends to dividends and by piling the one up on top of the other that this tremendous amount of $40,000,000 of capital and debt was created. The history of the company shows no change of policy. In 1874, the company bought up its own stock and the stock of other telegraph companies, and accumulated a fund of over $15,000,000, which was held in one shape or another in the treasury of the company. An investment of $1,000, in 1858, in Western Union stock would have received up to the present time stock dividends of more than $50,000, and cash dividends equal to $100,000 or 300 per cent. of dividends a year. These have been some of the dividends declared: In 1862, 27 per cent; 1863, 100 per cent; in 1864, 100 per cent; in 1878, $6,000,000; in 1881, one of $15,000,000 and another of $4,300,000; in 1886, 25 per cent. The Western Union plant, exclusive of its contracts with railroads, could be duplicated for $35,000,000. Its present capital is $86,000,000. It has realized $100,000,000 of net profits in twenty-five years by its high charges."

INCREASE OF CAPITAL.

THE SOUTHERN ELECTRIC SUPPLY COMPANY, St. Louis, filed statement of increase of capital from $10,000 to $25,000.

HEAVY SUBSCRIPTIONS FOR THOMSON-HOUSTON STOCK.

The subscriptions to the 10,000 shares of the new stock to be held by the Thomson-Houston common stockholders closed last week. They aggregated 33,500 shares, or more than three times the issue. The subscribers will be awarded 30 per cent. of their bids.

STOCKS AND BONDS.

HALIFAX, N. S.—A Halifax dispatch says: A trust deed has just been registered in the register of deed's office, of this city, in which the Halifax Illuminating and Motor Company, Ltd., which a short time ago took over the street railway, have transferred to the Suffolk Trust Company, of Boston, all the real and personal estate of the company, with appurtenances thereto belonging, in trust for the equal pro rata benefit of shareholders for $300,000, debentures of the company being issued therefor in the sum of $500 each. The mortgage previously held by the Suffolk Company has been paid off.

A SIMPLE DESCRIPTION OF ARC AND INCANDESCENT LAMPS.

Sir David Salomons contributes to the October *Lippincott's* an interesting treatise on "Electric Lighting," from which we extract the following very simple and lucid popular description of the two forms of the electric light:—

In the arc lamp the current passes through two carbon rods, which are separated from each other by a very short distance. In order that the current shall leap this interval, the rods are made to touch each other, and then they are separated; a flame, consisting of heated gases, passes between these carbon rods, which flame must not be mistaken for visible electricity. The powerful light is produced by the intense heat to which the ends of the rods are raised. Suitable apparatus is connected with these carbons, in order that they may be fed as they burn away. Otherwise the distance between them will increase, and eventually the current will cease to flow. This form of light is termed "arc" light, because the flame resembles in shape an arc or a crescent.

The incandescent or glow lamp consists of a very fine filament of carbon, hermetically sealed in a glass globe from which the air has been exhausted. The ends of the filament reach the outside of this globe by being attached within in it to two platinum wires which pass through the glass to the outside, where they are dealt with in some convenient way whereby they may be attached to the circuit. The current consequently enters the filament at one end and leaves it by the other. The filament becomes white hot during the time that the current passes through it, and is not consumed, since it is not in the presence of air. The high resistance of the carbon filament necessitates a great loss of pressure in the current during its passage, and is converted into light-giving heat. If the pressure of the current is greater than that for which the lamp was constructed, too much current will pass through the filament, and it will be destroyed. On the other hand, if the pressure is insufficient, the temperature to which the filament ought to be raised will not be reached, and the light will be far less than it should be under normal conditions. The light given by any lamp diminishes in far greater proportion than the equivalent fall in the pressure of the current; and the inverse is true. For instance, a lamp intended to give a certain light with a given pressure of current would give less than half its light with a fall of 10 per cent. in pressure. On the other hand, a four per cent. increase of pressure above the normal would produce at least double the light intended.

FINANCIAL MARKET.

QUOTATIONS ON ELECTRICAL STOCKS.

Mr. F. Z. Maguire, Electrical Securities, of 18 Wall street, this city, reports the following quotations of October 11th, from New York, Boston and Washington :

OBITUARY—WILLIAM SPRAGUE.

It is with regret that we have to announce this week the untimely death, by his own hand, of Mr. William Sprague, at Seattle, Washington. Mr. Sprague was well known in electrical circles in Chicago, to which city he went from Washington, D. C., and joined the forces of the Great Western Electric Supply with the intention of working his way to the front of the profession as an electrical engineer. He subsequently left the Great Western Company and was engaged upon underground electrical work in Chicago, and about three weeks ago accepted an advantageous position on the Seattle *Journal*, in Seattle, Wash. Mr. Sprague, who was the son of ex-Governor Sprague, of Rhode Island, and grandson of Chief-Justice Chase, was a bright and well educated young man, and would undoubtedly have made a brilliant success in the electrical profession. His remains will be taken to Providence and buried in Swan Point Cemetery there.

DEATH OF DR. EMIL STOHRER.

The death is announced of Dr. Emil Stöhrer, the inventor of numerous appliances in telegraphy. Among them was a dial telegraph operated by alternating magneto-electric current devised in 1846, and a two-point register (1850) which printed two lines of dots and dashes, partly chemically and partly mechanically.

LEGAL NOTES.

THE TELPHERAGE INTERFERENCE—HUNTER VS. JENKIN.

The Board of Appeals of the U. S. Patent Office has decided the interference case of R. M. Hunter vs. Fleeming Jenkin in favor of Jenkin. The late Prof. Fleeming Jenken, who coined the word "Telpherage," obtained a British patent in 1882 and a U. S. patent in 1884. Hunter filed an application in 1886—about twenty months after the issue of the Jenkin patent—which was put into interference with that patent.

The Board of Appeals holds that, even if Hunter conceived the invention in 1879, as he alleged, he had forfeited his rights by laches. The decision is of general interest because of the invention involved, and also because of its important bearing upon the vested rights of patentees. In another interference between Hunter and Miller on somewhat the same subject, the decision of the Commissioner was in favor of Hunter, though Miller had a patent, the application for which, however, was pending concurrently with the application of Hunter. Hunter's proof in both cases was the same ; but in the Jenkin interference lack of diligence was the ground upon which the Board based its decision against him.

SOCIETY AND CLUB NOTES.

THE AMERICAN STREET RAILWAY ASSOCIATION.

The Association will, in accordance with announcement, meet at Buffalo on Oct. 15, the Hotel Iroquois being headquarters. A large attendance is expected, and electricity promises to be the leading topic.

THE TELEGRAPHERS' BALL.

The telegraphers of this city will give their annual ball on Oct. 15. One of the events of the evening will be the presentation to Miss Kittie B. Stephenson, of a handsome cairngorm brooch from the Hon. James D. Reid, as a special prize, Miss Stephenson having been the first lady winner in the fast-sending tournament at Hardman Hall.

WHAT IS SAID OF "THE ELECTRICAL ENGINEER."

THE ELECTRICAL ENGINEER, which has recently appeared as a weekly publication of 50 to 60 pages from the office, 150 Broadway, is the oldest electrical journal published in the country. It is now probably the leading technical electrical periodical of America.—*N. Y. Daily News.*

No more authoritative or better conducted journal for electricians is published in this country than THE ELECTRICAL ENGINEER. By its weekly visits is assured thorough and masterly instruction regarding all improvements and advancements in electrical science and associated topics.—*Troy Times.*

THE BAXTER MOTOR FOR ELECTRIC RAILWAYS.

The electric street railway people and in fact all street railway companies about changing to electric power will be interested in the new slow-speed motor being brought out by the Baxter Electric Motor Co., of Baltimore. The armature speed is only 42 turns per mile per hour—*i. e.*, with a car going at the rate of five miles per hour, 210 turns per minute—eight miles, 336 turns per minute, etc. The performance of this new motor will be looked forward to with interest.

INVENTORS' RECORD.

Patents issued October 7.

Alarms and Signals:—*Electric Guest-Call*, G. P. Ransom, 437,798. *Electrical Transmitter and Indicator*, D. Keley and M. C. Parkhurst, 437,859. *Combination Lock and Alarm*, R. Bauman, 438,049. *Burglar Alarm*, W. J. Ackerman, 438,127.

Conductors, Conduits and Insulators:—*Insulator*, T. F. Gaynor, 437,685. *Covering for Electric Wires*, D. Brooks, Jr., 437,918. *Aerial Conduit for Electrical Conductors*, A. A. Knudson, 438,003. *Pole for Electric Wires*, E. Verstraete, 438,086.

Dynamos and Motors:—*Regulator for Electric Generators and Motors*, R. Lundell, 437,704. *Electric Motor*, J. Emmner, Jr., 437,832. *Electric Motor*, G. Little and G. J. Little, 437,835. *Commutator*, H. H. Blades, 437,844. *Brush-Holder for Electric Motors*, E. A. Sweet, 437,946.

Lamps and Appurtenances:—*Arc Lamp*, R. H. Beach, 437,767. *Electric Light Fixture*, J. E. Brown, 437,851. *Pulley Attachment for Electric Lamps*, T. H. Brady, 437,883. *Electric Arc Lamp*, C. W. Hazeltine, 437,901. *Terminal Switch or Cut-Out for Electric Lighting Systems*, W. F. Smith, 438,118.

Measurement:—*Electric Meter*, J. Einstein and S. Kornprobst, 437,754. *Electric Meter*, A. Reckenzaun, 437,763. *Galvanometer*, T. Harris, 437,926.

Miscellaneous:—*Electric Valve-Controller*, L. Bell and F. H. Roat, 437,673. *Electric Safe-Lock*, G. L. Damon, 437,682. *Electric Steam-Generator and Water-Heater*, H. R. ALTERNATING VERSUS CONTINUOUS CURRENTS IN RELATION TO THE HUMAN BODY.[1]

BY H. NEWMAN LAWRENCE, M. I. E. E., AND ARTHUR HARRIES, M. D.

THE present paper is supplementary to a preliminary paper on the same subject read before the Institute of Electrical Engineers on the 27th of March, 1890.

In that paper it was stated (page 1, Soc. J., Vol. 86, 1890) that "our experiments have not been made with the powerful currents dealt with in electric lighting and distribution of power," and this admission, together with the difficulties inseparable from the accurate measurement of alternating coil currents, are points in connection with our paper which have given rise to much discussion in the electrical and other journals.

In the present instance, however, we have endeavored as far as possible to obviate criticism on these grounds.

1. By using currents directly from lighting circuits—both alternating and continuous.

2. By using currents directly from a dynamo whose rate of alternation could be accurately ascertained.

3. By using currents of high E. M. F.

4. By using an instrument for the measurement of alternating currents, whose accuracy at the reading of our former paper was theoretically questioned by one or two speakers, but which has since been tested and proved to give correct readings by an eminent practical electrician, thus confirming the accuracy of the readings formerly recorded by the instrument, as well as those which are contained in our present paper.

Another practical point to which special attention has been given in this paper is that our experiments have been made chiefly with the skin in a state of nature, so that the conditions of experiment as nearly as possible resemble those which might be expected to exist under accidental circumstances, that is to say, under circumstances when contact with the conductors was unexpected and therefore unprovided for.

The following are the conclusions arrived at:

A. When the human body, with the skin in its normal unmoistened condition, comes into contact for an appreciable time with bare metal conductors of a dynamo-generated continuous current passing at about 100 volts in such a way that the current passes from hand to hand, and the total contact area is about 90 square centimetres,—

1. A current of about 0.016 ampere will pass through it.

2. This current can be borne without discomfort for 15 to 30 seconds.

3. After about 30 seconds unpleasant burning sensations become marked and quickly increase.

4. The subject is perfectly able to release himself at will during any portion of the time of contact.

B. When the human body comes into contact with dynamo-generated alternating currents, alternating at about 60 to 70 per second under the same conditions as above,—

1. A current of about 0.025 ampere will pass through it.

2. This current is *six times greater* than that which produces discomfort.

3. Instantly the subject is fixed by violent muscular contraction and suffers great pain.

4. The subject is utterly unable to release himself, but remains exposed to the full rigor of all the current that may be passing.

C. When circuit from electric light or power conductors is accidentally completed through the human body, the danger of serious consequences is many times greater when alternating than when continuous currents are passing at equal voltage, and this is still to a large extent true if the voltage of the continuous current be double that of the alternating.

1. With both forms of current a reduction of contact area materially reduces the amount of current strength that passes.

2. With the alternating current, if the rate of alternation be reduced below 50 per second, the sensations of pain accompanying muscular fixation will be increased, while if the rate of alternation be increased, the pain will be diminished.

Finally, we would remind those gentlemen who so commonly speak as if voltage were the chief or only factor in the danger of accidental contact, that *current strength is the important item*, and that, according to Ohm's law, current strength is dependent not only upon E. M. F., but upon the total resistance in circuit at the time of accidental contact.

To make statements based upon voltage only, such as newspaper reports of a recent execution have contained, is not only distinctly misleading, but calculated to induce the uninitiated to form erroneous conclusions.

1. Abstract of a paper read before the British Association meeting, Leeds, September, 1890.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

ELECTRIC LIGHTING IN BALTIMORE.

The Brush Electric Company, of Baltimore, Md., is now making improvements and additions to its already very extensive alternating current electric lighting plant, which will give it a total capacity of twenty thousand 16 c. p. lamps; and thereby the Baltimore central station plant will become one of the largest alternating current incandescent lighting plants in the United States. This fact does not only reflect very creditably upon the population of Baltimore for appreciating the advantages offered by electrical illumination generally; but it also proves the rapid growth of the popularity of the alternating current system of incandescent electric lighting.

It was in the early part of 1887, a little over three years ago, that the Brush Company made the first contract with the Westinghouse Electric Company for the installation of alternating current apparatus aggregating a capacity of 5,000 lights. The undertaking was then looked upon as more of an experimental test of the new Westinghouse system than anything else. The Baltimore company had been frequently urged to extend its system of lighting all over the city, but the management had not been able to comply with this demand because the electric lighting system in operation would not enable them to cover any large territory without the putting up of several additional power houses. In other words, it was not suitable for long distance lighting. But as the Westinghouse Company claimed for its alternating current system that it was especially adapted to cover a large area in a safe and yet economical manner, it was thought advisable to try it. This was done, and it is only just to remark that from the very moment the wiring was completed, the apparatus put up and the current turned on, the Westinghouse alternating current system proved an unqualified success.

From that time the popularity of the new system was in Baltimore an established fact. The demand for the new light grew at an enormous rate, and before long the company was compelled to increase its plant. The Westinghouse Company was called on for additional apparatus of three thousand lights capacity. But even this did not long satisfy the demand, and twice again the company increased its capacity by three thousand lights, until at the beginning of the present year, the central station plant of the Brush Electric Company, of Baltimore city, had a total capacity of fourteen thousand alternating current incandescent lights

This last addition has again been necessitated on account of the demand which has been made on the Baltimore plant, and when the installation shall have been completed, there will be but two cities in the country with larger capacities of alternating current incandescent lighting apparatus—Pittsburgh, with sixty thousand lights, and New York, with fifty thousand.

WOODBRIDGE & TURNER.

This enterprising and successful firm of electric railway engineers and contractors, 74 Cortlandt street, find themselves very busy at this season and are increasing their force and enlarging their office. The following is a list of roads they have built and equipped: Augusta Street Railway, Augusta, Ga., 16 miles, 10 cars; Brooklyn and Jamaica Railway, Brooklyn, N. Y., 10 miles, 6 cars; Chattanooga Electric Street Railroad, Chattanooga, Tenn., 6 miles, 6 cars; Chattanooga Electric Street Railroad, Mission Ridge Extension, Chattanooga, Tenn., 1 mile, 2 cars; Chattanooga Electric Street Railroad, St. Elmo Line, Chattanooga, Tenn., 5 miles, 3 cars; East Reading Railroad, Reading, Pa., 1¼ miles, 2 cars; Hartford and Wethersfield Street Railroad, Hartford, Conn., 3 miles, 3 cars; Marlborough Street Railway, Marlborough, Mass., 3 miles, 3 cars; Naumkeag Street Railway, Willow's Branch, Salem, Mass., 2 miles, 6 cars; Nashville and Edgefield Street Railway (in part), Nashville, Tenn., 9 miles, 10 cars; North Edgefield Street Railway, Nashville, Tenn., 2½ miles, 2 cars; Quincy Horse Railway, Quincy, Ill., 11 miles, 13 cars; South Nashville Street Railway, Nashville, Tenn., 5 miles, 10 cars; Wilmington City Railroad, 8th Street Line, Wilmington, Del., 1½ miles, 3 cars; West End Railroad, Brighton Branch (in part), Boston, Mass., 10 miles, 20 cars; Troy and Lansingburg Street Railway (in part), Troy, N. Y., 6 miles, 6 cars; Amsterdam Street Railway, Amsterdam, N. Y., 4 miles, 6 cars.

THE RIES ELECTRIC TRACTION SYSTEM IN CANADA.

An interesting novelty is now on exhibition, says the *Montreal Gazette* of Oct. 2, in the office of Mr. D. H. Henderson, room 12, Temple building. It is a model locomotive fitted with an invention by Mr. Elias E. Ries, by which, it is claimed, the traction power of a locomotive is increased by from twenty to thirty per

cent. The invention, which is very simple in character, was explained to a number of railway men and others yesterday afternoon by Mr. Albert H. Henderson, general manager of the Ries Electric Traction and Brake Company of Baltimore, who made the experiments very entertaining. These went to show that the invention, which should be seen to be understood, increased the power of an engine on a heavy grade by about 20 per cent., and it is agreed by the promoters that its adoption by railway companies generally would prove an economical venture. The model will be on view at Mr. Henderson's office for several days and should be seen by all our railway engineers and others interested.

THE INTERIOR CONDUIT CO'S UNDERGROUND WORK AT MINNEAPOLIS.

The Interior Conduit & Insulation Co., of New York, who have some 150 miles of their underground conduits in successful operation in Minneapolis, carrying the feeders of the overhead trolley system of the Minneapolis Street Railway, will have an excellent exhibit of their admirable system at the Convention of the American Street Railway Association, at Buffalo. The exhibit will consist of the one-half size model of their new man-hole, and will show their improved methods of entering the conduits into the same and other interesting details of the system.

MR. C. C. WARREN.

Mr. C. C. Warren, heretofore connected with the railway department of the Westinghouse Electric and Manufacturing Co., has resigned his position. In accepting the resignation the company have acknowledged the valuable services rendered by Mr. Warren, and have expressed their regrets at the severance of their connections. Mr. Warren proposes to return to Chicago.

GROWTH AND ACTIVITY OF THE CENTRAL ELECTRIC CO.

When the Central Electric Company moved into its present quarters, 116 and 118 Franklin street, Chicago, last January, it was thought that the immense floor space would be sufficient for a healthy increase of the business for five years at least, but in less than six months they have been crowded for storage room and have had to go outside to obtain relief. This is evidence of the immense growth in the electrical business generally, but is particularly expressive of the success of the Central Electric Company. It is not hard to account for this success, as a glance through the establishment will show any one at all familiar with the technique of the business that the Central have gathered to themselves a list of high class specialties that are in constant demand, and could not help making any concern of healthy business methods grow. The personnel are men of tried merit and experience in the business, and attend closely to the needs of their patrons and deserve success.

The orders received for Okonite wire by the Central Electric Company within the past week have been greater than ever before in the history of the business, and this speaks volumes for this excellent and unsurpassed wire, as there have sprung up many competitors that have attempted to challenge Okonite, but Okonite still maintains its lead and high prestige.

The Central Electric Company have made advantageous arrangements to furnish telegraph, telephone and electric light poles at the lowest market rates, having established a yard in Chicago, where they will keep on hand a full stock at all times.

The Central Electric Company are decorating their handsome store with a fine line of high glass electroliers and single brackets. This department of their immense business is becoming a very important one, and the most fastidious taste in this line can be satisfied by examining their stock of these goods.

CHARLES L. EIDLITZ.

No name is better known in architectural and building circles in New York city than that of Eidlitz, and it is now the intention of Mr. Charles L. Eidlitz to extend that reputation in the field of electrical work. He has purchased from Mr. Augustus Noll his interest in the firm of Augustus Noll & Co., in which he was formerly a partner, and is now running the business under the firm name of Charles L. Eidlitz, at 10 West 23rd street, this city. He has also closed out his interests in the New York Electrical M'f'g. Co., of which he was formerly treasurer. Mr. Eidlitz, although operating under the new arrangement but three weeks to date, has already secured contracts for electric lighting work amounting to $30,000, and he has several other orders maturing. He does not limit himself to electric light wiring, but prepares specifications and plans, and undertakes large bell and burglar alarm installations.

AN ELECTRIC ROAD FOR SAN FRANCISCO.

The new stockyards company that is to establish meat-packing works at Baden in San Mateo county will run an electric railroad from that place to San Francisco. Passengers will be carried during the day, and all night light freight trains carrying meats and vegetables will be run. This road will serve to develop the southern suburb of the city, which has long needed rapid transit.

NEW ENGLAND TRADE NOTES.

T. M. Foote Regulator Company is the name of a company organized some time ago for the purpose of manufacturing and introducing the T. M. Foote intermediate speed regulator, a machine specially designed for application to water wheels, steam engines, electric motors, or any source of power which is apt to have a variable speed, so that a perfectly regular speed may be transmitted to the work to be done. The application to dynamos, which of necessity require a perfectly constant speed is peculiarly serviceable, when they are driven by variable power, and especially when water power is used. The regulator resembles in some degree a friction clutch, and is absolutely positive in its action, and is little liable to get out of order. The company have already a large number of these regulators in service, and they are at present engaged in putting in a 40 inch regulator, of 130 h. p., in the plant of the Consolidated Electric Light and Power Company, in Dover, N. H. The headquarters of the company are at 271 Franklin Street, Boston.

Drake, Paysan & Whittier is the name of a new partnership formed in Providence, R. I., for the purpose of doing a general electric light and power construction business. They will pay special attention to the installation of insolated plants, and will also handle a complete line of electric light and railway supplies. Mr. J. I. Drake is well known, having been for years connected with the Russell Electric Manufacturing Company, of Providence, the well known manufacturers of the Russell mast arm. Mr. S. R. Paysan has been in the general electrical business in Providence for 14 years, and Mr. R. H. Whittier was for some years connected with the Rhode Island Telephone and Electric Company, of Providence. The company is already in receipt of large orders, and its prospects are very bright.

WESTERN TRADE NOTES.

Mr. G. A. Edward Kohler, Western representative of the Eddy Motor Co., has sold a one-horse power Eddy motor to the United States Dental College, of Chicago, for use in their laboratory. Also a 20 h. p. machine to Mr. Andrew Cummings, proprietor of Thomson's Restaurant, where it will be employed for driving an Excelsior arc dynamo. This is somewhat of a novel but highly useful and effective arrangement.

The Illinois Electric Material Company are enjoying rapidly increasing patronage and the orders for their specialties are large and numerous. They are making large sales of their now famous "Canvas Jacket" wire. Their latest departure is the presentation of a handsome silver plated pencil, designed in the form of a spike, to all purchasers, would-be purchasers of "Canvas Jacket," or anyone desiring one, and it may be advantageously employed to note the good qualities of their goods and send in orders. All should drop them a line and receive one of these elegant and tasteful mementoes by return mail.

The Western Power Construction Co. report the demand for McIntosh-Seymour engines ever on the increase and they have on hand quite a number of important deals about to be consummated, so satisfactory have the engines already installed been. They have just sold the Chicago Edison Company another high pressure automatic engine, 18½ x 18, of 200 h. p. capacity.

Chas. A. Schieren & Company, through their Chicago office, recently received an order from the Louisiana Electric Light Company, of New Orleans, La., for 160 feet of 72 inch double leather belt and 550 feet of 48 inch double leather belt, the former being one of the largest and heaviest belts ever manufactured. This remarkable order has just been followed up by a second one for 150 feet of 72 inch double leather belt from the same company, which speaks well for the satisfaction the first one is giving.

The Electric Merchandise Co., of Chicago, have issued to their many patrons and friends a very beautiful and neat little invitation card for the Street Railway Convention, Oct. 15th, 1890, at the Iroquois Hotel, Buffalo, inviting all to call and examine the devices of their manufacture as shown in parlor F. Mr. W. R. Mason, who requires no introduction, so well known is he amongst the fraternity, will be in attendance and explain his numerous new and useful appliances and specialties for street railway work.

THE

Electrical Engineer.

VOL. X. OCTOBER 22, 1890. No. 129.

ELECTRIC RAILROADING IN TEXAS.

ONE of the interesting features of electric railway work is that it operates as a direct encouragement to the extension of long suburban lines, which could not possibly be equipped or made to pay except by resort to electricity as a motive power. Already a large number of electric roads have been built or are under construction in small towns and outlying districts, where it had before been utterly impossible to interest capital. Many horse roads constructed under similar conditions have lingered along or even been abandoned, but at the present time, the purchase of their stock or franchises has become quite a prominent industry, the intention in every case being to adopt electric motors. Wherever the plan has been resorted to and carried out, the effect has been instantaneously beneficial.

We present on this page an interesting picture of suburban electric railway extension. The photograph was taken at Fort Worth, Texas, and shows the end of one of the roads there of the Rae system, put in by the Detroit Electrical Works. Not a house is in sight. The illimitable prairie stretches out and around, and the only objects to catch the eye are the road, the cars and the cattle grazing peacefully. It will be noted that the cattle are utterly indifferent to their novel electrical surroundings. Their immediate banishment will, however, be the result of this invasion of their pastures, for the population of the city flows that way, and thanks to electricity is provided with pleasant and inexpensive new homes, of which every man can be his own landlord.

ELECTRIC RAILROADING IN TEXAS.—SCENE NEAR FORT WORTH.

A NEW STREET CAR MOTOR.

BY E. S. PILLSBURY.

IN connection with a discussion which has been recently carried on mostly by our English cousins, in regard to a new type of alternating generator brought out a short time ago by Prof. Elihu Thomson, the writer wishes to call attention to a motor recently designed by himself for street car traction, but which might by slight alteration be adapted to the generation of either continuous or alternating currents.

The machine, which is illustrated in the accompanying engravings, would appear at first sight to be quite similar to the Thomson alternator, but on close examination, it will be seen to be quite different. Like the machine referred to, it possesses a stationary armature and excites a multiple number of poles by a single pair of field coils; but while in the Thomson dynamo both fields act together to excite a revolving inductor, all of whose poles are of like polarity, in the machine here shown, coil F excites N poles Nos. 1, 3 and 5; while the core of coil F′ is

in magnetic circuit with s poles, Nos. 2, 4 and 6. Thus we are enabled, without sacrificing the advantages of this especial type of machine, to obtain a reversal of the lines of force through the armature coils instead of simply magnetizing them and allowing their cores to demagnetize themselves, and in consequence obtaining double the in-

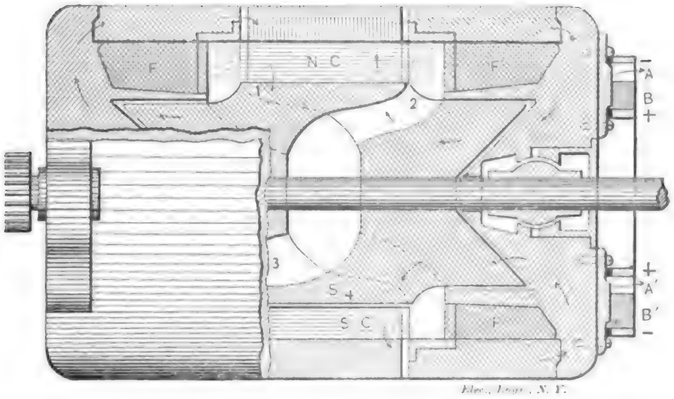

Fig. 1.—The Pillsbury Street Car Motor.

duction per turn. So much for the machine as an alternator.

But it is as a continuous current motor to which the machine shown is especially adapted. F and F′ are the field coils, and C is the armature. The magnetic circuits are completed as indicated by the arrow heads. The armature winding is that of a regular multipolar drum, each coil covering, in the six-pole machine shown, 60 degrees of the circumference.

A and A′ represent, in Fig 2, the position occupied by one coil. The points of commutation are evidently in the centre of the field induced by each pole. A slight thickness of metal is left on the under side of the armature to protect the pole pieces from eddy currents as well as to support the armature coils which are inserted from outside. The armature is stationary, the pole pieces revolving, as do also the carbon brushes B and B′. The commutator is firmly fastened to the end of the machine, the brushes pressing against it, and at the same time against the copper rings marked + and —, which form the armature terminals.

Let us see what we have gained by the method of construction thus indicated. It has been my privilege to examine a very large number of burned out street car arma-

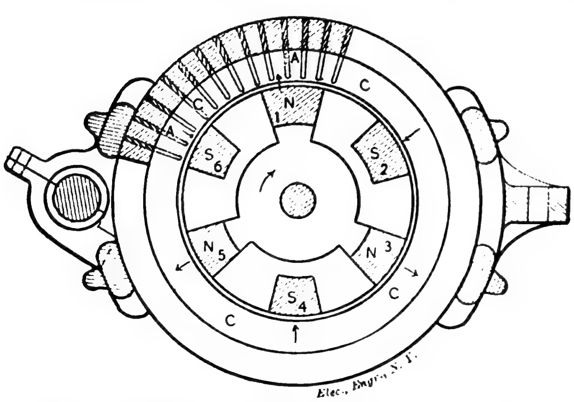

Fig. 2.—The Pillsbury Street Car Motor.

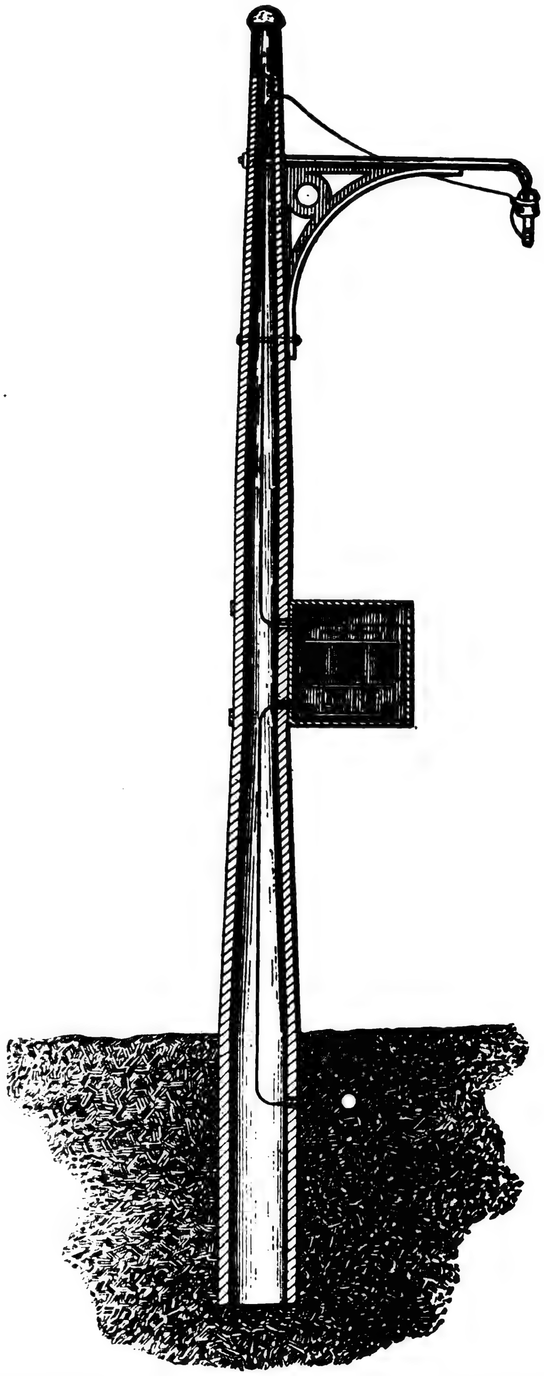
tures, and I will venture to say that 90 per cent. of these were burned out, or rather knocked out (as many were not burned out), by one of the three following causes, viz., water, vibration, and slipping of the coils on the core.

By using a stationary armature we can waterproof it much more thoroughly and avoid vibration entirely; while by using the toothed armature, we can absolutely avoid any slipping of the coils. We also have a very compact design, and can obtain at least twice the output from a motor filling the space beneath a car that can be obtained by the common designs. Again, we have our wire entirely protected by an iron sheath.

Owing to the increase in output, we propose to use single reduction in our gearing and thus obtain a noiseless set of gears. We have the solidest possible commutator, besides which it is a stationary one, and we hope thus to be able to keep it smooth enough so that it will not sing; it is also so placed as to be least likely to receive mechanical injury.

THE WHELESS OVERHEAD RAILWAY SYSTEM.

Our readers will remember that in our issue of Oct. 1 we described the ingenious electric conduit railway system



Pole of Wheless Overhead Electric Railway System.

designed by Mr. Malone Wheless and now in operation at Washington D. C. One of the principal features of the

system consisted in the arrangement by which the working conductor is divided into sections which are normally dead, but which are energized the instant a car enters upon any section; the latter again being de-energized when the car passes on to the next section. This action, it will be remembered, was performed by a switch contained in a box beside the track.

The same arrangement can evidently be applied with equal propriety to overhead systems and the accompanying engraving shows the manner in which it is carried out in practice. Here, it will be seen, the section cut-out boxes are mounted on the pole and connected to the underground feeder; the trolley line is suspended over the centre of the street. By this means each section of the working conductor, besides being controlled automatically, is under direct control for repairs and in case of accident.

MINIATURE ELECTRIC RAILROADING.

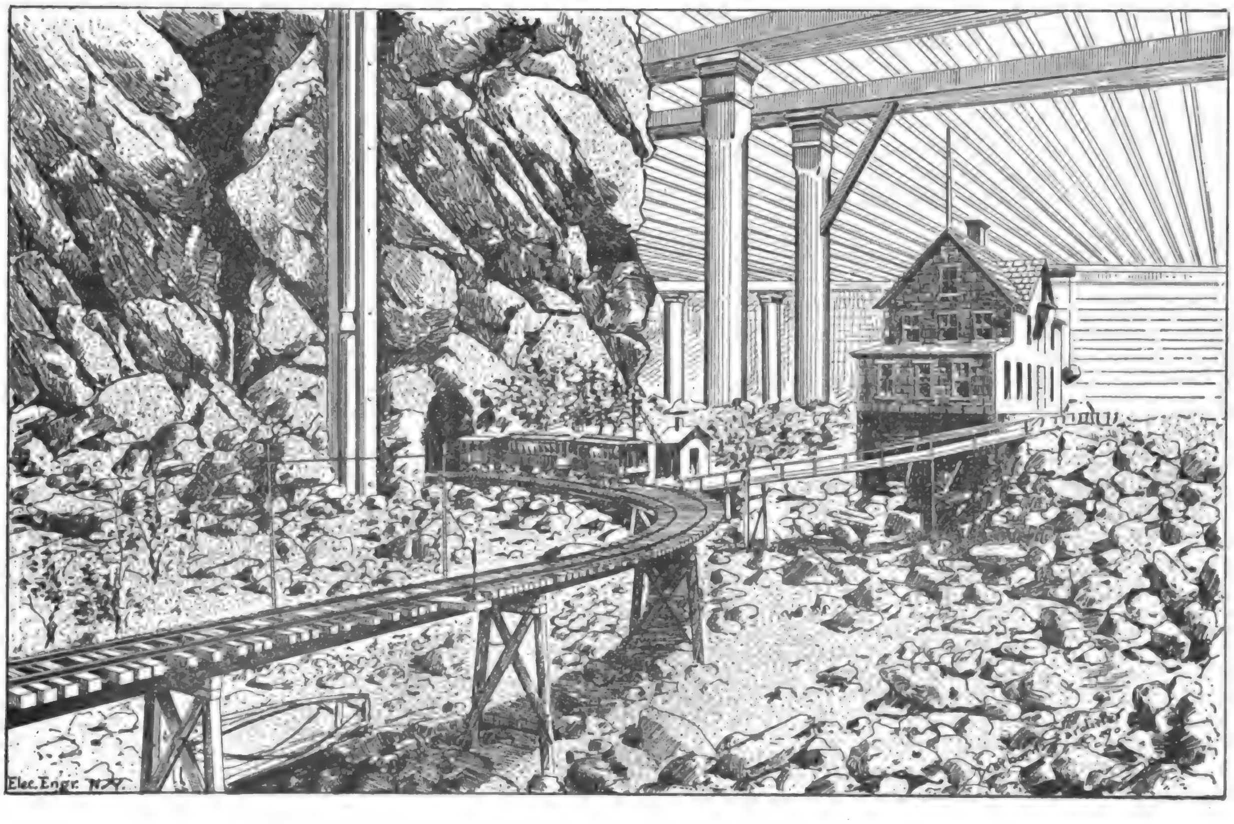
The Electrical Exhibition, just closed, at Minneapolis, was designed to demonstrate in every possible way the commercial application of electricity, and, as a consequence, many different kinds of apparatus for lighting, heating and power purposes were shown. In order to demonstrate the methods of electric railroading, and the uses to which the electric light can be put in railway working, a very ingenious miniature electric railway was operated, encircling the beautiful tower of light illustrated in our issue of Sept. 17.

This road was about 200 feet in length, supported by a trestle about three feet high above the floor, and used each rail as a conductor; that is, the two rails were used as the positive and negative conductors without any trolley system or third rail.

As shown in the engraving, the rolling stock equipment consisted of one motor car with two passenger cars. The motor was of the nominal $\frac{1}{8}$ h. p. type, 110 volts, and was fed by an Edison dynamo, which was one of those that supplied lights to the Edison Paris exhibit. The shaft of the motor was connected to the axle of the motor car by worm gearing.

The shape of the track was oblong, having four curves, a long tunnel under a large cascade, and two grades to illustrate ordinary application. The car, as it approached the tunnel, lighted miniature Edison lamps in the tunnel, for the purpose of illuminating it. It also lighted in advance each semaphore signal, and the station platforms. The road operated successfully from the start, with a single exception, when an obstruction was placed upon the track purposely, which derailed the entire train. The mill shown in the cut contained an overshot water-wheel, which was operated from the cascade above and illustrated the great milling industry of Minneapolis.

Throughout the whole exhibition this miniature railway attracted a very great deal of attention, especially from the small boys, and was very appropriately exhibited at Minneapolis, where the Edison Company are installing the largest and most comprehensive system of electric street railways in the world. The speed of this tiny train was estimated to be, in proportion to its size, equal to the speed of the Chicago limited express train on the Pennsylvania Railroad. The apparatus was built by Mr. Henry Parsell, of New York, and though small in size was accurately constructed, as its uninterrupted successful operation demonstrated.



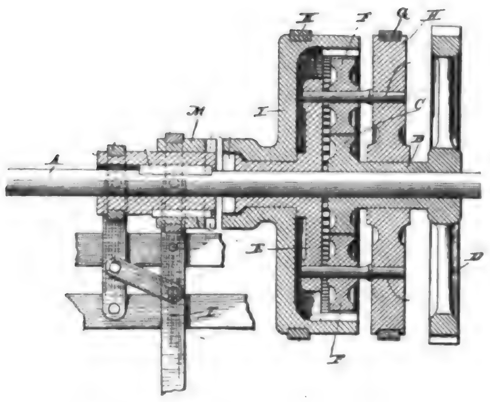
Miniature Electric Railway at The Minneapolis Exposition.

STORAGE CARS FOR DUBUQUE, IA.

The Accumulator Company, of this city, has just closed a contract with the Dubuque Street Railway Company, Dubuque, Ia., for six Edco cars, operated by "The Accumulator System." This contract was made after President Rhomberg, of the Dubuque Street Railway Company, had made an exhaustive test of the system for three months. It is the intention of Mr. Rhomberg to equip his whole road with Accumulator cars. Elsewhere in this issue will be found full details as to the system and its operation.

BALDWIN'S REVERSING GEAR FOR ELECTRIC CARS.

The most prominent direction in which inventors are at present at work in the field of electric railroading, is to relieve the motor armature of the strains which come upon it due to the frequent starting and stopping of cars. To avoid this a number of devices have been brought out, among



Baldwin's Reversing Gear for Electric Cars.

which a prominent class embraces an arrangement by which the motor armature is kept continually revolving, independent of the motion of the car.

A recent application of this nature is due to Mr. George R. Baldwin, of this city, whose gear is arranged so that the armature revolves continuously in the same direction whether the car is in motion, or not, but continues so, even when the direction of the car is reversed.

The method of construction by which this is carried out is shown in the accompanying illustration in which A represents the car axle. The armature pinion drives the spur-wheel D and its attached pinion C, which are loosely mounted by means of sleeve B on the axle A. This pinion C gears into the idler pinions F, F, revolving on pins fixed in the disc E and brake wheel H. These idler pinions also gear into the internal spur-wheel I. K and G are brake bands operated with one lever and can bring to a stop in turn either the internal spur-wheel I, or the brake wheel H, and its attached disc E. M is a double clutch to connect or disconnect from the shaft the disc or internal spur-wheel.

Taking the car at a stand-still, with the clutch and both brake bands loose and the armature revolving continuously, the different parts of the gear then revolve idly according to the laws of friction and inertia.

To start ahead, the brake G is applied and the inner clutch thrown into gear; brake K is now applied, the same movement loosening brake G; this brings the internal spur-wheel I to a stop and the idler pinions are caused to revolve around in it, carrying with them at a reduced speed the disc E whose rotation is communicated to the axle by the clutch M. To stop the car, brake band K is simply released.

To back the car, the inner clutch is withdrawn, the outer thrown in and brake band G applied; this causes the idler pinions F, F to revolve with an opposite rotation on their fixed pins and this reverse rotation is transmitted through the internal spur-wheel and clutch to the shaft.

It is thus seen that there is obtained a flexibility in the manipulation of the car independently of the motor's speed.

The constant rotation of the armature prevents the short circuits which are liable to occur from frequent reversals, and also prevents any considerable shifting of the line of commutation.

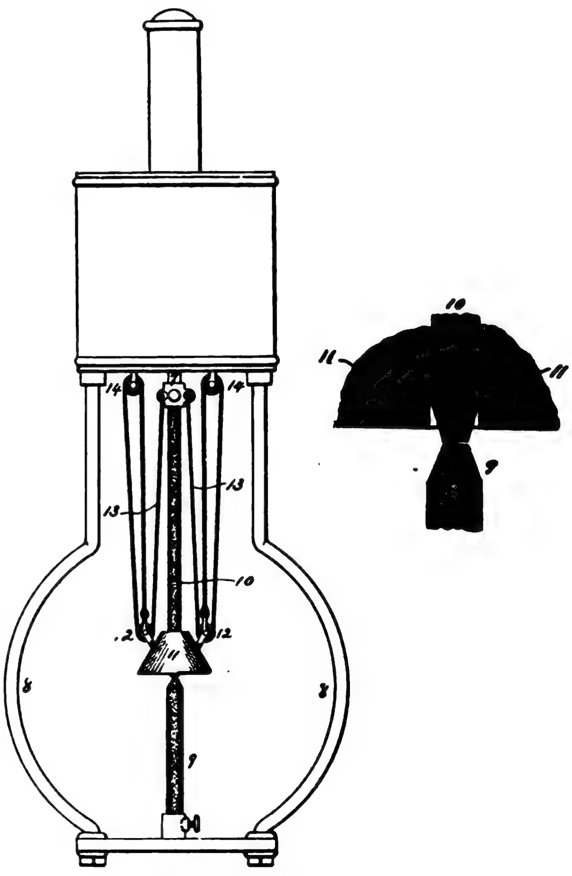
The armature is at its full speed when starting a car, thus using its own momentum to a good advantage; it is also working at its full power and greatest efficiency and is at the same time creating a counter electromotive force to prevent the excessive fluctuations of current which exert so great a strain on both the motors and generating plant.

HAZELTINE'S ARC LAMP.

An arc lamp recently patented by Mr. C. W. Hazeltine, of St. Louis, presents a distinct novelty in a peculiar method of prolonging the life of carbons. The accompanying illustration exhibits the invention clearly. Fig. 1 is an elevation of an arc lamp equipped with the invention, and Fig. 2 shows an enlarged view of the carbons near the arc, showing a part of the protective tip or shield in section.

The invention consists in the application near the arc of a protective tip or shield to prevent the rapid consumption of carbon, the tip or shield being fed as the carbon wears away.

To the upper carbon 10, a little above the arc—say one eighth or quarter of an inch—is applied a protective tip or shield 11 of refractory material, such as baked clay, porcelain or metal—having a perforation which permits the upper carbon to feed freely through it as the carbons burn away. In order to keep the protective tip or shield near the arc and receive the resulting beneficial effect, it is necessary to feed the same downward to compensate for the burning away of the lower carbon. The protective tip or shield is fed downward by the movement of the upper carbon, and to effect this a pair of pulleys are secured to the protective tip or shield, over each of which pulleys



Hazeltine's Arc Lamp.

passes a cord or chain. The ends of each of the cords are secured to the carbon-carrier, and after being carried over the pulleys 12 and 12 pass around pulleys 14 and 14, fixed to any suitable immovable part of the lamp. The other ends of the cords are secured to a bail of the movable pulleys 12. Each of the cords 13 may return upon itself three times, and will then make the feed of the pro-

tective tip or shield equal to one-third the feed of the upper carbon. In practice the lower carbon burns away about half as fast as the upper carbon when the protective tip is used. If, therefore, the upper carbon has to feed through two inches to compensate for its own consumption, it must also feed one inch additional to compensate for the consumption of the lower carbon. The feed of the upper carbon will thus be three inches in the case supposed. To maintain the protective tip or shield in the same relative position with reference to the arc at all times, it is necessary, therefore, that the shield should be fed one inch while the upper carbon is fed three inches. Care must be taken that the tip is not fed faster than the lower carbon burns away, else the tip in time will envelop the arc, and thus interfere with the proper functions of the lamp.

By applying this simple expedient to an arc lamp Mr. Hazeltine says he has found by actual practice that the consumption of carbons is decreased fully and even more than one-half, making carbons burn twice as long as they ordinarily would, without decreasing their candle-power. He is unable to account for this saving of carbon, nor does he limit the invention to any supposed theory of operation by which this result it attained. The protective shield or tip may possibly, he thinks, prevent the carrying away of any unconsumed carbon particles and their consequent dissipation and loss in the air, but may, on the other hand, operate to concentrate such carbon particles upon the arc and secure their complete combustion.

THE WENSTROM HYDRAULIC GEAR FOR ELECTRIC CARS.

It has often been pointed out that an arrangement by which the electric motor on a car could be driven continuously at a uniform speed, independent of the speed of the car is very desirable. Such a method, aside from other advantages, allows of the motor being constantly operated at its maximum efficiency, a point of great importance in the economical utilization of the current.

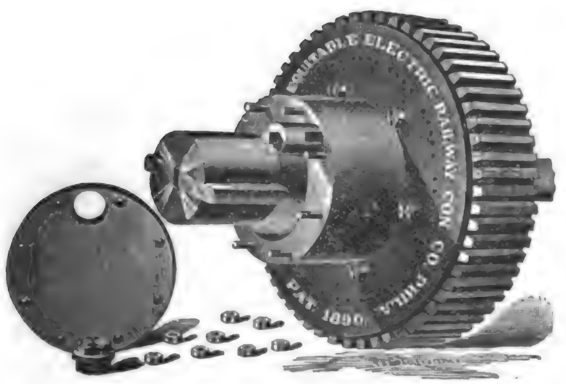


Fig. 1.—Wenstrom Hydraulic Gear, Showing Eccentric Box and Keys.

In order to accomplish this object, the Wenstrom Consolidated Dynamo and Motor Co., of Baltimore, have brought out a very simple device due to Mr. Atwood, one of their engineers, and which was shown to the delegates and visitors at the Buffalo Street Railway Convention.

The accompanying engraving, Fig. 1, shows the hydraulic gear in perspective with the end plate removed, and Figs. 2 and 3 show the same in end view and in section respectively. As will be seen, the rim which holds the wooden teeth runs loosely and free upon the axle. Within the rim, and fast to the axle is a metal disc, about three inches deep by five inches face, across which slides a brass key; the centre of the rim is hollow and is cast eccentric; in this the blank revolves, the sliding key following the interior of the eccentric box. An opening or port is cast in the rim connecting one side of the eccentric with the other through a by-pass valve. When the blank and key are in place oil is poured in, the end piece firmly screwed on and the gear is ready to operate. As the rim is revolved the oil is forced by the key, up through the opening through the open by-pass valve and into the other side of the eccentric, and, no resistance being offered, the blank and axle do not revolve.

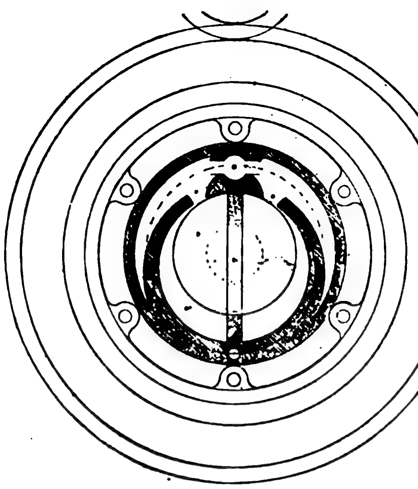

Fig. 2.—Hydraulic Car Gear—End View.

If, however, the by-pass valve be partially closed and the rim revolved the resistance of the oil is so great that the blank and axle are caused to revolve; thus by opening and closing this valve the entire speed of the car can be varied without relation to the speed of the armature, which may be kept running continuously at full speed.

It will be readily seen that with this arrangement a car may be geared to run 20 or 50 miles an hour on the level, and yet the same car may be driven up a 10 per cent. grade at only four miles an hour, with the armature running at full speed.

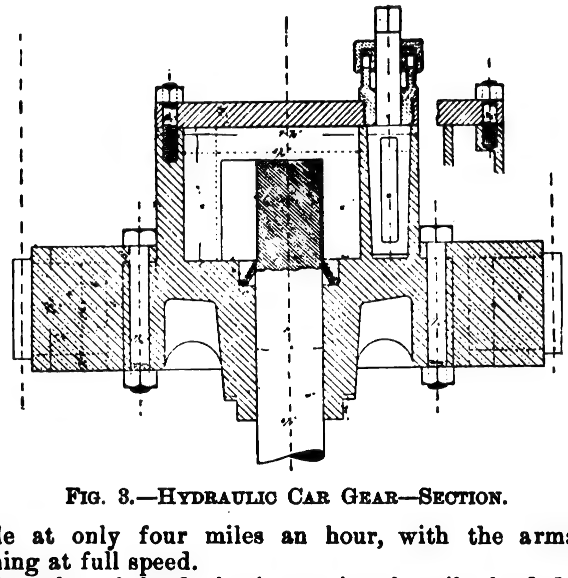

Fig. 3.—Hydraulic Car Gear—Section.

The value of the device in starting heavily loaded cars is also apparent, as any load can be started and without shock. The form of gear shown has been varied to meet different conditions but the principle remains the same in all.

The Hazeltine Electric Co. has been incorporated under the laws of the State of Missouri, with a capital stock of $650,000. The officers are: C. W. Hazeltine, president; D. R. Russell, vice-president; T. G. Portis, secretary; and W. B. Hazeltine, Jr., treasurer. The object of the company is to manufacture an attachment for arc lights which more than doubles the lifetime of the carbons. Arc lamps with the attachment are shown in operation at the Exposition, St. Louis.

NEW STEPHENSON ELECTRIC CAR TRUCK.

In applying the experience of over fifty years in the building of street railway cars, the John Stephenson Co., Ld., of this city, has designed an electric car truck in the construction of which wood material has been largely adhered to without sacrificing any of the qualities desirable in a truck of this nature.

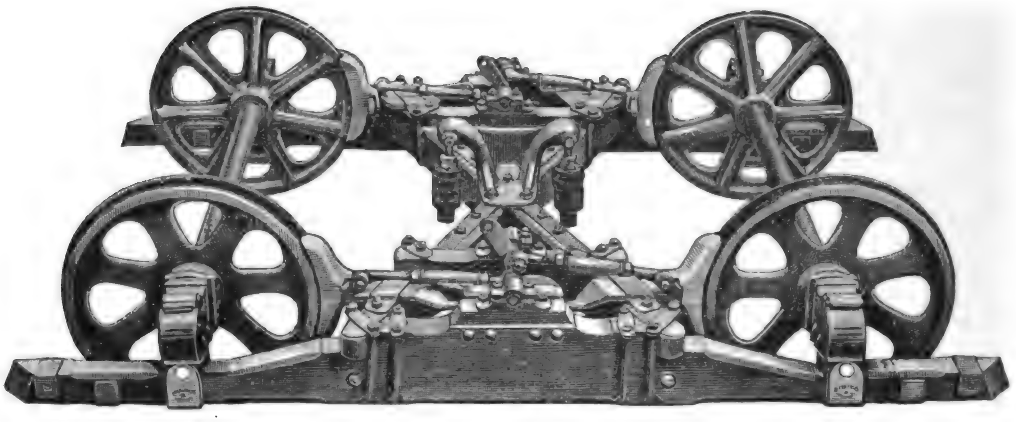

FIG. 1.—THE STEPHENSON ELECTRIC CAR TRUCK.

The accompanying engravings, Figs. 1 and 2, show the truck in perspective and in plan view, respectively, and indicate clearly the method of construction.

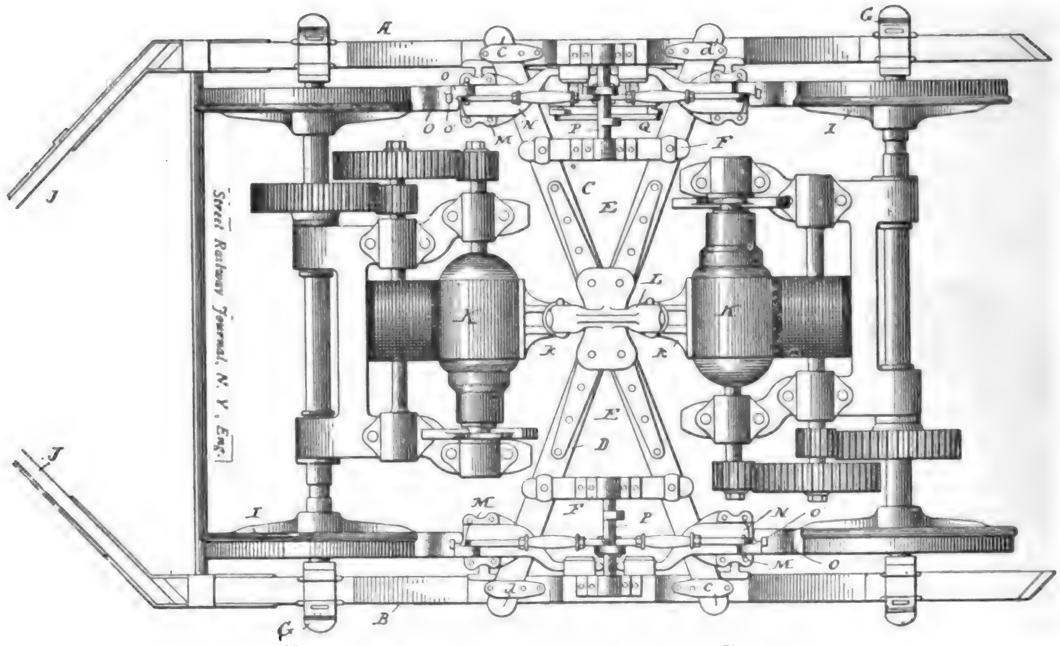

FIG. 2.—THE STEPHENSON ELECTRIC CAR TRUCK.

Among the advantages of the truck may be mentioned simplicity of construction, as but four pieces are required for the truck-frame, and the truck has within itself all needful bracing. It affords maximum room for machinery, while carrying motors and powerful brakes, free from dependence on the car body, and it is not subject to looseness of joints or change of form, and has especial facilities for repairs.

It will be seen that each motor on its axle and wheel is held to the car by three bolts, viz., a hinge joint bolted to each of the two axle-boxes and the nose bolt connecting that end of the motor with the goose-neck at the x-centre of the truck; with the three bolts named, withdrawn from their places, and the end of the car lifted, the motor with its axle and wheels may be rolled from under the car, and another motor with axle and wheels put in place in a few minutes.

It is claimed for this truck that it affords in the highest degree quiet, ease and comfort to passengers because the motor, brakes and other machinery are detached from the car body and carried by the truck with insulators intervening between the car-body and its bearings on the trucks; and for the same reason jostling and concussions are avoided. It also diminishes the wear of wheels and rails, passes curves and switches with great ease, prolongs the life service of the car and its machinery and requires less electric energy to propel the car.

A NEW ATLANTIC CABLE COMPANY.

A number of capitalists, headed by C. W. Bonynge, of San Francisco, are making arrangements for laying a new cable across the Atlantic Ocean.

The undertaking is capitalized thus: £800,000 of stock is to be taken up by eight men, at £100,000 each, to be fully paid up and no debentures issued. The cable is to be laid from Valentia Bay, on the west coast of Ireland, to a point on the American coast near New York if possible. Mr. Bonynge, now resident in London, is a San Francisco banker and broker. He says that the enterprise is already guaranteed as to its capital. It is not known whether any contract has yet been made for manufacturing the cable.

THE WINSTON-SALEM ELECTRIC PLANT.

ONLY those familiar with electrical advance know how great have been the strides made in the South. The development of the natural resources in the South has naturally brought with it enterprise in many collateral directions, and among these the electric light and power have been remarkably prominent in the last few years, hardly a day passing without the announcement of the formation of some new company for the generation and distribution of current.

A striking example of what can be done by energetic work is shown by the results obtained at Winston-Salem, N.C.

Winston and Salem are called the Twin Cities, and are practically one city, as they are directly adjoining one another, and the division line is practically in the middle of the town. The Twin City Company, which was recently organized, purchased a small local company that had been in operation at Winston for about two years, and which had an arc light plant of 50 Brush lights, and an incandescent plant of 500 Brush lights, on the two-wire system. The plant has now been converted, a new company organized, with a railway included, and a thirty-year exclusive franchise obtained. It has secured the arc light contract for both cities, comprising about 80 arc lights, and a new plant has been installed and built, everything being under one general head and management.

The accompanying engraving, Fig. 1, shows the exterior of the power building and the car house. Fig. 2 shows a perspective of the dynamo room.

The incandescent electrical plant consists of four 400 light Edison incandescent generators, with a total of 1600 lights capacity; the arc light plant consists of two 50 light Brush arc machines and the railway plant of two 50,000 watt Edison generators. The steam plant consists of two 15″ x 16″ Ball engines, one 12″ x 12″ Ball engine, three horizontal tubular boilers, heaters, pumps and general steam plant.

The plant has been built in the most substantial and thorough manner throughout; the building is entirely fire-proof, and follows the general New England "mill construction," (with one-story open roof), in floor and roofing, the rest of the building being entirely of brick. That it is fire-proof is shown by the insurance given, in a town like this, where there is practically no fire department, the insurance being at the very minimum rate. The building, the plan of which is shown in Fig. 3, comprises engine and dynamo room, 60′ x 60′; boiler room, about the same size; offices and workshop, and a car house 90′ x 60′, with a pit under the entire house.

The railway equipment consists of five miles of track, covering the general territory of the town, and reaching to all the depots and large factories. There are seven passenger cars and four freight cars running, the company intending to do a large freight business from factories and for building work.

There are 38 tobacco factories and warehouses in the town, which ship 15,000,000 pounds of tobacco every year. The roads have been very bad in this neighborhood, and the grades very steep; hence the company expects to do a profitable business in this line of freight handling.

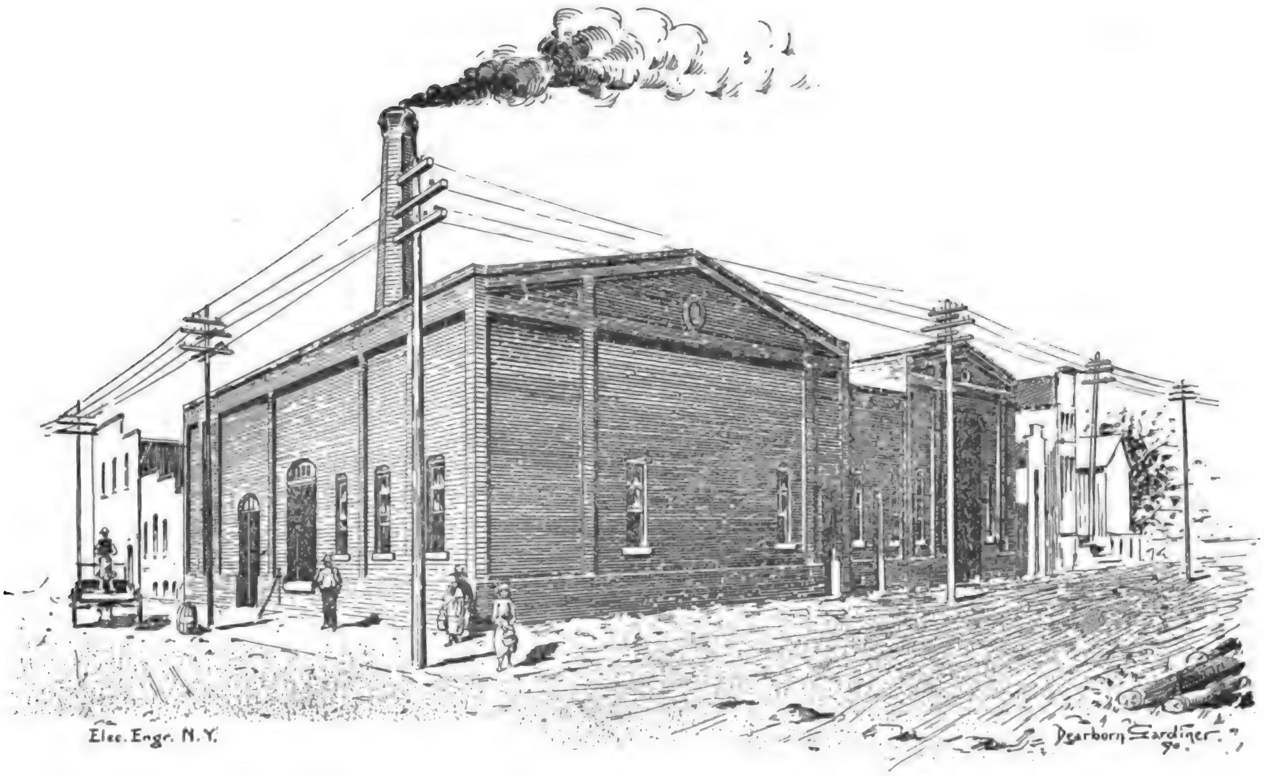

FIG. 1.—THE WINSTON-SALEM, N. C., ELECTRIC LIGHT AND POWER STATION.

The town is in one of the finest parts of North Carolina, and at present is the second city in the State. Besides the tobacco manufactories, there is a large Military Academy just being completed. Salem is the oldest Moravian town in the South, and has the oldest Young Ladies Academy and Boarding School in the Southern States, with over 500 scholars. A large winter resort hotel is also being erected there.

The plant was started up about the middle of July. The Field Engineering Company, of this city, who make a specialty of railway and central station construction, were the general contractors for building the steam plant, electrical plant and for the line construction. The track was laid by the Twin City Company, under the supervision of Mr. J. L. Ludlow, city surveyor and engineer of the company. The work was carried on under the difficulties of obtaining material so far from main sources of supply, but nevertheless accomplished in a short time.

Although the plant has been running only a few months, it has clearly demonstrated the advantages to be gained by a combination plant of this kind, which is one of the first of its class. In a small plant the labor account amounts to about 50 to 60 per cent of the operating expenses, and by combining the plants for lighting and railway purposes the labor account increases very little, thereby effecting a large saving. This is fully demonstrated by the operating accounts of the company. Mr. J. S. Badger is general manager for the Twin City Company at Winston-Salem.

The plant at Winston-Salem, is owned and operated by the Twin City Construction Company, of which Mr. J. H. McClement is president, Mr. F. A. Mason, secretary and treasurer, and the principal owners are Messrs. McClement, Johnson and Sprague. The Twin City Company is the general company, controlling the Winston-Salem Electric Railway and Lighting Company, of which Mr. F. J. Sprague is president. These are practically one and the same company, and are composed of New York parties, Messrs. McClement, Sprague and Johnson being the principal owners and controllers.

Great credit is due to Messrs. Sprague, McClement and Hawks, the principal promoters of this enterprise, for the pluck shown in attempting and successfully carrying out a piece of work, the returns from which already confirm the correctness of their judgment. The consolidated property on the basis of the first three months' operations, upon what is at best but a partially developed enterprise, is earning a dividend of about 8 per cent. over all fixed charges.

De Soto, Mo.—B. J. Arnold, St. Louis, representative of the Thomson-Houston Electric Co., has closed a contract for 1,300 incandescent lights for De Soto, Mo. Two 650 light alternators will be used.

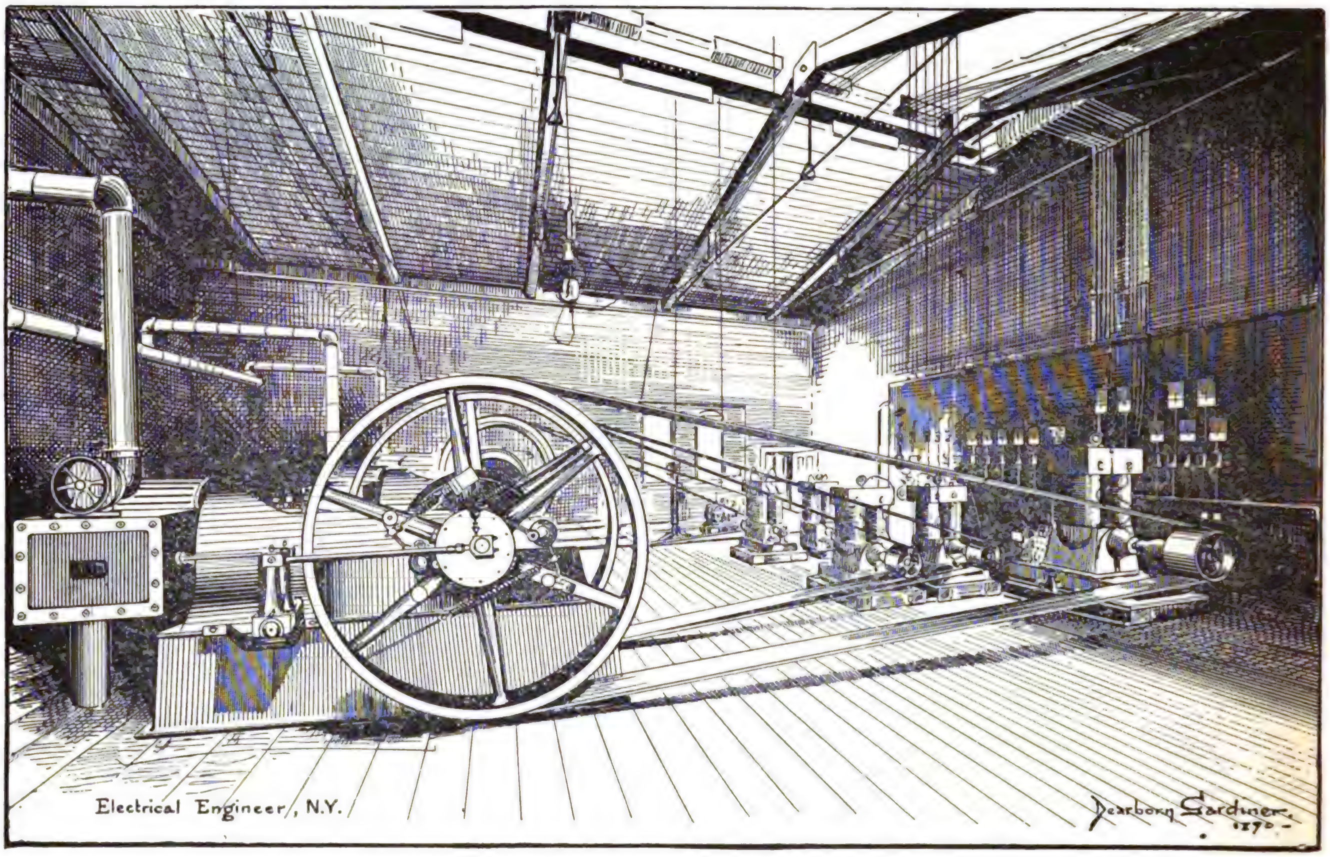

Fig. 2.—The Winston-Salem Electric Light and Power Station.

ELECTRICITY IN A SILVER MINE.

Since the operation of electric machinery of the Westinghouse manufacture has been such a wonderful success in several Pennsylvania coal mines, the demand for that company's apparatus is rapidly increasing, and its fame has even extended to the large mining districts of Colorado. The result of this has been that the Westinghouse Company is now engaged in manufacturing power apparatus for the operation of a silver mine owned by the Gold King Mining Company, of Telluride, Col., Mr. L. A. Bunn, of that city, being the president of the company. The mine in question is situated on the top of a mountain about 2,000 feet high, and as the cost of coal is a great factor in the operation of a mine under such circumstances, the advantages of electric power over steam can be easily appreciated. At the foot of this mountain is a very strong waterfall, and this power the mining company intends to utilize in conjunction with the electrical apparatus. It has been decided to place the electric plant containing apparatus to generate 100 h. p. near this waterfall, and by this means the power is to be transmitted to the motors at the summit of the mountains, where the mining operations are being conducted.

The Emerson Electric Maufacturing Co. has been incorporated under the laws of the State of Missouri; capital stock, $50,000. The company will manufacture the Emerson electric meter for alternating currents, also other electric machinery and appliances. Permanent quarters have been secured at 513 Elm street, which is being fitted up with electric power and a full line of machinery, tools and accessories for the manufacture of all kinds of electrical apparatus. The officers are J. W. Emerson, president; C. R. Meston, secretary; and A. W. Meston, lately of the Southwestern Electrical Engineering Co., consulting electrical engineer.

EDITORIAL ANNOUNCEMENTS

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

VOL. X. NEW YORK, OCTOBER 22, 1890. No. 129

I believe this is the last convention that will ever seriously consider horses for the operation of street railways.—President T. Lowry.

FAREWELL TO THE HORSE—AND CABLE.

IT is not a little singular, the more so because the coincidence was quite accidental, that while one of the papers read at the great Street Railway Convention in Buffalo last week was on the "Perfect Street Railway Horse," President Lowry in his opening address said: "I believe this is the last convention that will ever seriously consider horses for the operation of street railways." What a wonderful change of front this is! Only two years ago, in Washington, one of the delegates to the convention then sitting there, after listening to all the claims the electrical people were making, rose and entered his protest against all that new-fangled talk. He came there to learn something about horses. He wanted to know how to shoe them, how to feed them, how to dispose of their manure. And as he grumbled, there was evidently in more than one spot a sympathetic response and echo.

But the street railway companies of America are rapidly going out of the fertilizer business, and so far from caring whether they can get a perfect horse or not, their President says they will discuss horses no more. Another striking feature of the occasion was that the gentleman who was to report on cable systems did not do so, and asked for another year's time. The probability is that when the next convention comes around, President Lowry's successor will say: "I believe this is the last convention tat will ever seriously consider ca bles for the operation of street railways."

Nor was this all. President Lowry, whose ability and foresight no one familiar with his career can question, threw aside for electric motors, a brand new cable plant worth nearly half a million dollars. Some of his fellows thought him mad, but every new electric road brings fresh tributes of proof to his courage and enterprise. Electricity has changed the whole aspect of the industry even in the short time since he took his memorable action. "Heretofore," he said in his address, "street railway securities have not been looked upon by the financial world with favor. However, since they have been so successfully operated by electricity, the financial men of the country are looking to its development and application to street railways as an additional reliable security for the investment of savings and trust funds."

Having ourselves strenuously advocated electric roads at a time when there was not a single one in operation in the country, we may perhaps be pardoned if we thus emphasize Mr. Lowry's remarks to-day, when more than 30 per cent. of American street railways are definitely committed to electricity, and the new accessions to the electrical ranks average nearly ten a week. It is not a supersanguine electrical inventor that is uttering these things but one of the leading citizens of one of the greatest Western cities, and a man whose worth has won him the presidency of the American Street Railway Association. Moreover, what he said was but the gathering up in a few pithy sentences of the universal sentiment of all the hundreds who met in Buffalo last week.

This moment of triumph, however, has for those interested in electrical development its duties as well as its pleasures, and electrical engineers must co-operate with local companies to perfect the apparatus and to render the service the acme of safety and comfort. To quote Mr. Lowry again: "The street railway company should be required to equip its road with the finest and most modern cars, construct the best and most substantial tracks so as to inconvenience the public as little as possible in making repairs, and in short, supply the road in every department with the best and most modern appliances of all kinds."

A question naturally arises as to which field, in the near future, will see the greatest activity, that of the large cities or that of the smaller communities. The point is an interesting one, as the conditions to be met are extremely different. The fact that all the large cities are supplied with some means of rapid transit, makes the change to electricity slower, perhaps, for the reason that there is the existing investment. Still, in the matter of new lines, and especially of elevated roads, there is every ground for believing that they will all, and soon, be electrical. New York is slow in the matter, but both Boston and Chicago are getting ready for electric elevated roads. Turning, however, to the other class of towns and cities, we find that only 476 of them enjoyed rapid transit advantages at the beginning of this year, with a total of 807 roads. How inadequate this service to needs is may be inferred from the fact that even the Census of 1880 showed 494 towns and cities with a population exceeding 5,000. Taking into account the increase during the last ten years, one can realize without much effort how greatly rapid transit facilities have lagged behind. In a word, it might be conservatively estimated that at least two or three hundred communities

around or above 5,000 population are awaiting electric roads, to say nothing of the suburbs of cities of more imposing proportions. There are also straggling hamlets, contiguous to each other, whose necessities of this nature are most pronounced, and where the advantages of electricity with its capacity for extended distribution will be most strikingly exemplified.

RAILWAY MOTOR PROBLEMS.

WHILE the majority of electric cars now in operation and building are equipped with motors and gearing of the type or plan developed several years ago, indications are not wanting to show that in a comparatively short time we shall see a decided change in the method, or rather in the details, of construction of the driving mechanism in electric cars. The main objective point towards which constructors are drifting is, naturally, the avoidance, as much as possible, of all gearing, and the elimination, anyhow, of one of the two pairs of reducing gears from motor to car axle. The means by which this can be effected are various. The most obvious, is evidently that of reducing the initial maximum speed of the motor sufficiently to allow of the discarding of at least one of the intermediate gears, and one of the methods ready at hand is now being taken up and consists in the employment of multipolar motors. By increasing the number of poles acting upon the armature the torque or turning moment can be increased almost in direct proportion to the number of such poles; and since the work of a motor is equal to the speed multiplied by the torque, an increase in the latter necessarily allows of a proportional diminution in speed to obtain the same power. The construction of multipolar machines for stationary purposes has already given rise to a variety of designs, which bid fair, however, to be largely increased by inventors in their endeavors to apply them to traction purposes. Our readers will therefore be interested in the railway motor proposed by Mr. E. S. Pillsbury, which is described elsewhere in this issue, and in which the designer has sought to meet some of the prime conditions of successful operation.

But while some are rightly bending their energies in the direction just indicated, others are seeking an additional solution of the problem in a gear, which, while permitting the motor to revolve constantly at its most economical speed, will allow the car itself, at the same time, to be driven at any desired speed. We have already described a number of such arrangements, mostly of a mechanical nature, and in this issue another such is to be found. The search after a method which shall permit of such a regulation without shock, and hence involving no rigid parts, has led to the serious consideration, in more than one quarter, of an hydraulic method of transmission, in which the power is transferred through the medium of a liquid. Our readers will remember such a device, consisting of a turbine-like arrangement which was recently described in our columns and was also due to Mr. Pillsbury. In this issue we draw attention to another ingenious application of the hydraulic method,—namely, that just brought out by the Wenstrom Company, in which a very simple device permits of a ready variation of car speed independent of the motor. While undoubtedly obviating the strains which would otherwise be brought upon a motor run at greatly varying speeds, the question naturally arises as to the efficiency of such variable transmitting gear. Its use must, of course, involve some loss, but it is argued, and with good reason, we think, that such loss is considerably more than compensated for by the higher average efficiency obtainable in a motor running at its most economical speed, while it affords in addition all the other advantages above pointed out.

We must, however, not lose sight of the fact that the advocates of direct gear from motor shaft to car axle have claims upon our attention which it would be folly to ignore. Indeed, recent progress in this direction has been so marked that we are certain to see a more extended application of direct gear in the near future.

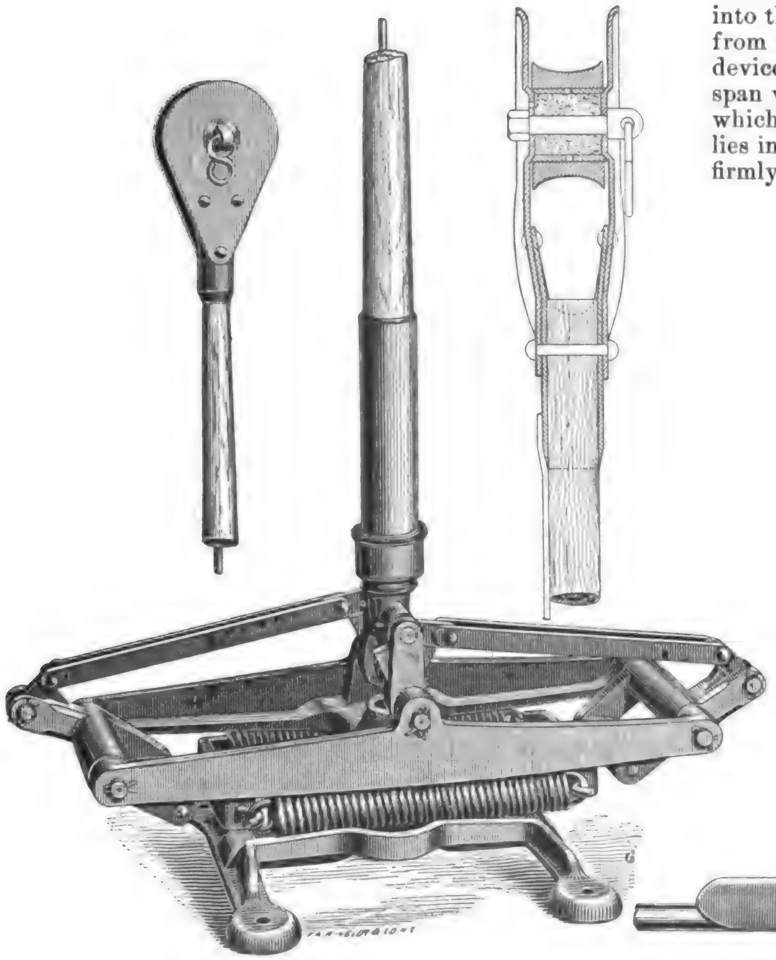
These, in brief, are the conditions which confront the electric railway engineer. Each method has its own particular advantages and local conditions as well as other considerations must dictate the one to be employed. There is certainly variety enough to meet all the conditions which may arise in practice.

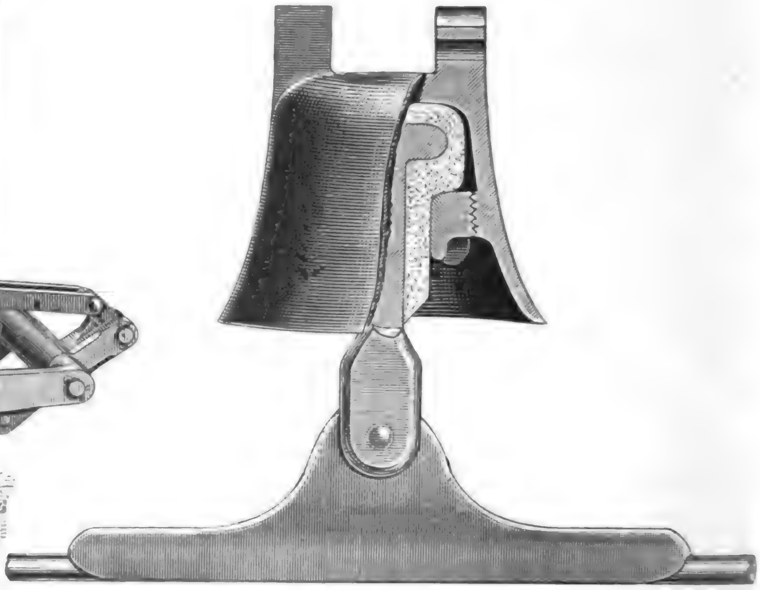
COMBINATION CENTRAL STATION PLANTS.

IN our last issue, in reviewing the history of electric lighting and power in this country, we took occasion to point out that experience afforded good grounds for the assumption that the future central electric station, in smaller towns at least, would be a plant combining within itself all the elements necessary for a general distribution of current-power for any and all purposes to which heavy currents are applied. That we are nearer to the realization of such a development than might perhaps have been imagined will be realized upon the perusal of the description given on another page, of the Salem-Winston combined arc light, incandescent light and railway power plant. Recognizing the economy of operating the various branches of work under one head, the promoters of the enterprise wisely acquired the rights of an existing company and with this as a nucleus have built up a business which after only a few months shows a good balance on the credit side. The course here pursued was evidently in marked contrast to a practice which has obtained in our smaller towns, of working electric light and railway plants entirely independent of each other, in the face of the fact that the cost of attendance in small plants is the largest item in maintenance, and that this item remains fixed over a considerable range of size of the plant. But without waiting for this increased economy to be realized by companies yet to be organized, it is evident that the same benefits can easily be secured by existing concerns by mutual arrangement. The Winston-Salem plant is another example of the opportunities for profitable investment to be found in the electrical field, and will, we hope, be the pioneer of many others as its promoters themselves have been pioneers in two of the most important branches of applied electricity. A feature of the Winston-Salem enterprise, which also deserves special notice is the introduction of freight traffic as a part of the railway business. This has already been attempted in one or two instances and no reason is apparent why the handling of freight should not be equally as profitable as that of passengers, especially as it could be carried on at night when the passenger traffic does not of itself pay.

THE EMMET TROLLEY AND LINE INSULATOR.

Although the trolley illustrated in the accompanying engraving may be new to many electric railway men, it has been in use for about a year on a few roads, during which time every detail has been thoroughly standardized. The general mechanism of the base can be readily understood from the engraving. There is a battery of four springs suspended between the lower extremities of a pair of rocking levers which are pivoted at opposite extremities of the main frame. The springs are attached to swivelling blocks with screw bolts so that the tension may be adjusted from both ends. The levers are fitted with lugs which control their motion so that one holds fast while the other rocks, thus admitting of the same battery of springs being used for motions of the pole in both directions.





Figs. 1 and 2.—The Emmet Trolley Arm and Trolley Wire Insulator.

This obviates the necessity of always bending the pole one way and makes it possible to keep a light wooden pole quite straight.

The rocking levers are connected to the pole base by links. The positions of the various centres, and the lengths of these links, etc., are so arranged that the upward pressure of the pole is accurately graded to the conditions of service, and the springs are never subjected to excessive strains. The pole may be tied down flat to the car roof for an indefinite period. The highest point of the apparatus when the pole is down is nine inches above the car roof.

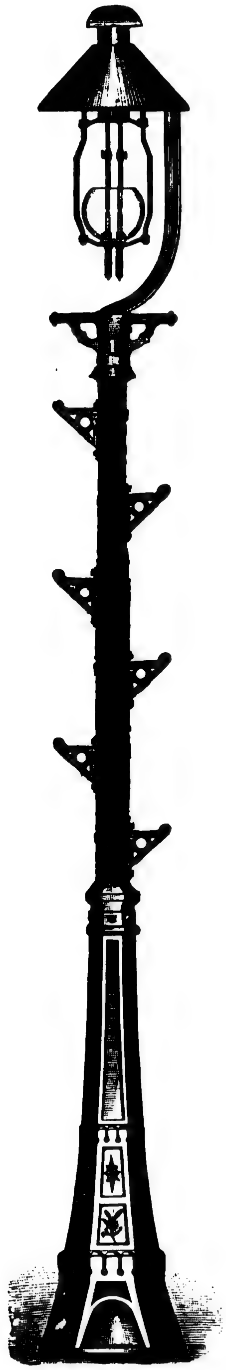
The contact roller and head illustrated in the same engraving have some novel and very convenient features. The guiding flanges, it will be noticed, are stationary, and the sheave runs between them. The shaft or spindle is a 1¼ inch brass tube, which acts at the same time as an oil reservoir, being packed with felt and oiled through a hole in one flange. The advantages of this head are its extreme lightness, sure lubrication, minimum injury to wires, and minimum cost of maintenance in repair. The sheave contains about a half pound of brass. It can be changed from the rear platform of a car in one minute and its life has been in some cases over three months, one having actually made 10,000 miles. The same firm also manufacture a wheel trolley, which weighs only a trifle more than the one illustrated; it has the same method of lubrication. These wheel heads are furnished in aluminum if desired, at a slight additional cost. The wheel head is used with the same pole and spring device. The bell trolley line insulator, illustrated in Fig. 2, is an economical and thoroughly serviceable device. It is made of iron and has a malleable iron stem with a button; this is encased in semi-vulcanized rubber, and is held firmly in place by a ring which screws into the interior of the bell. The insulation is protected from the weather; it is tough and elastic, and the whole device is practicably indestructible. It attaches to the span wire in a particularly convenient and secure manner, which, however, is not shown in the cut. The span wire lies in grooves in the lugs on top of the insulator, and is firmly held there by a piece of wire, which passes through holes in the same lugs and is attached to the span wire on each side by a half connection. These devices and many others covering the whole field of overhead railway work are manufactured by Messrs. Emmet Bros., of this city.

The Walworth Light and Power Company, whose central station is at 33 Hawley street, Boston, have installed a 150-horse-power nominal Lane & Bodley Corliss engine. The engine has one cylinder 18″x42″ and makes about 75 revolutions per minute with about 75 pounds of steam. The high speed engines have all been taken out and the dynamos are run from a countershaft by means of the Evans friction system, two dynamos being driven from each pulley. The Walworth Company by this means have reduced considerably their running expenses, and when it is taken into consideration that they supply about $7,000 worth of steam heating for offices in the vicinity, with their exhaust steam, it will be seen that the station can be operated very economically. They are at present running about 1,000 incandescent lights and 50 arc lights, and are increasing continually.

THE COLUMBIAN STREET LAMP POST.

In electric lighting systems for street illumination a demand has arisen for posts that, in addition to filling the well known electrical and mechanical requirements, shall present a symmetrical and pleasing appearance, and a glance at the accompanying illustration will show the success in that direction, which has been obtained by the Western Electric Co., in their new "Columbian" street lamp post.

The lower part or base of the new post, which is of cast



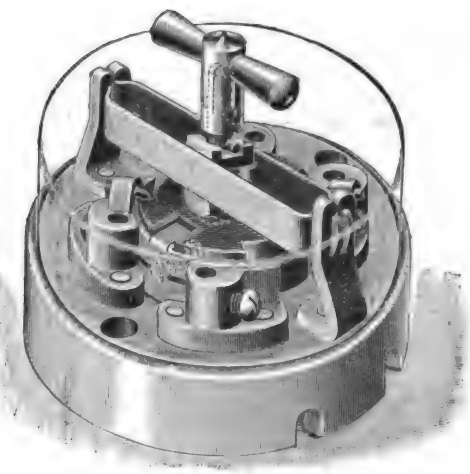
The Columbian Arc Lamp Post.

iron, has a broad circular footing, which, when bolted to the walk, gives the post great stability. Above the footing the base assumes a hexagonal section, and rises in graceful curved faces, paneled and ornamented in a tasteful manner. One of the panels is hinged so that it may be opened to give access to the switch. The wooden portion of the post extends downward through the cast iron base to the sidewalk, and above the base is provided with neat malleable iron steps, while at its upper extremity is carried a single side arm lamp support with switch-board and hood of the well known pattern adopted by the Western Electric Company. The height over all is 21 feet 2 inches.

THE PERKINS SNAP SWITCH.

The necessity of a quick make and break in an electric light and power switch is now well recognized, and to meet this requirement Mr. C. G. Perkins has recently designed the snap switch, shown in the accompanying engraving, the manufacture of which is now being carried on by the Perkins Electric Switch Co., of Hartford, Conn.

As will be seen in the accompanying engraving the moving contacts carry at their centre a lozenge-shaped piece which moves between two springs, so spaced as just to span the narrow side of the lozenge. When the handle is turned, the longer ends of the lozenge press against the springs, distending them until the long



The Perkins Snap Switch.

ends bear full against the springs. The slightest movement beyond that point, however, at once causes the springs to complete the throw of the switch by a snap movement, and to open or close the contacts independent of the movement of the handle. It will also be noticed that in order to facilitate the quick snap the lozenge is provided with roller bearings so as to reduce the friction to a minimum.

The parts are mounted on a porcelain base and are all made interchangeable. The construction is such that a good rubbing contact is obtained.

These switches are made so as to be used in connection with both concealed and cleat work, and both in single or double pole types. They range in capacity from 10 to 100 amperes.

ELECTRIC RAILWAY WORK OF THE THOMSON-HOUSTON ELECTRIC COMPANY.

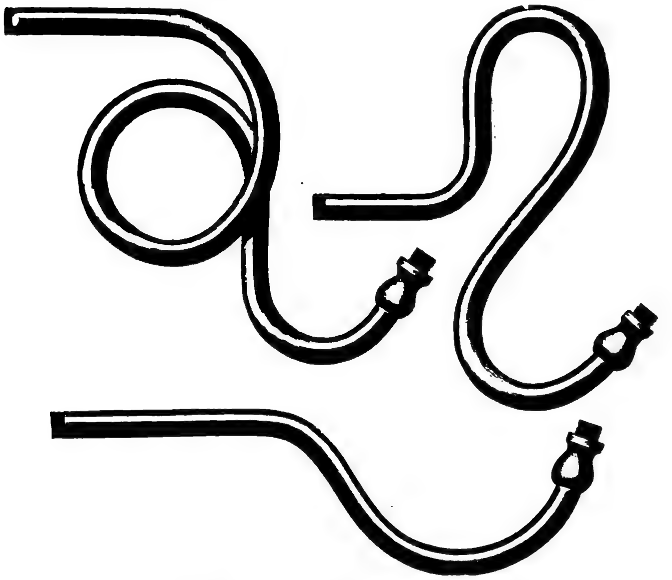
During the past two months the Thomson-Houston Electric Company has been actively engaged in completing the construction of, and has put in operation, electric railways at Concord, N. H., Shreveport, La., Newark, N. J., St. Paul, Minn., Memphis, Tenn., Anaconda, Ont., Helena, Mont. These roads comprise 50 motor cars, and 33.54 miles of track. The St. Paul road was put in operation on Oct. 6th, 1890, and has been running satisfactorily ever since. The Concord Horse Railroad, Concord, N. H., 8 cars and 7 miles of track, was started Oct. 8th, the trial car having on board the officials of the road, and invited guests. Everything in the working of the system was excellent, and the best of results are anticipated by the officials of the road. The road of the Shreveport Land and Improvement Company, Shreveport, La., 4 cars and 5.25 miles of track, was put in operation Oct. 4th, and opens up for residence a large territory owned by the Shreveport Land Company. The initial run was made without an accident of any kind, every car being utilized, and working to the entire satisfaction of all present. The City and Suburban Railway, Memphis, Tenn., 5 cars and 5 miles of track, was formally opened at 5 A. M., on Oct. 6th, 1890. The cars all worked well and their operation on daily schedule time since the time of starting, has convinced the residents of Memphis that the benefits of rapid transit have in no sense been exaggerated. On Oct. 4th, the city of Newark turned its back on horse car traction and inaugurated

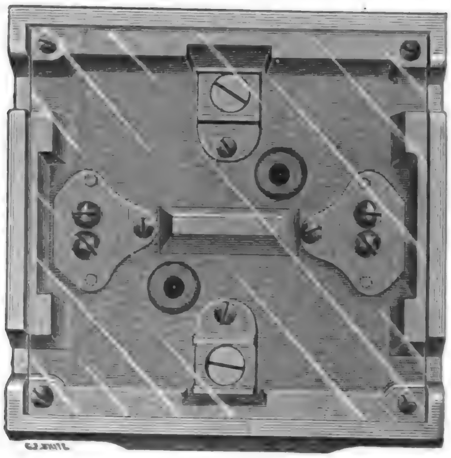
a new system which is working to the entire satisfaction of those interested in the road, and the public as well. The trial trip was a complete success. The local company have equipped 5.75 miles of track, and have 20 cars in operation. The people are very enthusiastic over the new method of transit, and predict a grand success for the electric cars in the future.

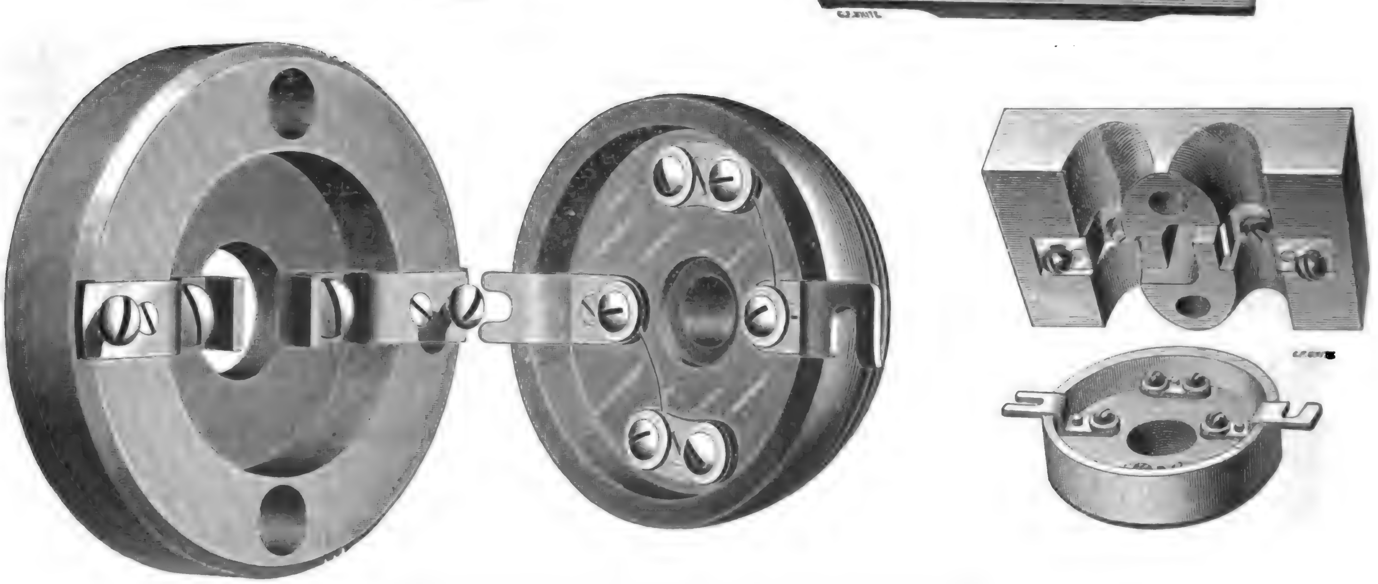
On Aug. 2d, 1890, the Thomson-Houston Electric Company commenced the equipment of the Alamo Street Railway, San Antonio, Texas, and on Sept. 25th, 1890, in less than two months, had laid 10 miles of track, put up the overhead construction, and had 10 cars in operation to the entire satisfaction of all concerned. It will be seen that this was remarkably quick time, and only goes to show that the Thomson-Houston Company employ only thoroughly competent men in their railway department.

NEW K. W. CUT-OUT SPECIALTIES.

We illustrate in the accompanying engravings two new K. W. cut-outs, which are being actively pushed by the Pettingell-Andrews Co., of Boston. The engraving Fig. 1 shows the K. W. bracket cut-out, showing the base for screwing on to a wall, pillar or other convenient place and the cut-out cover into which it is fastened; and any desired shape of bracket, three of which are shown in the engraving, Fig. 2. When the bracket is fixed in its place, in order to insert a new fuse, all that is necessary is to detach the cover carrying with it the bracket, in the simple manner well known to all users of K. W. cut-outs. Fig. 3 represents their most recent form of K. W. cut-out for moulded work, and is made in porcelain. We illustrate also the "Boston Branch cut-out," Fig. 4, which is also being introduced by the Pettingell-Andrews Co. This cut-out is made of porcelain and can be used for from 50 to 100 ampere currents. The mains come in from behind and are in electrical contact with the two brass pieces shown with three screws, while the branches run through the upper side of the box through the slots shown, and connected to the mains by fuse wire. The top of the cut-out is covered by a sheet of mica.







FIGS. 1, 2, 3 AND 4.—NEW "K. W." CUT-OUT DEVICES.

SOME RECENT WESTINGHOUSE WORK.

Among the contracts for alternate current electric lighting apparatus which the Westinghouse Electric and Manufacturing Company obtained during the last week is one from the Elmira Illuminating Company, of Elmira, N. Y. This company was organized only a little over a year ago with a view of supplying the citizens of Elmira with light. The plant erected was furnished with an apparatus of 750 lights capacity. The demand for the modern system of illumination, however, increased to such an extent that the Elmira Company was obliged to arrange for several additional alternating current machines. Three times an increase had to be made to the capacity, until to-day the central station has generating machinery for a capacity of 3,750 alternating current incandescent lamps, the last contract being for 1,500 lights.

The Westinghouse Company is also manufacturing apparatus for several other alternating current central station plants, which are already operating the Westinghouse system. There is the Oswego Electric Light Company, of Oswego, N. Y., where the capacity is not sufficient to meet the demand and a 750 light machine is being added to the plant. Lincoln, Neb., where the Lincoln Electric Light and Power Co. has been operating the Westinghouse alternating current system in a central station plant of 1,950 lights capacity, will also have more light shortly, the company having just concluded a contract with the Westinghouse Company for apparatus to generate 1,600 16 c. p. incandescent lamps.

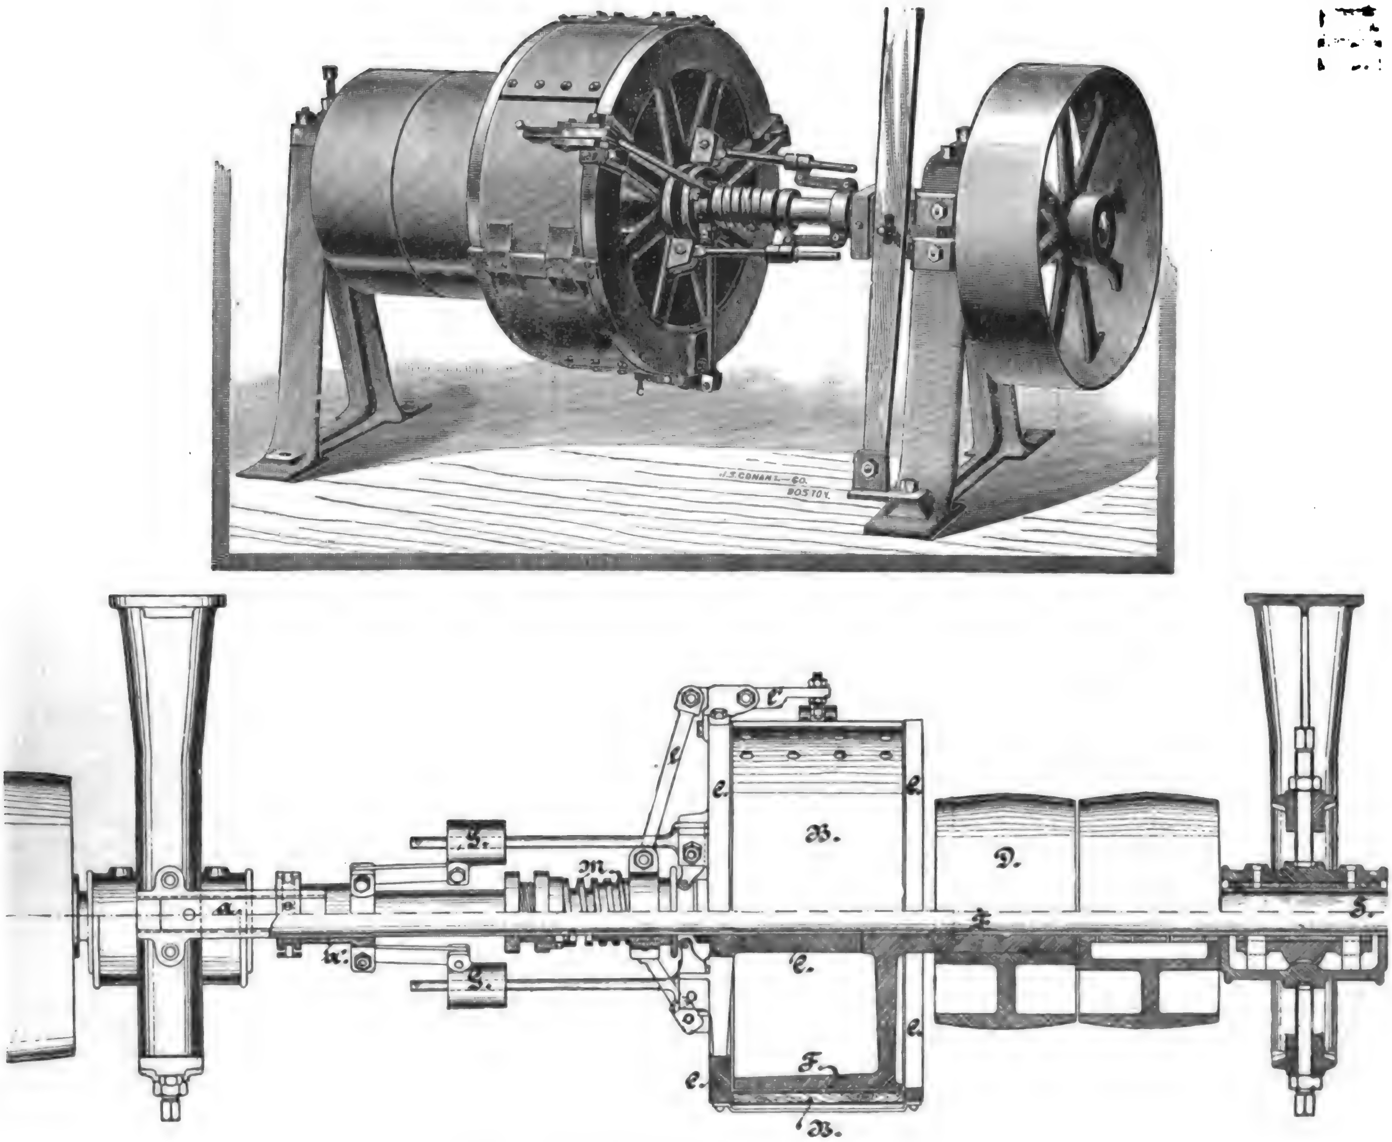
Electric lights were introduced in Tampa, Fla., in 1887, and since then the Florida Electric Company, of that city, has energetically gone to work to prove to its patrons the many advantages accruing from the use of electric illumination. Operat-

ing the Westinghouse alternate current system of incandescent lighting, their task was, of course, an easy one, and it is gratifying to know that a few days ago the company contracted for additional apparatus which will enable the Tampa central station plant to generate sufficient electricity for furnishing the city with 1,900 16 c. p. incandescent lamps.

Apart from these increases in the generating capacity which the Westinghouse Electric and Manufacturing Company has contracted to furnish, the alternate current system is also being introduced in new central stations at Durango, Cal., a plant with 750 lights capacity, and at Orange, N. J., the Westinghouse Company is also going to install a plant with its apparatus for 750 lights.

THE FOOTE SPEED REGULATOR.

While perfection in the construction of governors for steam engines and turbines has brought the regulation of such prime movers to very great perfection, there is still room for improvement in this direction and the importance of uniform speed, especially in the driving of dynamos, is too well known to need further pointing out. Again, while under small changes of load the ordinary governor may maintain the speed satisfactorily, there are numerous cases in electric work where violent fluctuations in load take place, for instance, in electric railway work.



FIGS. 1 AND 2.—THE FOOTE SPEED REGULATOR.

In order to obtain uniform speed, therefore, under all conditions, and especially in such cases where the source of power is irregular in its action, Mr. T. M. Foote has recently designed an intermediate speed regulator, Fig. 1, which automatically compensates for all changes in load and delivers power at a uniform speed to the driving pulleys of the dynamo or other machinery driven.

The main features of the regulator are a friction-coupling between the driving-pulley and the shaft to be driven, and a governor, which controls the pressure of the friction. As will be seen in Fig. 2, the driving-pulley D is fast on the projection sleeve of the friction-wheel F, the two forming one member of the friction coupling, and rotating freely on the shaft S. The other member of the friction-coupling consists of three brake-shoes B, which cover two-thirds of the friction wheel and are made of leather, backed with wood and sheet steel, which latter projects beyond the shoe, serving to fasten the same to carrier C, and giving the necessary elasticity to the shoe.

The brake-shoes are forced against the friction wheel by the spring M, which acts through levers l and l', levers l' having their fulcrums on the carrier C, which is fast to shaft, so that they all rotate together. The arms of the governor G G at their fulcrums have each an extension at right angles, which press against the spring M, so as to diminish the pressure of the same on the combination of levers and brake-shoes. The relative tension of the spring M and the amount of the weights on the arms of the governor, are determined and adjusted according to the horse-power and the speed that are desired.

This relation being adjusted, and the speed of driver D being in excess of that required for shaft, the action of the regulator is as follows: The arms of governor G G, at the predetermined speed, assume a position forming a certain angle with the shaft, and reduce the pressure of brake-shoes B on friction-wheel F to a certain amount, and this angle cannot change, nor consequently can the pressure on F, as will be seen subsequently, so long as the speed of F remains greater than that of shaft S and for which the machine is adjusted.

As the pressure of B upon F depends upon the position of the governor G, so the position of the governor depends upon the speed of shaft S; and again this very speed of shaft S depends upon

the pressure of brake-shoes B upon the friction-wheel F; so that we have three actions, pressure, centrifugal power, and revolution, forming a cycle in which each depends directly upon its predecessor and controls the next one. These three actions are constant and therefore simultaneous, and are so linked together, that the tendency of one to vary from its predetermined condition, causes the other two to react upon itself in direct opposition to its original tendency.

Let us suppose, for example, that the pressure of the brake-shoes B on friction-wheel F were increased ten per cent., the speed of shaft S would thereby be increased in the same proportion. This increase of speed again, would increase the action of the centrifugal power and throw out the arms of the governor ten per cent. beyond their normal angle, and here the counteraction would take effect, for the arms of the governor in flying out, act directly upon the spring M and diminish the pressure of the shoes on wheel F. The weights of the governor and the tension of the spring being properly adjusted, the counteraction reducing the amount of pressure must be exactly equal to the increase of pressure that caused it, and both being simultaneous, neither can take effect, so that the result is perfectly uniform speed.

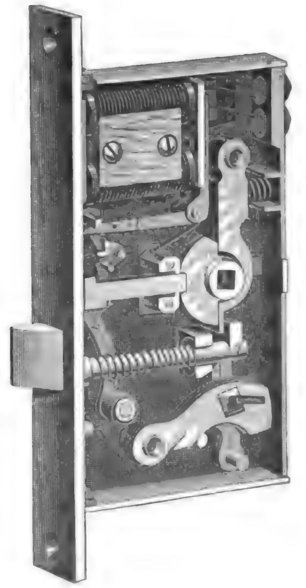
The shipper *a a'*, which changes the position of the weights on the governor, is an addition to the regulator, which increases its value in many places. By altering the distance of the weights from the fulcrum of a governor, the action of the same is greatly changed, and there is thus obtained a change of speed of over thirty per cent. while it is in motion, and still any speed it is placed at will be maintained without variation.

Besides numerous applications of the Foote regulator to the driving of dynamos for lighting and power, etc., its great sensitiveness is shown in its application to the manufacture of incandescent lamps. These having to be flashed at a predetermined voltage, it is essential that the current used for that purpose be always kept to the standard. The Foote regulator has accomplished this to perfection, thus almost doing away with the breaking of the carbon filaments, and increasing the output almost threefold.

The regulator, which is built by the T. M. Foote Regulator Co., of Boston, is especially adapted for dynamos driven by turbines and irregular acting engines.

THE THAXTER ELECTRIC LOCK.

The advantage of being able to control the opening of doors by the pressure of a push-button situated at any convenient place is now so well recognized that many private residences, apartment houses and banks are being equipped with electric door openers. In order to fulfill all the requirements of such a lock, the Electric Gas Lighting Co., of Boston, are now offering



THE THAXTER ELECTRIC LOCK.

to the trade the improved Thaxter electric lock, which possesses a number of advantages.

The lock, which is both a front door lock and an electric lock combined, is shown in the accompanying illustration.

The pressure of a button, conveniently located, closes the circuit, and the current passes through the magnet, releasing a lever; the spring then throws back the bolt from the tumbler, when the outside knob can be turned and the door opened. The door locks itself when it closes.

The catch of the lock can only be released by the push-button inside the house, or by use of the pocket key, but can not be released by thumping on or jarring the door. In fitting the Thaxter electric locks no cutting of the door jambs is necessary, which is an important advantage.

WHITE AND CARHART ELECTRIC BELL.

The accompanying engraving illustrates a new form of electric bell, the invention of Mr. J. W. White, of Providence, R. I., designed for all classes of work where electric bells are used. The

THE WHITE AND CARHART BELL.

frame is of cast iron and is shaped like a horseshoe, the magnets and hammer being similar in design to those of all other bells. The chief difference is in the bell itself, which is composed principally of a spiral steel wire, which may be either flat or round in section, free at one end and attached at the other to a metal sounding base shaped like an ordinary small bell. The sound given out by this bell is soft and much more melodious than that of other bells. The bells are neatly finished, and no cover is required, the horseshoe shape giving it quite a handsome appearance and making it an ornament to any location. The price is only a trifle higher than those of the ordinary manufacture. The bell is being put on the market by Mr. E. M. Carhart, 18 Custom House street, Providence, R. I.

NEW YORK ELECTRICAL SOCIETY.

A very interesting paper will be read before the Society on Thursday, Oct. 23, at 8 P. M., by Lieut. Bradley A. Fiske, U. S. N., on "The Modern Electrician in Time of War." The meeting will be held in Prof. Chandler's lecture room at Columbia College. All who are not members of the Society are cordially invited to attend.

BROOKLYN INSTITUTE'S ELECTRICAL EXHIBITION.

The Department of Electricity will make an exhibit of electric batteries of various forms in the large hall of the Union for Christian Work, 67 Schermerhorn street, on Friday evening, October 31, from 7:30 to 10 P. M. The exhibit will include not only batteries in working order, but the parts of batteries and appliances used in the manufacture of them.

Each member of the Department who desires to make an exhibit of apparatus of the kind described should inform the Chairman of the Committee on the Exhibit of Electric Batteries what exhibit he proposes to make, and what table space he will require, at least three days preceding the date of the exhibit. Persons not members of the Institute desiring to exhibit apparatus should make application at least four days before the day of the exhibit.

REPORT ON ELECTRIC MOTIVE POWER TECHNICALLY CONSIDERED.[1]

BY DR. W. L. ALLEN.

To go over the entire subject of electricity for street railways, and consider all the technical details, would occupy too much of your time. The subject naturally divides itself into

(I.) The Central Station.
(II.) The Transmitting Line.
(III.) The Motors.

The National Electric Light Association has so fully and exhaustively considered the matter of power or central stations that, most fortunately for street railway men, this subject is one that troubles us but little; but there are some points in which our work differs materially from that of an electric lighting station.

The engine we require must be strong in all its parts, for there is no work where the demands on it vary so suddenly and so frequently, from the entire absence of load to the extreme capacity of the engine, as in street railway work. Some roads report that the cars average but five horse-power each; supposing that such a road has eight cars in operation with one 150 h. p. engine in the station, and, as is often the case, the cars either become bunched or happen to start at the same instant; here a sudden demand is made upon the engine for 150 or 200 h. p., while a moment later the meter may register but 40 h. p. You will, of course, be provided with safety plugs and current breakers, but you cannot allow safety strips to be blown out half-a-dozen times a day, possibly just at the moment you are ascending a heavy grade.

Electric light men state that a station with a number of small high-speed engines is more economical on account of being more flexible in its operation, but in their business the loads upon the station vary gradually, while we may be called upon at any moment for our maximum capacity. To arrange our station for this varying load, and at the same time avoid operating a tremendous engine on an average light load, is a problem that experience must solve for us. We are also more greatly troubled by lightning than we should be. There should first of all be established as perfect a ground connection as possible, either by means of a well or a deep hole; it is better to have two grounds, and thereby make sure of a moist contact for galvanized ground-plates or rods; then, with proper lightning-arresters so placed that they can be conveniently examined and kept in order, we will be fairly well protected; but with our great lengths of exposed trolley wires we are very certain to have frequent calls upon our lightning arresters, and those in use at the present time are not such as to warrant perfect confidence.

Are we not all personally firm believers in the overhead system of transmission? What can there be simpler, cheaper, more durable and more convenient? We have only poles, bare copper wire, galvanized iron span wires, insulators and, where needed, additional feed-wires, of which these last can be placed under ground if desired. It is a rare thing to have a trolley-wire break except at the curves. Curves are certainly troublesome on account of the constant liability of trolleys to jump off at some sharp angle, and the trouble is more generally due to faulty trolley stands, wheels or springs than to the overhead wire. For insulators we have only those for the straight line and those for the curves; and I show you a sample of each, such as were used two and a half years ago on one of our lines. It is not to be wondered at that street-railway men at that time considered electricity, for the rough usage required by street-railway work, to be in an embryonic stage of development. There is little to be asked for in the way of improvement of what we now have for overhead material. There is practically no difference whether we use the Thomson-Houston system, Sprague-Edison, Westinghouse or what not. A single trolley wire which may be large and heavy, say, No. 00, and thus avoid feed wires where distance for transmission is not too great; or the wire may be small, say, No.4, light and easy to handle, with, in that case, the necessary feed wires. We can take our choice and find equally good results with either. It will often be convenient to utilize both plans, with the large trolley wire in the central parts of the city where feed wires might not be desirable, and with the small overhead and feed wires to reinforce the suburban parts. Undoubtedly the small wire is more easily handled and repaired in case of a break, and the feed wire prevents a dead line being the result of a break. The rail bonds may be galvanized iron, which cost but four cents, instead of tinned copper, and the supplemental ground wire can be of the same material. The supplemental wires do not give any better return except so far as to prevent a bad break in the return circuit which might occasionally be caused by the breaking of both rail bonds at neighboring joints. Rails on both sides of track should be connected with bonds.

It will not be necessary to discuss the merits of the conduit system or the storage battery. Actual experience has proven that there need be so little trouble or danger from the station and overhead line that we cannot concede the need of either conduit or storage battery, so far as *we* are concerned. It is true that the ever-restless mind of the public has been so stirred up by accounts of the numerous successful storage-battery and conduit railways that it has suddenly (and to us most unpleasantly) become aware of the fact that we are using poles, and while we are congratulating ourselves upon the beauty and symmetry of our neat line of poles, it suddenly demands that we remove what it terms our unsightly poles. Nearly everyone of the street railway men present will uphold the statement that the only problem before us, and the one about which we are always anxious, is, "What can we do to keep our motors out of the repair shop?" We don't worry about our station or our overhead wires; we scarcely have time to think of them; we are constantly at work upon and perpetually annoyed by our motors; a lame armature, a burnt field magnet, a broken gear, these are our everyday trials. A motor, such as is made by the Thomson-Houston, Sprague-Edison, or Westinghouse Companies has among its mechanical parts an axle-gear and intermediate shaft gear, shaft-pinion and armature-pinion, and the axle and intermediate shaft and armature have each their boxes or bearings. We want gear and pinions to be wide and heavy enough not to break. We don't want any more pinions like this, which was in use two years ago. We want gear of some material that will be reasonably durable, and at the same time noiseless; cast iron may do for the axle-gear, which is large and runs slower, and steel for the intermediate shaft pinion; steel, we believe, is better than bronze, as it lasts longer and is less expensive. To overcome the noise, it is necessary either to have the gear covered and running in oil, or to have the gear of wood or the pinion of raw hide. The large gear on the axle and intermediate shaft, if made with wooden teeth and used with steel pinions, certainly runs noiselessly, and it ought to make the life of the pinions much longer. Care must be taken to have the keys in all gear and pinions, tight and self-retaining. The shaft-boxes and bearings must be made of some compound metal that will not wear out too fast, for but little wear on the armature bearing will allow the armature to scrape on the pole-pieces of motor, be damaged and laid up for repairs. Aluminum bronze gives satisfaction as material for the bearings.

The electrical parts of the motor in which we are most interested are the armature, field magnets and the controlling switch or rheostat. The armature of an electric motor is its most wonderful and interesting, as well as its most expensive and troublesome part. A street car is the most overloaded vehicle known to mankind. It may run a week with a light load and then suddenly receive enough passengers to load fairly well three or four ordinary cars; the motorneer may forget to oil either the car or motor, he may reverse the motor accidentally, or purposely, to avoid an accident; these and many other causes require of an armature more work than it is capable of, hence a burn-out. On the other hand, the armature itself may be at fault; an armature such as we use to-day consists of a shaft surrounded by a metallic core. Around this core is wound the best insulated wire, each coil terminating at the same end of the armature and being attached there by means of solder or screws to the bars of the commutator. The shaft of the armature will, in a few years, become worn by its bearings, and it would be well to have bushings or sleeves placed around shaft at those points, such as the Thomson-Houston Co. use, which sleeves can be renewed. As there is no wear to the core and as the commutator can be renewed when worn down, which ought not to occur in less than two or three years, an armature should then have as long a life as one could desire were it not for the coils of wire. Where these coils cross around the head of the armature they chafe on each other and destroy their insulation. Where they end in the commutator they loosen; by an excessive load or careless driver they burn out. It may be possible to repair the armature by re-winding one coil or by re-fastening the loose ends, and even when a deep coil is burnt the total re-winding with new wire should not cost but $40 or $50. Could we but prepare for the burn-outs by having the car on some side track near the repair shop, where it would not interfere with our running time or cause a hindering of cars, we would not feel so aggravated. but it happens invariably at the time we need every car most urgently. We can watch our gear and bearings and when worn they may be replaced at our convenience or at night, but an armature gives out without warning. It is on this account that those systems advocating but one motor to a car must give us positive assurance of *no burn-outs*, for were it not for the double motor now so generally in use we would see crippled cars being *towed* into the shop greatly to our discomfiture. In the matter of minor details, such as cables, terminals, trolleys and gearing, the electric manufacturers have made the greatest improvements during the past eighteen months, but so far as we can obtain information based on actual facts, there has been but little improvement in the armatures. The Edison Company has recently announced a new armature, but we have been unable to learn what results it may show.

The switch box, such as used by the Sprague-Edison and Westinghouse, is an apparatus that if given proper care so as to keep the brass plates and buttons smooth, ought not cause much trouble. It is arranged so as to distribute the current through differ-

1. Read before the American Street Railway Association, Buffalo, N. Y. Oct. 15, 1890.

ent parts of the magnets or the motor according to the degree of speed or work required. It is somewhat in the way of passengers when the platform is overcrowded. The rheostat used by the Thomson-Houston Co. is out of the way, being underneath the platform, although it is burnt out occasionally and damaged by rain leaking through the platform; these defects should be easily overcome. It is claimed that owing to the use of the rheostat of the Thomson-Houston Co. and the resistance coils as used by the Westinghouse Co. that the cars start much more easily and without jerking, and that the motor is less liable to burn out, as they avoid throwing in an excess of current. The first claim is true, but we cannot find evidence to support the latter claim. On the other hand, it has been claimed that motors using a rheostat require on an average run from 15 to 20 per cent. more power than the Sprague-Edison motor. It does not necessarily follow that this is due to the rheostat; it seems likely that it is due as much to a difference in the winding of armature or fields. It would be most desirable, therefore, to ascertain from our various members the actual number of burn-outs of fields and armatures, of both varieties of motors, and at the same time the average power used per car. This cannot be obtained by writing for reports, as many roads do not keep an exact record or will not report the same. The grades of roads must be considered, the car mileage, and loads carried, also the system or manner with which motors are repaired and cared for.

This is a matter of the greatest importance. Our fuel costs about $1 per car per diem, and our repairs over $1.50 per car per diem. If we can save 10 per cent. on fuel each day by giving up the rheostat we do not want to do it at the expense of adding 25 per cent. to our repair account, which we all know is too large already. As an example of the approximate cost of repairs I give the cost of four 30 h. p. Sprague cars for the six months ending October 1, 1890, each car making 90 miles a day, a grade 1,900 feet of 9 to 9¾ per cent., one 300 feet of 5 per cent., one 300 feet of 8 per cent.

MECHANICAL.

3 bronze intermediate pinion at $14	$42 00
3 steel intermediate pinion at $9	27 00
8 steel armature pinion at $7	56 00
4 intermediate gear at $11	44 00
2 main gear (axle) at $16	32 00
6 axle brasses at $4.50	27 00
8 shaft bearings at $4.50	36 00
12 armature bearings at $2.75	32 00
	$296 00

ELECTRICAL.

180 carbon brushes at 10 cents	$18 00
6 trolley wheels at $1.25	7 50
3 field magnets at $20	60 00
6 armatures repaired at $35	210 00
	$295 50

For labor—

2 motor repair men at $50 per month	600 00
Total	$1,191 50

Average per diem per car, $1.62.

There are other minor repairs that would increase this about 20 cents a day.

Fuel, saw-dust and slabs, $1.30.

This fuel is about equal to screening or slack at $1.50 a ton; a greater number of cars would reduce this fuel account per car. During the six months the expense on the overhead line was less than $25 on five miles of line.

We have learned of an eight-car road running at $1 per car for fuel, another six-car road at 90 cents per diem per car. We do not believe in any case that the fuel will equal the cost of motor repairs. The first year of operation must not be taken as a fair estimate. The prices for gear and bearing will vary considerably from those given above. Some axle brasses cost $9, while those above are given at $4.50. Aluminum or some such compound may be mixed and used to decrease the cost and increase the durability of bearings; it was sold a few years ago at $3 and upwards per pound, now at $1, and it is stated can be produced for twenty cents per pound.

In the matter of gear the Westinghouse Company has so boxed the same that it can run in oil and grease; this must undoubtedly add much to the life of the gear and pinion and at the same time practically deaden the noise. Whether this boxing will stand the wear and jar, time will best demonstrate.

The following report of a road operating Thomson-Houston motors is most valuable in showing the proportion of cars disabled from electrical and mechanical causes during fourteen consecutive days in July, 1890:—

Equipped.	Operated.	Disabled.	
		Electrically.	Mechanically.
286	150 to 200		
"	"	0	15
"	"	0	12
"	"	2	12
"	"	5	8
"	"	0	11
"	"	3	11
"	"	3	9
"	"	1	10
"	"	5	7
"	"	2	11
"	"	2	15
"	"	2	13
"	"	1	12
"	"	0	12
		26	158

In seven consecutive days in August:—

Equipped.	Operated.	Disabled.	
		Electrically.	Mechanically.
308	150	3	10
"	"	5	11
"	"	0	9
"	"	4	7
"	"	0	5
"	"	4	5
"	"	1	8
		17	55

During seven consecutive days in September:—

Equipped.	Operated.	Disabled.	
		Electrically.	Mechanically.
312	150	2	3
"	"	5	3
"	"	3	2
"	"	3	3
"	"	0	5
"	"	1	4
"	"	1	4
		15	24

From this it appears that in July about 1 per cent. of the cars operated were disabled each day from electrical causes and about 6 per cent. from mechanical causes, and this during a period of extraordinarily heavy business.

During the August period the electrical trouble appears to have increased slightly in excess of 1 per cent. and the mechanical decreased to about 5 per cent., and in September the mechanical trouble decreased to about 2 per cent. This decrease was probably due in some degree to a lighter business and less mileage. As the report does not state the nature or degree of the electrical disabilities, it is not fair to assume that they were all due to crippled armatures, but we can deduce from it that a car ought to run 100 days without electric repairs.

NEW YORK SUBWAY RENTALS.

The Consolidated Subway Company notified all of the electric light companies in New York City to pay before October 17, the rentals already due and overdue for duct space in the New York subways; and that in the event of their failure to pay these rentals or a portion of them, the Subway Company would either cut their wires and cables or remove them, or both. The companies have in the meantime protected themselves by an injunction from Judge Barrett, of the New York State Supreme Court.

PUBLIC AND STATE TREATMENT OF CORPORATIONS.[1]

BY G. HILTON SCRIBNER.

A YEAR ago when it was my pleasure by reason of appointment, to present a paper before this Association upon this topic, attention was called to many of the unjust burdens imposed upon corporations by the public and the State, and so this paper may prove, although written from a different point of view, a repetition in part of the conclusions then reached.

But the ill treatment of corporations is also repeated with every session of legislature and courts, with each issue of press and political platform, and therefore continual protest upon our part, though that protest shall often rehearse the story of kindred and like wrongs inflicted and borne before, cannot be amiss.

Petition and protest, patient and persistent, has often secured a hearing and effected a removal of undeserved political and social disabilities, and so to review again some of the facts and considerations which in substance have already been considered, can do no harm. But aside from the fact that it is our duty always to complain in indignant and yet dignified terms against unjust and iniquitous treatment at the hands of the public and State, it certainly should be a matter of anxious thought and investigation on our part to discover toward what result the present trend of public opinion and usage of corporations are leading and what is likely to be the end so far as the control and use of their property is concerned, unless a change of sentiment and action regarding them is affected.

It is no longer a contention with intelligent people whether corporations are required to pay higher taxes and bear more public burdens in proportion to their property or to the protection and benefits received than private individuals. It is no longer a debatable issue with any class of persons, intelligent or otherwise, that in a dispute between a corporation and an individual before a jury the corporation without regard to the merits of the case is bound to be beaten if the court does not interfere for its protection.

No one can longer doubt that before congress, the State legislatures and even more conspicuously, before the local authorities of municipalities, all corporations not only stand at a disadvantage in securing that legal protection which the individual may obtain without asking, but they are more than ever before in constant danger of being preyed upon in every conceivable way by these legal guardians of the public weal, under whose exactments every corporation has at some time and in some way come into existence.

No man of observation and experience will longer deny that to be prominently and officially connected with corporations, either in ownership or management, constitutes a constant and strong element of ineligibility on the part of any otherwise fit man for elective public office. Now, nothing can be more evident upon a moment's reflection, than that corporations of all kinds are but associations of a number of citizens to do what cannot so well be done by one, or a small number of persons, and that the State in all cases, has been the earliest discoverer of the utility of these associations, and the promoter of these combined efforts in all those departments of industrial economy in which they have been authorized to act and into which they have been by the state first invited.

It is undoubtedly true that even in this age of the world and under the most potent influences of our best civilizations, selfishness still remains a stronger impulse and motive than a sense of justice with that majority of the people which in this country have the right to rule. It is, therefore, quite useless to appeal to the sense of justice of either the courts, the legislatures, the press or the public in pleading the cause of corporate rights or in any attempt to relieve those whose property and industry are involved in corporate undertakings, from the injustice and imposition which is constantly and everywhere inflicted upon them.

So long as those large classes which embrace in their combined membership all the learned professions, also the agriculturists, the artizans, trades people, all wage earners, and indeed all who live by industrial work and enterprise (who constitute the majority in almost every community) believe that the interests and welfare of individuals and classes may be promoted by preying upon corporations, so long will those who live by corporate industries and investments suffer all the undeserved ills of unequal taxation and legislative injustice which are now being visited upon them.

If the fact were clearly demonstrable that it is no more detrimental for those whose industry and capital are invested in corporate undertakings to be thrifty and prosper, or even to become wealthy, than it would be for them to reach the same condition by individual effort, then of course the classes above referred to might perhaps in time be made to see that they were not, after all, conserving their own best interest by indulging in so much prejudice against corporations or allowing their cupidity with so slight an admixture of justice or a sense of right to characterize and control their dealings with them. It is true that these classes, whose interests in corporations is really and only parasitical, always provide themselves with what they hold to be fit excuses for their views and conduct.

One of the most common and at the same time fallacious excuses for placing inordinate burdens and restrictions upon corporations is the allegation that the corporation enjoys valuable franchises and exceptional chartered privileges, for which it has given no adequate consideration. That it has a wide scope of some kind of authority, and at the same time little or no competition; in other words, that it is a monopoly clothed with unusual powers taken from the people—all of these assumptions are unfounded and false.

Let us for a moment examine one of the most frequent charges, indeed it is about the only charge, which those who are prejudiced against corporations put forward to fortify others and justify themselves in their depredations upon them. It is claimed, for instance, that railroad companies exercise the right of eminent domain in establishing and securing their rights of way under the proceedings for the condemnation of land. Now, nothing could be further from the truth. In the first place, the State itself, under its own organic law or constitution, can only exercise the right of eminent domain against the vested rights of any citizen when it is found to be necessary to take private property for public uses. But public uses are necessarily its own uses—neither more nor less.

The State is the organized public. Moreover, private property cannot be taken by the State even for its own public uses except by giving a full compensation therefor. In the case of railroad corporations and all others where the right of eminent domain is exercised, the State takes the land for its own advantage while the corporation pays for it, and in return only receives an easement or right to use it for certain specified purposes. The railroad company loses even this limited claim upon it when it ceases to so use it, and it reverts without payment to the original owner of the fee. So in no sense does the railroad company exercise the right of eminent domain. The State, on the contrary, does exercise it for its own benefit and purposes, while the company pays whatever the State shall determine to the owners whose occupancy has been thus disturbed by the State itself for the necessities of the public.

The courts have held, it is true, that in the case of quasi public corporations the company is in some sense the agent of the State in the taking of land and in exercising some of its other functions; but this is a confession, so far as it goes, that the State is the principal in all cases and is in perfect accord with the doctrine here urged, that in all cases where the right of eminent domain is exercised, it is exercised by the State, and in the interest of the public and in no sense and to no extent in the interest of the corporation as such.

The only act which the company does which would have the semblance of actual ownership in the premises is that it pays the owner the full value of an absolute title in fee for that which the State has taken in its own behalf, while in return the company only acquires an easement, and that forever after the company pays taxes upon the same annually at an assessed valuation much higher than is assessed upon any other land in the neighborhood which is still held in fee. What is true of steam railroad companies in this respect is also true of street railroad companies.

No street railroad company acquires any property in the street itself, but only a right to use the street in a manner which, in the opinion of the Legislature, will best conserve the interests of the public, which is in fact the State. In other words, the company simply acquires the right to use the street for that particular purpose, and no other, for which in the judgment of the State the street was originally opened and dedicated.

This is a right which the individuals composing the public have without special permission and thus which belongs to the whole public. So when the organized public or State authorizes a certain number of its members to lay down railroad tracks in the public streets, for the transportation of passengers, at a fixed rate of fare and under many restrictions and special obligations, all duly set forth as conditions precedent to the occupation of the streets, and the operation of the railroad therein, it is only fair and reasonable to suppose that the public, or State, has consulted only its own interests in making the proposition, and likewise that those individuals constituting the company in accepting the offer, have been moved to do so by a similar motive. It is therefore not only sheer nonsense but unfair and even positively dishonest on the part of the public, or State, to demand of the company afterwards anything not named in the charter, or to impose any new burden upon the company, upon the ground that the public has parted with something which it once owned, when neither as matter of fact or law has it parted with anything whatever, and would not be justified in breaking its bargains even if it had parted with something extremely valuable.

In no civilized country could any individual, under the laws and usages thereof, so deal with another. It has been reserved to the American people under republican form of government to "Eat its cake and keep it too," in dealing with those modern associations of industry and capital called corporations, and which have done more, by the way, to develop the resources of the country than all other causes combined. In all the multiplicity of de-

1. A paper read before the American Street Railway Association, Buffalo, N. Y., October 16, 1890.

fenses of the individual, both as to personal and proprietary rights embodied in the constitution of the State of New York, there is not one word of command or suggestion that taxes should be equal or uniform. The Legislature may, if it chooses, under and by authority of the constitution, place the entire burden of the State, and even of counties, towns and municipalities, upon those whose property is managed by corporations. It must be a very careless observer of the drift of public opinion and of legislative policy for the last few years who has not discovered that this very thing is now in course of accomplishment.

As before stated, the specious and unfounded excuse for this condition of things put forth daily by the press and thoroughly believed in by the general public, is that corporations of all kinds enjoy special privileges which place them under eternal obligations to the State and to the public, in other words, under a never ending obligation to everyone who is not interested in them except in this parasitical way.

Let us examine for a moment and see, if possible, whether there is any truth whatever in this pretended excuse which, if it were sound in fact, would not, as has been shown, justify the State or public, under any circumstances, in dealing with corporate property or the persons who own it on any different basis from that assumed in dealing with individuals and their interests. Remember that the question is, whether corporations enjoy by virtue of law any exceptional privileges? To bring to a focus at once all the factors and considerations bearing upon the solution of this question without a long argument backed by a still more tedious recital of examples and details, let us ask whether corporations would gain or lose by the enactment of a law declaring that the scope of all corporate rights and liabilities shall hereafter be extended and restricted to whatever citizens may legally do.

Such a law would give to the corporation the right to hold whatever property it chose to acquire, and to have it treated and taxed by the State as individual property is treated and taxed. It would give the corporation the right to conduct its business affairs without inspection or supervision. It would give it the right to engage in any industry it chose and to carry it on wherever it should find it most convenient to do so. It would give it the right to keep its own affairs to itself instead of spreading them upon public records and publishing a great part of them in the public newspapers. It would give the corporation the right to make its business as profitable, without question, as thousands of able business men have made theirs, to say nothing of the right to vote, hold office and be represented in the Legislature.

There are hundreds of limitations beside, hedging the actions of the corporation on every hand to which the private citizen is an absolute stranger in his business life.

It is true that citizens as such cannot under existing law issue money nor secure by law an easement for the purpose of railroading. But all citizens who choose may at any time and anywhere do these and all other things which any corporation may do by combining pursuant to general laws, their efforts and capital for such purposes.

There is but one great monopoly either in property or authority in this country and this is the privilege and franchise of those who have no invested interests in corporations and who constitute the majority to tax the property and restrict the actions of those whose property is employed through corporations without limit and thus protect their own lands and goods from public burdens and their own business from competition by this unjust imposition upon the property and business of others.

In several States corporate property now pays the entire State tax, leaving all other property free and clear of this great annual burden.

In all the States corporate property is excessively and unjustly taxed, and the business and affairs of all corporations are subjected to visitation, inspection and restriction by State and municipal authority in a manner and to an extent which is unfair in most cases, and in others simply outrageous.

It is not true then in any sense that a corporation is an association of persons enjoying exceptional privileges and exemptions as compared with individuals; on the contrary, it is an association authorized by law for some specific purpose which has been recognized and approved by the State, but with abridged rights, limited scope, restrained activities and increased liabilities and control, as compared with those of the citizen.

What reason, or justice, or decency is there then in maintaining two systems of taxation, one for corporate and another for individual property?

When a corporation has paid taxes at the current percentage for the year upon all its real and stands ready to pay upon all its personal estate, why should its capital stock be assessed and taxed? Why should it pay still other license fees and assessments, and additional taxes based upon its earnings gross and net. By this unjust method of stock assessment, the railroad company is compelled to pay an annual tax upon the good will or prospects of its business and which is assessed usually at three or four times the value of all the personal property it owns. One instance is as good as another in showing to what extent street railroad companies are imposed upon in this matter of taxation. The rate for the last year in the city of New York for city, county and State tax on personal property was 1.686, or a little less than 1¾ per cent. Not one person in a hundred liable for personal taxes, paid even at this low rate, anything whatever, and the hundredth one, it is safe to say, did not pay on one-hundredth part of his personal estate. Now one street railroad company owning but $344,000 of personal estate all told, paid beside its real estate tax $38,000, which is a little more than eleven per cent. in one year upon its entire personal property, not estimated at a low valuation, but computed at cost, without any allowance for wear and depreciation. All other companies in New York paid at about the same rate without any deduction for indebtedness, bonded or otherwise.

Why should a hundred or more bills be introduced at each session of the State Legislature, all intended to the best of the ability and ingenuity of their authors to injure or annoy corporations in the transaction of their business beside those intended to shift additional burdens from individual to corporate property, the first of which are never criticised by the public or the press, while the latter are always greeted with commendation and applause.

Before courts and juries, corporations in dispute with a citizen have come to be dealt with so unjustly that as a rule they find it less oppressive to appeal to their adversaries and abide by their judgment, stimulated and warped as it must be by cupidity, than to go before these tribunals of professed impartiality. During the last year a case for a trifling injury to the person was tried in the Superior Court of the City of New York in which the corporation with which the writer is connected was the defendant. The jury seemed intelligent, the judge ruled fairly, and the case was on both sides well presented. To the astonishment of both parties, the jury, after a short deliberation, brought in a verdict for $5,000, which, however, was settled the next day for $2,000—all parties concerned well knowing that in this case, at least, the jury had committed an act under the forms of law for which every one of them should have been fined the full amount of the verdict, had they had lacked the legal protection of jurors or acted from a less excusable motive than unfounded prejudice.

This course of treatment of corporations by the public and the press, the Legislature and the courts can in the nature of things have but one ending if continued long enough.

Corporations will at last, one and all, surrender or sell to the State upon such terms as a venal Legislature may offer, the various industries which can no longer with profit be carried on in opposition to its interferences and under the increasing burdens and oppressions which by striking bills and otherwise it has placed upon them.

It is even now the constant appeal of all labor unions, that the State shall take not only into its control but ownership, all quasi public corporations. Nor is their course in this respect illogical, for public ownership and management would not only open to them the most direct avenue to corporatate property and earnings, but it would prove a long stride toward the distribution of all wealth, and render the dream of the Socialist a possibility.

Our free schools, free press, and that exhaustive discussion of all public questions preceding the frequent elections under a democratic form of government, has at last taught all classes, including laborers, in this country what their material interests are. They are fully instructed not only as to their physical wants, but how to supply them.

Now large numbers of persons bound together by avocations and associations, and which we call classes, have always without exception, in all countries and in all ages since the dawn of history, regarded their wants and their rights as synonymous, and such will be the rule in the present case.

To-day the world over, and in this country more than any other, labor and capital, the former willingly and the latter under the lash, are on a dead run for the same goal. And this goal—this consummation, ignore it as we may—call it what we will—disguise it as we please—is no other, in fact, than absolute State management—and State management is neither more nor less than State socialism of the German type.

To-day a very simple and evident truth is flashed over the Vanderbilt system, that "to be a Knight of Labor is inconsistent with the duty of a railroad employè," and the chosen chieftain of the laborer screams back from Scranton, "to-morrow the government shall own and manage all your corporations." Here you have the very gist of the labor question. In its last analysis, it is a question of control. This, and this only, is in dispute between labor and capital. It is an "irrepressible conflict" between two great classes as to which shall possess and control what labor has produced, and is producing. Now if anyone can tell which is the most numerous class—those who have control, or those who want it—the ins or the outs in ownership, it will not be difficult to determine which class, stimulated by eager politicians, will ultimately carry the elections and control the government.

Conservatism, it is true, usually comes with responsibility, but it is only a conservatism in dealing with the disputes of others after self interest has been fully satisfied.

Whatever may be said against Mr. Powderly's proposition, that a government, to be controlled by him and his followers, and which by that time will be his and their government, shall seize the corporations for their own benefit, it must be admitted that

he is simply and only following to its logical conclusion the theory and practice which the present government has already inaugorated, that of treating the property belonging to one class of citizens differently from that belonging to another. Those who think themselves Mr. Powderly's betters in morals and in many other ways, say boldly, let us prey upon corporate earnings by every means in our power, and Powderly says, let us seize the entire plant and so take all their earnings.

The doctrines proclaimed by the press, the pulpit and the bar, taught in the counting house, the shop and the field, enacted by the Legislature, enforced by the court and confirmed by the jury, is that corporate earnings may be seized and taken by unjust and unequal assessments, taxes and judgments, and in many other ways, simply because they are corporate earnings, for the comfort, uses and relief of those who have no proprietary interest in them. Now to do this, is not one whit more commendable than to follow Mr. Powderly to the logical consummation he announces, that of taking the whole, while it is much meaner than his method, as petty larceny is more contemptible than grand. It is, besides, more aggravating.

Those who maintain the right of legal forage upon property not their own through unequal taxation, interference and restrictions, not only violate their own professions, but seek flimsy excuses for their course and try to shut their own eyes to the fact that they are constantly doing in a retail way what Mr. Powderly proposes shall be done at wholesale.

Is it to be supposed that either class will succeed in a peaceful and lasting transfer from other pockets to their own without compensation? Can such systems be firmly established and maintained in America and revolution avoided? There is not the slightest probability of it.

The age has past (if there ever was one), when injustice and oppression in any form can be systematically practiced by one large class of society upon another of the same race, with any result but that of final disaster and ruin to those who expect to profit by it.

When corporations are taken by the State, no one else will want them on the same terms, and the Carnival of the public, while in possession, will be brief and unsatisfactory.

It is an unpleasant task to sound a note of warning, and generally an unwelcome one, but he lacks sagacity, no less than courage, who seeks to hide an evident future or hesitates to look any unpleasant prospect in the face.

It is possible that a fortunate and timely change in public views and sentiments may yet turn back the tide of confiscation and distribution, which has been already begun.

It is possible that statutes may he repealed, ordinances rescinded, and decisions reversed, so that the property of one class shall no longer be seized upon for the benefit of another, but is it probable?

He must be an optimist indeed, who can discover in the present attitude of the Legislature or the courts, the press or the public, anything which is prophetic of such a just and desirable consummation.

SPIRAL OR TRANSITION CURVES FOR STREET RAILWAYS OPERATED BY MECHANICAL MOTORS.[1]

BY E. A. WOOLLEY, LINCOLN, NEB.

In ordinary railroad practice spiral curves are, in theory, no new thing, although even in this field they have never received the attention which the importance of the subject demands.

I feel safe in making the assertion that there is no road in the country where they have been introduced that would now think of building a railway, involving what might be considered even moderately sharp curvature, without the use of spirals.

In the construction of street railways, we are obliged to use curves very much sharper than the engineer of an ordinary railroad is ever called upon to contend with. At the same time our rolling stock is comparatively little better adapted for traversing sharp curves. So long as street cars were operated by animal power only, the speed was necessarily slow and the need of transition curves but little felt. With the introduction of mechanical motors the weight of our rolling stock is immensely increased, and at the same time the maximum speed is probably three times greater than with the old system of horse power. The practice of running cars in trains immensely increases the difficulty, so that now the blow given by the leading outer wheel as it first strikes the outer rail at the entrance of the curve is probably ten times greater than with the horse car.

So long as circular curves only are used, there is but one way of reducing the shock to passengers and cars and the constant danger of derailment at these points, and that is, to reduce the speed of the train. In the crowded business streets of a great city this reduction of speed is perhaps no disadvantage.

There are, however, many places in the suburbs and outlying districts where a reduction of speed would not be necessary but for the presence of the curve. It is in such places as these that the spiral will have the greatest advantage, although even at slow speed the passage of a sharp curve properly "spiralized" will be found infinitely smoother and better in every way.

In the practical application of the spiral to street car curves I have not as yet been able to give it as thorough a test as I could wish. However, I have done something in this direction. During last March, while in the employ of the Denver and Berkeley Park Rapid Transit Company, at Denver, Col., I laid out a curve of one hundred and forty feet radius, using spirals 100 feet long. The line was built to a three feet, six inch gauge and operated with Baldwin steam motors, weighing about 32,000 lbs., with trains of from one to three eight-wheeled cars, each thirty feet long. This was my first experience with a sharp curve spiralized. The first train to pass this curve was sent round at a speed of ten miles per hour. No jar whatever was felt upon entering the curve. Afterwards it was tried at higher speeds, until finally, as a test, an engine was sent round this curve at twenty-five miles per hour, and still there was no sign of shock or jar when entering or leaving the curve. This line had previously been in operation something over one year, and a great many passengers were in the habit of locating the point where they wished to leave the train when coming home at night by passing this curve. After the spiral curve was put in, dozens were carried by their stopping-place on account of the trains passing the curve so smoothly that sitting in their seats they did not notice it. Afterwards I made another test with a curve of seventy feet radius, with results proportionately good. As yet I have had no opportunity of testing the advantages of the spiral on curves of forty and fifty feet radius, but I firmly believe that by using spiral transition curves we may double the speed in passing any given curve without increasing the danger of derailment, and with much less strain or shock to cars and motors.

In regard to the methods of laying out these curves, I use a method in some respects different from any one else, so far as I know, but the methods of Wellington, Searle, or Henck may be used. Either will give satisfactory results. Perhaps the best method as yet published may be found in a pamphlet, *The Railroad Spiral*, by Prof. D. M. Greene, of the Rensselaer Polytechnic Institute, of Troy, N. Y.

It will matter but little what method is used. But care should be taken to lay out the spirals accurately, and in laying track, rails should be curved very carefully, If points are set on spiral from five to ten feet apart the trackmen can stretch a line of one rail length along spiral and take ordinates for curving rails directly from the stakes.

THE EDCO STORAGE BATTERY STREET CAR.[1]

BY D. H. BATES.

The horse is a noble and extremely useful animal, but he seldom combines high speed with great endurance. The fast trotter is made to run his mile in from two and a quarter to three minutes, but he does it only on rare occasions and is well fed and cared for between times.

It was not until yesterday, when Mr. Odell's very interesting paper was read, that I had any idea of the innumerable obstacles to be surmounted in first securing a perfect street car horse, and second, in maintaining him in a constantly efficient condition.

Judging from the expressions of a large number of street car men with whom I have talked on the subject of storage battery cars, I have inferred that your street car horse was ready for continuous hard work at all hours of the day or night. That it took no time to change horses at the end of a trip, and that you only fed them at night, after a sixty mile run, and that oats and hay were always cheap.

For all these or like requirements must be met with in our storage batteries, if they are to satisfy the average street car official.

But when we undertake to show that the energy requisite to propel a sixteen foot car with its average load of passengers at the horse car rate speed must be increased 100 per cent. if the speed be doubled, and that the cost of producing that increased energy, by whatever means you employ, must necessarily be doubled, the scientific fact is perhaps admitted, but if storage batteries are the medium it is always taken for granted that they ought to do double the service at half the cost.

The overhead systems in operation throughout the country have demonstrated to you, gentlemen, the fact that electricity is not the coming power, but the power already come. The mileage of street roads in the United States which in June, 1890, were operated electrically is, according to the eleventh census, $8\frac{4}{100}$ per cent. of the entire mileage, but omitting 59 cities the proportion runs up to 25 per cent. This means one of two things, either that as a rule the authorities of our large cities will not allow overhead poles in the street, or that street car managers prefer to await the

1. A paper read before the American Street Railway Association, Buffalo, N. Y., October 16, 1890.

1. An address delivered before the American Street Railway Association, Buffalo, N. Y., October 16, 1890.

result from the use of the electric system on a small scale in the towns and smaller cities before introducing it in the cities on a scale of greater magnitude.

The overhead systems already introduced in many places have so far improved upon the horse and mule that the public, once given rapid transit, would not go back to slower methods and are clamoring everywhere for such facilities.

You street car owners and representatives, however, must look at the resultant in the matter of cost per car mile and net profits, and before some of you yield to the loud demands of the public for rapid transit by adopting the overhead system we beg of you to carefully consider the merits of the storage battery.

1. It will propel a car just as fast and just as efficientiy with all that that implies as the trolley system. Every word that can be said in favor of the trolley system applies equally to the storage battery.

A storage battery car is capable of much work that a trolley car cannot accomplish.

a. Storage battery cars can be introduced gradually, one or two at a time, in connection with horse cars, cable cars or trolley cars.

We have already had proposals from a cable road for a few cars to be run at night when the cable could only run at a great proportionate expense, and from a trolley road where an extension was needed on a route that did not permit of trolley poles.

b. Storage battery cars can be run over any track or route where a horse car can be run, thus avoiding blocks in cases of fire, processions and other obstructions.

Transfers of cars can, with this system, be made from one road or route to another in cases of necessity or convenience in handling an unusual traffic.

c. In cases of break down at power station during hours of heavy traffic storage battery cars could run for two or three hours with the 33⅓ per cent. reserve always remaining in the double sets of batteries.

Now, as to the figures relating to the battery system.

What is the cost of a storage battery car plant?

What does it cost per car mile to maintain?

What does it cost per car mile to operate?

Let us take a unit of 50 cars: Fifty cars at $1,000, $50,000; storage plant engine, nominally 500 h. p. (triple expansion), $12,-500; 500 nominal h. p. boilers 50 per cent. margin, $10,000; 50 sets of car motor equipments, each consisting of two 15 h. p. slow speed motors capable of being exerted up to 20 h. p. each for brief periods with dust tight covers, gearing and motors running in oil starting, regulating, reversing and speed, switches, lamps, signals, batteries, etc., complete, $249,400.

Central station equipment, including dynamos, rheostats, switches, reserve batteries, shifting appliances, etc., complete, $128,400. Grand total, $450,300—say $9,000 per car for everything except buildings, road bed and tracks.

MAINTENANCE PER ANNUM.

Steam plant, 10 per cent	$2,250 00
Cars, 10 per cent	5,000 00
Electric plant exclusive of batteries, 10 per cent	21,500 00
Batteries, 20 per cent	31,680 00
Shifting appliances, 5 per cent	200 00
Total maintenance per annum	$60,630 00
Maintenance per car per annum	$1,212 00
Maintenance per car day	3 32

Maintenance per car mile (on basis of 120 miles per day), 2¾ cents. With a smaller run the wear and tear would, of course, be reduced.

DATA RE POWER PLANT AND COST.

Horse power required	500
Time required for producing such power	18 hours
Total horse power hours	9,000 hours
Coal per horse power with triple expansion engine	2 pounds
Coal per day 18,000 lbs., or	9 short tons
Coal being estimated at $3	$27 00

LABOR.

One chief engineer	$4 00
Two assistants at $2.50	5 00
Two firemen at $2	4 00
Two assistants at $1.50	3 00
Six shifters at $1.50	9 00
One electrician	4 00
Two assistants at $2.50	5 00
One dynamo man	3 00
Total labor	$37 00

SUPPLIES.

Water per day	$5 00
Oil and waste	2 80
Appurtenances and miscellaneous	2 80
Total supplies	$10 60

RECAPITULATION AND SUMMARY.

Fuel per day	$27 00
Labor per day	37 00
Supplies per day	10 60
Total cost per day for operation	74 00
Cost per car day for operation	1 48
Cost per car mile for operation	$1\frac{4}{100}$
Cost of maintenance per car mile	$2\frac{75}{100}$
Total cost of maintenance and operation per car mile	$3\frac{99}{100}$

The following are some of the conditions fulfilled by this company with its storage battery cars.

1st. That each car will be delivered in first-class order with appliances for keeping it well under control, and for readily operating it with such skill as would be possessed by an intelligent car driver after suitable instruction.

2d. That each car will be run fifteen (15) miles an hour on a straight level and suitable track in good order when carrying fifty (50) passengers, or an equivalent weight not exceeding 6,000 pounds.

3d. That each car with the above load will ascend grades not exceeding three per cent., and not longer than 500 feet, at the rate of at least five miles an hour.

4th. That two sets of batteries per car shall be delivered, either of which when fully charged shall be capable of propelling a loaded car as above on a straight level and suitable track for a distance of sixty miles if required, when it shall be replaced by the reserve battery, which meanwhile shall have been fully charged. Each battery can be charged while its alternate is being used. As a matter of policy, we advise retaining one-third of the charge of the battery, as a reserve for emergencies.

5th. That the batteries when treated according to printed instructions, and their parts renewed as required, will remain in an efficient condition.

We have already touched upon some points of advantage in the storage battery traction over the trolley system. We will now refer to the inherent defects of the trolley system which do not pertain to storage traction.

1st. The disfigurements of streets by double lines of poles and trolley wires, with cobwebs at every curve.

2d. The frequent interruption of the entire system by a break down at the power station or in the feeder wires.

3d. The great and sudden fluctuations in the load which make such break-downs of the power plant extremely frequent, many such break-downs having already occurred. With trolley and cable lines, the extremes of no load and full load are reached suddenly from one to a dozen times every five minutes. This is not only destructive to the machinery (steam, electric and cable), but frequently causes a break-down of the whole line, involving heavy outlays for repairs, serious loss of revenue and dissatisfaction on the part of the public.

4th. Bad economy in the power station, due to the fact that maximum power must be provided in the engines and dynamos instead of the average power as provided in the storage system, causing the engines with the trolley system to run with an average of about half their load and therefore uneconomically; with storage battery traction the engines and dynamos run with an even and unfluctuating load continuously, giving the best possible economy of coal and increasing the life of the plant.

Economy and inconvenience of operation as compared with requiring an expenditure of energy in all portions of the line, even though but one or a few cars may be running. For suburban roads and all night runs this feature is of special importance.

6th. Liability of generators and motors being burned out by lightning passing through the bare trolley wires through the motors to the ground.

7th. Liability to motors burning out with the high voltage current.

8th. The business public is inconvenienced by the derangement of the telephone service due to induction and leakage from the trolley lines to such an extent as to make the telephone service useless and dangerous.

Last, and perhaps most important, at least to the general public, the trolley system requires a current of high potential conducted along bare wires extending over the entire route of the line, always liable to contact with electric light, telegraph, telephone, district messenger, fire alarm and police alarm wires, the system thus being a constant menace to life and property throughout the city. Contact with any foreign wire may lead to a conflagration such as destroyed immense values of property in Lynn and Boston within a year, and death to horses and human beings,

numerous instances of both having been frequently reported in the public prints.

Therefore we feel warranted in asking street car companies to give storage battery traction, which possesses none of these disadvantages, and involves none of these dangers, a fair trial under reasonable conditions, and under the supervision of men experienced in the various branches of engineering involved in the business, and who have had nine years' experience in the manufacture and use of storage batteries.

NINTH ANNUAL MEETING OF THE AMERICAN STREET RAILWAY ASSOCIATION, BUFFALO, N. Y., OCTOBER 15, 16, and 17, 1890.

The Association held its convention in the Buffalo Library building, beginning at 10:30 A. M., on Wednesday, the 15th, with President Thomas Lowry in the chair. The attendance throughout was extremely large, there being 400 to 500 gentlemen in attendance, including from 175 to 200 street railway men actively engaged in the field.

Mr. Lowry then spoke as follows :

PRESIDENT LOWRY'S ADDRESS.

I am pleased to meet you in this beautiful city of Buffalo, assembled in the Ninth Annual Convention of the American Street Railway Association.

I congratulate you on the progress made and past good work of the Association. When organized in 1882, in the city of Boston, street railroading was in its infancy, but much rapid advancement has since been made in city passenger traffic that the United States Government has deemed it of sufficient importance to incorporate in its Census Statistics, for 1890, a report on Street Railways in cities of over 50,000 inhabitants. In this report 56 cities are included, and out of a total of 3,150 miles of track in these cities,

2,851 miles are operated by horses,
260 miles by Electricity,
255 miles by Cable,
221 miles by Steam.

and the balance, about 60 miles, being the Elevated Roads in New York and Brooklyn. This report would seem to indicate that in the larger cities the faithful old horse is still the favorite propelling power for street cars.

The first special subject on which we are to receive a report from a committee appointed at the last Convention, is "A Perfect Street Railway Horse." From this we must assume that the Association has not yet discarded the idea that the horse is the most reliable power for street cars.

In the smaller cities electricity is generally being adopted, and I am informed that there are already in operation in cities and towns outside of those enumerated in the Census Report, about 1,600 miles of electric street railways. I am so thoroughly convinced that electricity is the coming power for street railways (except on heavy grades where the cable is best suited) and that it will prove so effective as a means of rapid transit for cities, that I believe this is the last Convention that will ever seriously consider horses for the operation of street railways.

Rapid transit in growing cities is becoming a necessity. While Municipal Corporations in the larger cities, for many reasons, are slow to grant new privileges to corporations, and in the case of electricity they are very closely scanned and criticised, it will soon become self-evident that a municipal body can grant no greater boon to its middle and laboring classes than to provide them with the means of rapid and cheap transportation to and from homes in the suburbs, where they can live under a clear sky and in a health-giving atmosphere. When the people of a city understand clearly the great benefits of rapid transit, by electricity or other improved motive power over horses, they will demand that their city authorities grant such rights as will enable street railway companies to operate by the most improved methods.

Heretofore street railway securities have not been looked upon by the financial world with favor. However, since they have been so successfully operated by electricity the financial men of the country are looking to its development and application to street railways as an additional reliable security for the investment of savings and trust funds. This should give encouragement to street railway companies to give their various cities the most improved and best possible service. They will not only please their patrons but the investment will prove very profitable. If street railway companies do this, no better security can be offered for the savings of the widow and orphan than a good street railway bond in a thriving city.

In order to bring this about, Municipal Corporations should grant liberal franchises for street railway improvement. The bond of the street railway company should be as good as the bond of the city in which it is located. The growth of the city is, to a large extent, dependent on street railway extensions, and the prosperity of the street railway company means the prosperity of the city in which it is located. It is one of the largest factors in the development of any city and as necessary as are its schools and its churches.

On the other hand the street railway company should be required to equip its road with the finest and most modern cars, construct the best and most substantial tracks so as to inconvenience the public as little as possible in making repairs, and, in short, supply the road in every department with the best and most modern appliances of all kinds.

In view of the agitation of the labor question, it may not be out of place for me to say a word on that subject. In so doing it will only be the expression of an individual opinion, not intended to bind the Convention to the views expressed. When organizations are formed by laborers and others for the purpose of building up and dignifying its members as men and women, or to improve their moral, physical or financial condition, no one would foster or favor them more than he who now addresses you. Unfortunately, however, most of the present so-called labor organizations are the worst delusion and snare into which a laboring man was ever entrapped. One recent "strike" on the New York Central road developed a state of cruelty, depravity and wrong that should make it the absolute duty of every corporation, having public interests to subserve and charged with providing for the comfort, convenience, business necessities, and above all the life and property of its patrons, to refuse to employ or retain in its employ any one who does not renounce his connection with the "Knights of Labor" or any other labor organization, the rules of which permit employés of a corporation to be "ordered to strike." Men have a right to quit work with such notice as the contract with their employers requires, either singly or in a body, if the terms of their employment are not satisfactory; but they have not the right to interfere with those employed to supply their places. The first duty of a lawyer is to his client, of a doctor to his patient, a minister to his congregation, and a teacher to his pupil. The engineer, the conductor, the switchmen have even a greater responsibility, as the lives of the passengers are in their keeping, and in order to properly discharge it they must be loyal to their employers. They cannot be plotting or laying out rules for their employer and be faithful in the discharge of their duty. "The laborer is worthy of his hire," but when he seeks to change the relation between himself and his employer, by asserting himself as master, he ceases to be the laborer that is "worthy of his hire." He also unfits himself for any kind of advancement. A man, to be successful and take advantage of promotion earned by efficiency, must be contented and perform his work cheerfully. A "labor agitator" cannot be contented or work in the interest of his employer. A few days ago United States Commissioner Rogers rendered a decision at Baltimore, in a case where four sailors were arrested for refusing to go aboard a schooner after they had signed articles to do so. The Knights of Labor interfered and undertook to defend the prisoners. I cannot express my views better on this question than to quote from the decision of Commissioner Rogers, who said :

"I perceive you are men of intelligence and no doubt know and appreciate the advantages of union. Every man has a perfect right to unite with his fellow man to better his condition in life. There is one great mistake made, however, and that is the constant conflict of labor and capital. Now, I can't see why such a state of affairs should exist, because labor is in itself capital, and capital merely represents labor. A capitalist you will find is a man of strictly sober habits. He has to keep a clear head, and the man who to-day earns a dollar and to-morrow morning wakes up with 75 cents in his pocket is the man who may become a capitalist. No doubt your union is a good thing—the land we live in is a union. But now let me impress upon your minds that, while you have a perfect right to form a union, you have no right to interfere with the manner in which another man conducts his business. When a union attempts to interfere with or molest a free-born American, or tries to prevent his earning a living simply because he does not join that union, it then becomes a conspiracy, and amenable under the law and punishable by the court. The great trouble with the unions is that they overstep their bounds and endeavor to force people to do as they direct, and that is an act in direct violation of the laws which grant an American citizen his liberty. In these days of enlightenment and freedom, the press—the most powerful agent of the people—is ever ready to air the grievances of anyone who is oppressed or molested. Nothing, from the great acts of a Government to the death of a pauper, escapes the eagle eye of the press. Tyrants fear the press more than any other power which can be brought to bear against them, and the press of America, as it is to-day, edited by men of the greatest and highest order of enlightenment, is the bulwark of the country. Now, in conclusion, let me say to you that the man who endeavors to persuade you to fight against capital, except in a legal manner, is no friend."

The following is an extract from the Report of the Executive Committee:

"The subject 'Electric Motive Power Technically Considered' was selected for the purpose of having the cobwebs, which were for the most part confessedly before our mind's eye, brushed away from this occult science in order that it might be as plainly comprehensible to the ordinary street railway man as to the expert who manipulates the wires."

The necessity for this knowledge is becoming greater as the days go by, for the transition of roads from horse to electric power is of almost daily occurrence, so rapid is the progress made by electricity as a motive power. In this connection we take occasion to say that the information which it is hoped will be freely given at this meeting concerning the cost of operation by electricity will, doubtless, still more rapidly hasten the emancipation of the horse from his bondage.

The Treasurer's Report was read, and showed the financial transactions during the year to be as follows:

Receipts	$7,165.91
Expenses	5,389.96
Balance on hand.	$1,775.95

No report was offered on cable work, Mr. J. C. Robinson, to whom the subject had been assigned, asking for a year's delay in its presentation.

The next paper was that of Dr. W. L. Allen on "Electric Motive Power, Technically Considered."[1]

This paper among other topics was discussed in executive session on Wednesday evening. The subject was taken up again on Thursday morning, when those present representing electric systems were invited to make statements as to their respective systems and devices.

MR. D. H. BATES, of the Electrical Accumulator Co. made an address on the Edco car.[2] He added that the figures were based on 10,000 miles operation with 3 cars. He mentioned that Dubuque was equipping a road with 8 of their storage cars, the success attained there with the cars now running having led to the larger contract.

MR. CHADBOURNE, of Chadbourne & Hazelton, representing the Wenstrom system, then made a neat and effective extemporaneous address as to their street car work. They have a road equipping in Pennsylvania, which will be running in a few days. He touched on the various points of their well known motor, alluding particularly to the features of slow speed, the dispensing with the intermediate shaft in the gear, the use of their wooden toothed gears, and the continuous running of the armature as effected with the help of the "hydraulic valve gear," described for the first time in this issue of THE ELECTRICAL ENGINEER.[3] Mr. Chadbourne claimed a reduction of half the machinery under the car, and a saving of not less than 10 per cent. in power consumed. As to the wooden gears, he cited the testimony of Mr. Harrington, of the Atlantic City, N. J., road, as to their superior efficiency and lasting qualities.

MR. MALONE WHELESS followed with a brief and pithy description of his electric railway conduit system as operated in Washington, the only and full description of which appeared in THE ELECTRICAL ENGINEER of Sept. 24. He touched rapidly on the principles of operation, including that of energizing only the section of the conduit over which the car is running, and it was evident when he closed that a most favorable impression had been made.

MR. KNIGHT NEFTEL, of the United Electric Traction Company, of New York, said:

It is unnecessary for me to say anything regarding the value of storage battery traction, after the very apt remarks made by my friend of the Accumulator Company. I will simply give concisely our results in operating ten storage battery cars on the Madison Avenue Line in New York.

The equipment of each car consists of 108 Julien cells in 12 trays, nine cells in each, total weight, 3,600 pounds. The motors in use, until recently, and on the old cars now running, are of the Thomson-Houston type. We have now constructed a motor especially adapted to this class of work, and which is now being put on this line. An estimate of cost of operating has been submitted to you by another company, based on the performance of 50 cars. Our experience with ten cars in actual operation over an extended period, which, by the way, is the largest storage plant in this country, and next to the largest in the world, is as follows:

Generating plant, 8 horse-power per car. For ten cars 15 batteries are necessary. Rate at which each battery is charged, one and one-half hours, for two hours discharge. One charge is adequate for a run of 40 miles on a level track. With the old cells and the old type of motor, these ten cars were operated at 10.6 cents per car mile; with the improved batteries and the new type of motor, the life of the existing plants of the battery, at the present rate of disintegration, is at least three years. The negative plates, the other half of the battery, are as durable as the motor. It is generally conceded that the reason storage batteries have not been applied more extensively is the lack of confidence in the endurance of the batteries and litigation on patents.

We are prepared to demonstrate to you practically the life of the batteries, and the question of patents has been greatly cleared by the final decree giving Charles F. Brush, of Cleveland, a fundamental award of priority.

Our batteries are manufactured under the patents of Brush, Julien, Morris, Salom and others. We are now equipping a road in Indianapolis, Ind., on this system. Our company also furnishes overhead equipments, and we shall be pleased to have any member of the Convention visit the plant at Madison avenue and other roads equipped by us.

Mr. Graham, of Baltimore: Can you tell me the number of miles per day each car runs?

Mr. Neftel: Eighty. The maximum grade is about 5½ or 6 per cent.; there is a very severe grade for a short distance on one part of the road, between Seventy-second and Seventieth streets, going down.

Mr. Graham: What is the length of the grade?

Mr. Neftel: About two blocks.

Mr. Graham: Do you ever run on a grade higher than five and a half per cent.?

Mr. Neftel: Yes, sir; there is one grade which is seven and a half per cent. The motors will go up that, but, of course, it discharges the batteries very rapidly when you subject them to such heavy work.

Mr. Graham: Is the car capable of ascending any usual grade, say 10 per cent.?

Mr. Neftel: Yes, sir; it is simply a question of discharging the batteries.

Mr. Henry: When you say 10 cents per car mile, what is included?

Mr. Neftel: Everything, except the conductors and drivers. Of course, there is a reasonable amount for the repairs of the motors.

The Convention then adjourned till 2:30 p. m., when the subject was resumed by MR. E. E. HIGGINS, of the Edison General Electric Co., who made a very fine showing for the familiar work of that company and went into the details of construction. He spoke principally of the improvements that had lately been effected in the construction of the trolley, and the method of securing it to the car, and the improvements effected in the motors. He said:

"In the new apparatus that we are bringing out, we have made some very notable advances. In the first place, our armatures are wound upon an entirely new plan—one which we think is a distinct advance. In the old style what is known as the Siemens winding is employed; the wires are wound on the core and carried around at the end and form a conical shaped bundle, which gives a chance for play and abrasion; and this means short circuits and burn-outs. With the new armatures we have a new standard coil, some 60 of which go on to the core. They are so formed that the rear of the armature, and front alike, give no chance for motion. They are brought firmly in place, and you have a diameter of armature which is always the same, because the coils are standard. With this system burn-outs will be extremely rare. We do not claim that there will not be any; but we believe in the regular daily workings of the car, with proper management, nothing ordinary will burn out the machine except dead overloading. When it is burned out it can be replaced by any mechanic. The switches are on a little different plan. We have avoided the difficulty which has sometimes occurred of starting the car too suddenly, but which with careful management could always be prevented. We make it impossible to start suddenly by putting in a slow starting device, which starts the car gradually and effects a saving of power. It is not a rheostat. We are the only company that uses commutated field coils. We believe in them; we do not believe in the rheostat. You all know about our dynamos. The reason of their success is that they are a development and not an invention. Its efficiency is over 90 per cent. in the ordinary sizes, such as employed on street railroads; in some cases it is higher. One reason for its success is that its moving parts and centre of gravity is near the floor. The line construction of the company is acknowledged to be standard, in respect to simplicity, neatness and cost. We use the feeder system. That is a system of wiring in which the electricity is delivered at regular intervals of a few hundred feet into a trolley wire. This results in the fact that the electricity is delivered to a large mesh work of conductors in such a way that at every point in these conductors the pressure will be uniform."

MR. E. H. JOHNSON spoke with his customary eloquence of the Interior Conduit system as applied to underground work for carrying feeders for electric street railways and explained its many advantages.

MR. GEORGE W. MANSFIELD, of the Thomson-Houston company made some interesting remarks in regard to their system and its important features and merits.

1. See page 449.
2. See page 453.
3. See page 437.

In regard to new apparatus, we are constantly improving all our details. We are making the motor stronger wherever experience has dictated it to be necessary, and we are making it lighter wherever it is necessary. We are improving each detail of the entire apparatus, and increasing efficiencies; so that in a very short time we will have the most complete system. Our switches at each end of the car are under the hood of the car, so that in case of any accident or any trouble, the conductor at the rear end can cut the circuit, either with his switch or by pulling a trolley wheel down; and the driver also has that facility. We have a fuse box on our car, and it is a very simple matter to replace a fuse if the driver has been careless, or ignorant or unskilled, and turns his current on too quickly. That operates as a check against the man as well, as a record can be kept of the number of fuses used. We have a lightning arrester which we claim is the only one of practical value. As to our motors, we build 10, 15 and 20 h. p. of one type, and the same power of another type, so that we can use our motors either singly or double upon trucks of any gauge, from three feet three inches up to six feet. If the railroad men would get down to a uniform gauge, it would help us out very much. As to station apparatus, our dynamo has an efficiency of over 90 per cent. It will pull through more hard raps and do more service in a given space of time than any other. In our new work we are pushing ahead and building dynamos up to 2,400 and 2,500 h. p, and directly coupled to engines also. We are building heavy motors for excessive work and for tow work; and we are going into all sorts of devices and experiments in regard to constant speed motors and slow speed motors. We want to be sure first that any new thing is far superior to what we have, before we put it before the public.

MR. J. POTTER, of the Short Electric Railway Company, next addressed the meeting. He said: The Brush Company, as you know, has been in the business of building dynamo machines and electric batteries for many years, being the pioneers among the pioneers of that business, in the world. We have been building dynamos since 1876. We have recognized that the electric street railway work is the severest to which the dynamo machine has ever been subjected; and in starting out in our electric work, we aimed, as no doubt all others have aimed, to build a dynamo machine that would stand the rough work with as few failures by stoppage as possible; and in the next place to make the delays incident to such stoppage as brief as possible, and the repair work simple and inexpensive as possible. We claim that with our motor we have reached a high point of perfection in these respects. The difference in our motor is mainly in the type of armature, where we use a ring instead of the usual drum type of armature. There are many advantages which we obtain by the use of this type of armature. The bobbins or sections of the armature are all independent, and in case of any burn-out or trouble, it would be confined to a single bobbin. Again, we get a very great diameter of armature, as compared with others, and are enabled to use larger pinions and save greatly in wear. As a matter of fact, since the beginning of the present year, we have never burnt out a field magnet or armature coil in actual service. This will be confirmed by any road operating our system. The favor it has met with, and the large number of orders we are taking, speak loudest in praise of the system. Another feature is the insulation of the motor entirely from the frame-work of the car and from the ground. We think this is a great advantage. We believe that a great deal of the expense and trouble is due to the grounding of the motor, the bursting through and burning out of armatures, fields and commutators. This insulation is carried to the gears. We make them with an insulated web to deaden sound, and use steel pinions and steel gears, steel axle gears, and overcome the noise at the same time.

MR. W. J. CARRUTHERS-WAIN, president of the Tramways Institute of Great Britian and Ireland, was next called upon, and said: I came to this country with the hope of learning as much as I could about electric traction in America. What I want to know, and most people, is the item of depreciation and repairs; in other words, repairs and renewals, and the amount to be set aside as an annual sinking fund for the question of depreciation, which must inevitably ensue. It has struck me, not only in this assembly, but in many others, that figures, after all, are rather delusive. Electricity came under my observation this way. I was not satisfied, no man was satisfied, with the system of tramway traction in Europe up to within the last three or four years. We had leased a line from the Birmingham authorities, with the proviso that it should be operated by cable; but there was not enough business to make that system profitable. Electricity appeared to be the only feasible motive power; and in November, 1888, there was tried upon the Birmingham Central Tramways a self-contained electric motor, which was designed upon the Julien system by Mr. Thomas Parker, of the then Messrs. Elwell-Parker, Limited, and myself.

The directors of the Birmingham Central Tramways Company permitted the experiments to be conducted upon their lines upon condition that the electric motor to be used should be in the form of an engine, insisting that before they would consider the question of electricity at all in connection with their lines, they must be convinced by actual demonstration that the power was as great as, if not in excess of, their most powerful steam engines then in use; and when I point out that they are some 12 tons in weight, having cylinders nine inches in diameter, and carrying a pressure of 175 pounds to the square inch, you will agree it was no small task to attempt. However, upon actual trial the electric motor, although weighing only nine tons, when coupled to one of the steam engines, the electric engine hauled the steam engine in spite of the fact that steam was full on and pulling against the electric motor. We afterwards started and hauled with the electric car a load of some 30 tons up a grade of one in 32. We have also run with one charge of the accumulators 70 miles, hauling a car which, together with the load contained therein, weighed over six tons, and this on a very heavy grade of tramway traveling up a grade of one in 19, over 500 yards in length, during the day 10 times. This electric car has been so successfully run over their heaviest steam route, and given such satisfaction to the directors, that they gave an order for 12 electric cars, which have just completed what is undoubtedly the finest installation of its kind in the world.

The car is made to run upon a three foot six inch gauge, and is constructed to carry 50 passengers, 24 inside and 26 outside. It measures, over all, in length, 26 feet.

The foundation of the car is made of channel iron, strutted so as to give it great strength and rigidity. The car body is carried upon two bogeys of the ordinary kind, and the motor is geared to the axle of one bogey by a train of helical gearing. The accumulators are placed in trays, each tray containing eight cells, and these are carried under the seats of the car, the outer panels of which slide up behind the seats so as to admit of their being readily placed in position. The connections are so arranged that contact is made automatically as the trays are pushed in position. The whole forms four batteries. The switches are of the Julien type, and the car can be driven from either end. They are so constructed that the cells can be equalized and the batteries used either in parallel or series. The car, motor and batteries weigh nine tons, as against the steam engine and cars, 16½ tons, a large saving in dead load to be hauled. The work of charging the accumulators is reduced to a minimum by having a specially arranged balance lift or elevator. These work in pairs, one balancing the other. Each shelf is fitted with automatic connections, and is in every respect an exact duplicate of the car, so that when the accumulator trays are drawn thereon, automatic connection is made and the cells are charged whilst in position upon the rack without again being moved. We have 12 cars altogether, but are only running five. I may say, as a point of interest, that during the time that line was under construction, we worked it first by a system of horse tramways, and the average takings were about $750 a week. During the time the electric road was in process of construction, the receipts on the horse line were reduced to $600 a week. Immediately the electric cars were put on, the takings jumped to $1,250 a week. This was not due to any additional service, because it is precisely the same; not to any increase in population, because it has not grown so rapidly, but simply to the fact that we have been able to put on in place of the wearisome horse car a comfortable car moving by electric power. We have not renewed the plates at all. We expect to get a life out of our plates of six months. The question of profit on the workings of the storage battery is not a matter of speculation, but is a matter of dead certainty.

MR. E. L. WOOLLEY'S paper[1] was then read by Mr. Richardson.

MR. H. M. WATSON, the newly elected president, made a fitting speech after being introduced to the Association by Mr. Lowry, the retiring president.

A vote of thanks was tendered Mr. Lowry by the Association, as its retiring president.

The Convention then adjourned sine die.

WHAT IS SAID OF "THE ELECTRICAL ENGINEER."

THE ELECTRICAL ENGINEER of New York is now nearly nine years old. It started as a monthly, first increased in size as the electrical interests grew, and then became a weekly. It is now a magazine of between fifty and sixty (72) pages, and is one of the most reliable authorities on electricity in America.—*Boston Evening Transcript.*

NOVEL USES FOR ELECTRICITY.

The plant sold to Shailer & Schniglau, for the Lake View Tunnel, Water Works and Crib, by the Thomson-Houston Electric Co., Western Isolated Lighting Department, will be unique in some respects, as the dynamo will not only supply electric lights to the water works on shore, but will also be used to run the motor at the crib for ringing a fog bell, and the same dynamo will supply a number of lights to the light house on the crib, to take the place of the ordinary light house oil lamp.

---

THE EXHIBITS AT THE BUFFALO CONVENTION.

Never, perhaps, was a larger display of exhibits made than that at the Buffalo Convention. It filled up the Arcade building, it crowded every corner of the Iroquois Hotel, and it overflowed into all the streets surrounding those places. By a somewhat amusing course of events, the supply men, in their praiseworthy determination to be early on the ground, practically pre-empted the Iroquois, so that when the modest consumers of their wares came along no room was left. The consequence was that a very large number of the "White Button" delegates had to seek quarters at the Tifft House, so that the "Red Button" supply men at the latter place found themselves favored by the interposition of Providence with a remarkable influx of the very men they came so far to see and from whose agreeable society it had seemed likely they might be cut off. It is needless to say that the most was made of such a glorious and unexpected opportunity.

ARCADE NOTES.

The American Leather Link Belt Co., of New York, represented by Mr. G. H. Fisher, showed samples of their patent joint link belting which they guarantee as superior to all others for driving generators.

Messrs. Chas. A. Schieren & Co., 45-47 Ferry street, exhibited in same space with Am. Link Belt Co., their perforated electric belting, and said in rhyme:

"Buffalo Electric Cars are sure to run,
But that black belt all full of holes is bound to take the bun."

Mr. E. P. Atkinson ably represented this house, which is making a very bold and successful push for electric railway trade.

The New York Car Wheel Works, of Buffalo, N. Y., made a handsome exhibit of their machined street car wheels. These wheels are specially strong and durable, and particularly adapted to electric traction.

The Buffalo Belting Works, Buffalo, were represented by Mr. J. W. Aldrich, who showed some fine samples of their leather belt and hose. One of their most novel and useful specialties was a steel pulley covered with leather, both pulley and leather being perforated instead of the belt, as in the present usual method. This type of belt was supplied to the Brush Electric Light Company, of Cincinnati, being 140 feet in length, 48 inches wide, and weighing 1180 lbs.

Pratt & Letchworth, of Buffalo, N. Y., showed their street railroad hames and trimmings for horse car work. They have a new corrugated steel fastening, specially useful for all kinds of wood working and car building. Mr. G. S. Crosby was on hand explaining their various devices and appliances. They also make all kinds of steel and malleable iron castings. This company manufacture the Gould automatic coupler, so well known in railway work.

The J. G. Brill Co., of Philadelphia, exhibited the vestibule of an electric motor car with patented doors. Mr. J. A. Hanna explained their patent folding and sliding vestibule doors and their new ratchet brake.

The New York Indurated Fibre Pipe Company made a good showing with indurated fibre pipe for electric conduits. This pipe is now being used by the Buffalo street railway for their underground feeder system. Mr. Gerald C. Collingwood represented the company.

The Blondell Manufacturing Co., represented by Mr. Blondell and Mr. E. Packer, showed their new Blondell car gear, by means of which the post is enclosed in a casing which takes the wear instead of the post, the box having liners which can be taken out and replaced when worn, obviating all wear on the box itself.

The Aluminum Brass and Bronze Company exhibited their new aluminum trolleys which present some remarkable features on account of their light weight and non-corrodable properties. Mr. Frank G. Stone, assisted by Mr. L. Schmidt, had charge of the exhibit, and explained the peculiar advantages of aluminum.

Mr. C. S. Van Nuis made a full exhibit of his admirable Ajax switches, which are in extensive use everywhere, and are now too well known to need much comment.

Hale & Kilburns Manufacturing Company, of Philadelphia, exhibited their new patent reversible high-back tilting car seat, specially for street car, suburban and elevated work. Mr. E. L. Hendrick, the contracting agent, represented the company.

The Volk Bottom Grip and Automatic Cable Crossing was shown by a handsome model.

The Collett Car Brake Co. exhibited their special car brakes which operate with a ratchet, and thereby brake quicker than the ordinary style.

The Eureka Tempered Copper Co., of North-East, Pa., had on exhibition a fine sample board showing specimens of commutator sections, armature bearings, trolleys, overhead trolley wire and all kinds of wire. Their tempered copper is stated to have a tensile strength three times as great as that of ordinary copper. Another peculiar fact is that the copper after being treated by this process shows greater purity than the purest obtainable ingot copper. Mr. A. L. Daniels looked after the interests of the company.

Chadbourne, Hazelton & Co., of Philadelphia, Pa., showed the Wenstrom dynamos and motors, for which they are the general agents. They had some very beautiful models of their electric street car trucks with motors attached, remarkable for their slow speed, and having but one gearing between armature and car axle. One of the special features of their machine is the embedding of the armature conductors in the iron core, thereby protecting them and reducing the magnetic resistance between pole pieces and armature to a minimum; and their system of winding is such as to greatly facilitate necessary repairs. One of the special points of their system is their admirable wood gearing, illustrated in a recent issue of The Electrical Engineer, which is giving the greatest satisfaction. Mr. Beals, the New York State agent, resident in Buffalo, represented the company.

Bickford & Francis, 53 and 55 Exchange St., Buffalo, were represented by Mr. Gardener, who showed some very handsome samples of leather belting. Their "B. C. D." belting has gained an immense reputation for its excellence and durability.

F. S. Pease, 65 and 67 Main St., Buffalo, had a large case of medals obtained in all parts of the world for his improved oils, which are in large demand and shipped everywhere. Mr. D. I. Bloodgood, the general agent, had charge of the exhibit.

Lemuel Wm. Serrell, of New York, exhibited a very beautiful model of the Milliken patent electric railway pole, which he handles exclusively, and of which he has sold 4,500 for the work in Buffalo.

The Stanwood M'fg. Co., of Chicago exhibited their new steel steps for street cars. These are manufactured specially insulated for electrical work. Mr. Stanwood was on hand showing and explaining the numerous advantages of his steps.

Pierce Bros., of Boston, manufacturers of special trolley wire fixtures and devices for street railway construction, had a well appointed exhibit of their products made at their factory at Leominster, Mass. Mr. H. L. Pierce, representing the firm, was kept busy explaining and taking orders for their specialties.

John A. Roebling's Sons Co. of New York, had a fine sample board of their bare, insulated and lead covered wires and cables on exhibition. They were represented ably by Messrs. Bailey and Perrine.

The Gibbon Duplex Railway Track Co., of New York, exhibited their duplex railway track, specially devised for electrical work, doing away with all necessity for rail bonds or joint connections, it being a perfectly metallic circuit throughout. Mr. Gibbon had all he could do explaining his ingenious system.

The Rowell Switch was exhibited by Mr. Rowell, of the Rowell American Switch Company. This ingenious device was illustrated in a recent issue of The Electrical Engineer, and was designed to fill the want for an automatic switch setter operated from the car direct. It certainly does its work in a most simple and efficient manner.

The Connecticut Motor Company, of Plantsville, Conn., showed two of their latest improved motors, one of ½ h. p., the other of 2 h. p. wound for 500 volts so as to run on street railway circuits. Mr. F. O. Rusling was in charge of the exhibit.

The North American Construction Company, represented by Mr. W. L. Adams, Buffalo manager, set up for inspection a large and beautifully gotten up switchboard, comprising volt and ammeters, regulator lamps, switches and meters. They also showed a new pattern U. S. generator and alternating arc lamp, all of which apparatus except the two last were in practical operation and a source of great and continual attraction.

The Aenchbacher Railway Truck Company, of New Orleans, La., showed a model of their truck for street car work.

The Gould & Watson Co., of Boston, had a stand covered with samples of their excellent molded mica goods, which have been so largely used in electric street railway work.

The Garland Car Heater was exhibited by the manufacturers, The Michigan Stove Company, of Detroit, Chicago and Buffalo. This heater is well known among electric railway men for its many merits, and is in wide spread use. Mr. F. P. McCanna had charge of the exhibit and explained to the uninitiated the advantages of their heaters.

The Okonite Company, of New York, made an extensive display of their wires and cables in charge of Mr. T. McCoubray, the special agent of the company, who had no difficulty in proving the wonderful strength and durability of his insulation, and was

kept hustling taking orders for wire to be used in street car work, a field in which it has always given the highest satisfaction.

THE BERLIN IRON BRIDGE CO., of East Berlin, Conn., showed some very beautiful photographs of their bridge work. Mr. F. K. Field, the general agent, represented the company in his usual able manner, and was assisted by Mr. G. M. Harding. They handle iron work of all kinds, and build electric light and power stations entirely of iron. They have just taken a contract in Buffalo to build works for the Lake Erie Boiler Company.

MR. R. T. WHITE, of Boston, had a fine exhibit and was present showing a working model of his elevated road system which presents many new and striking improvements, and also his new cable system. His "Daisy" chairs were shown; they are solid iron, thereby widely differing from the ordinary steel frame chairs in general use.

THE JAS. SPEAR STOVE & HEATING COMPANY had a large number of their street car stoves on exhibition. Mr. A. J. Eickmeyer took care of the company's interests.

THE FULTON FOUNDRY COMPANY, of Cleveland and St. Louis, showed some fine electrical gears for street cars, of steel, rawhide and bronze. Messrs. White and Langdon represented the company.

EMMET BROS., 150 Broadway, New York, made a fine display of electric street car railway supplies, amongst which were many new and valuable devices. Mr. W. L. R. Emmet, represented the firm, who have a bright career before them.

ONE OF THE LARGEST and most prominent exhibits was that of the General Edison Electric Co. Their improved street car system was shown complete in every detail, comprising a Taylor elliptical spring truck equipped with two motors and double alternate toothed gearing. The motors have their armatures wound with the new Eickemeyer system of winding and are fitted with equalizing coils so that both take the same currrent. The switch board was a perfect work of art and contained all the necessary central station instrument and switches. The initial letters of the name of the company was on it in polished brass work formed of the regular switchboard appliances. The conduit tube system and two small Edison generators were shown. Mr. McGregor had charge of the exhibit. A new slate switch table was also exhibited, suitable for a power station and forming a most compact and complete arrangement. Near it was one of the new Lieb trolley, specially constructed, so that there is no strain on the car roof.

MISCELLANEOUS.

D. H. BATES, vice-president of the Accumulator Co., of New York, attended the convention and read a highly interesting paper on storage batteries. With him were W. W. Griscom, president, and E. A. Scott, of the Electro Dynamic Co., of Philadelphia. The electric car, equipped by the Electro Dynamo Co., and furnished with the Accumulator Co. batteries, was seen in practical operation at Cold Spring, and showed the rapid strides made in storage traction.

C. O. MAILLOUX and wife, of New York, were there, and thoroughly enjoyed their trip to Buffalo. Mr. Mailloux is engaged on highly important electric traction work in Washington.

J. ALEXANDER BROWN, representing *Poor's Manual of Railroads*, was in attendance at the convention, and distributed copies of their valuable book relating to street car lines, etc.

FRANK A. MAGEE, of the E. S. Greeley & Co., New York, was on hand hustling as usual for orders for this well-known house.

MESSRS. MUNROE & CAVELL, of *The Street Railway Gazette*, of Chicago, were on hand looking after the interests and comfort of all. They had handsome headquarters in the Iroquois and entertained their friends in royal style. They issued a very handsome souvenir, called "Some Familiar Faces," containing portraits of past and present street railway worthies.

C. T. CHAPIN, president of the Rochester Car Wheel Works, was in attendance.

MR. CLIFT WISE, the well-known engineer, was present. He is about to engage in electrical matters in New York, having now left Minneapolis.

J. W. FEIGEL, of the Feigel Car Co., was present at the convention, with Mr. Whittlesey. They are meeting with excellent success in the electric line.

THEO. LARBIG, of Holmes, Booth & Haydens, of New York, was on hand looking after the interest of his house and their wires.

C. B. HANNA, general agent of the car heating department of the Carpenter-Nevins Electric Heating Co., of Minneapolis, was in attendance. This company have reduced electric heating to a practical and economical basis, and have adapted it to a very large number of uses in general work.

W. J. COOK, vice-president of the McGuire Manufacturing Co., was at the convention. Their trucks are known from one end of the country to the other, and present some peculiar advantages for electric traction work. They were exhibiting two of their new trucks equipped with Westinghouse motors.

ELMER A. SPERRY, of the Sperry Electric Co., was present. The Sperry arc lamp and mining machinery are becoming more widely known and used all the time, and the new triple carbon arc lamp has produced quite a sensation. Mr. Sperry is devoting his attention to a number of new problems.

J. G. DORRANCE, who represents the Guarantee and Accident Lloyd's, and has his headquarters in New York, was present. Mr. Dorrance had some new features in insurance to offer street railway men.

THE WAINWRIGHT M'F'G. CO., of Boston, distributed a beautiful little set of celluloid tablets printed with their name and an engraving of their feed water heater, one of the sheets also containing a calendar for 1890-1891.

THE ALLEN PAPER CAR WHEEL CO., of Pullman, showed their new car wheels fitted to the McGuire truck. These wheels are in use under a number of electric cars.

THE INTERIOR CONDUIT AND INSULATION CO., of New York, made a most interesting display of their system for underground work, especially that for electric railway feeders, etc. It has already been adopted for Minneapolis and other places. A beautiful and large model was shown in the main hallway, first floor, where it attracted hundreds of visitors, and the company also had a number of small, highly finished miniature models, with case of polished wood, which street railway men could carry home. As is well known, the Interior system is now being extensively adopted also in car wiring, as well as for power houses, etc. The company were most ably represented by President E. H. Johnson and Mr. E. W. Little. It is also needless, perhaps, to add that Mr. Johnson's experience in electric railway traction caused much curiosity and inquiry as to his recent inventions in that line, as illustrated lately in THE ELECTRICAL ENGINEER.

A. D. WHITE, of Buffalo, shows a new ratchet track wrench specially designed for street railway construction, which comprises some unique points.

T. E. CROSSMAN, assistant to the secretary, Mr. Richardson, was present, conferring favors and information on every one as to the Association. We desire to thank him for many attentions and for much prompt and cordial assistance.

THE HERCULES CAR BRAKE & CAR STARTER, of Philadelphia, Pa., was handsomely exhibited.

THE HATHAWAY TRANSFER TABLE, of Cleveland, O., was shown by a full-sized table.

THE BALTIMORE CAR WHEEL CO., of Baltimore, Md., stated that their wheel exhibit is to be seen under every street car in Buffalo, and they showed a most emphatic testimonial letter from President Watson.

THE WESTINGHOUSE ELECTRIC AND MANUFACTURING CO., of Pittsburgh, exhibited in practical operation on the Cold Spring division of the Buffalo Street Railway Co., a large vestibule car containing features of striking interest. The car is thirty-four feet long and is painted cream color and white, and the interior is most handsomely finished. The trimmings are gold, and French plate glass, beveled, is used throughout. A beautiful smoking-room, fitted up in embossed leather, occupies one end. The car is constructed with aisles on each side, and seats in the middle back to back, and will seat forty persons irrespective of the smoking-room. The car body was built by the Pullman Palace Co., and is mounted upon the Hubbard trucks, manufactured by the McGuire M'f'g. Co., of Chicago, which are fitted with the new Allen patent wheels made by the Allen Paper Car Wheel Co., of Chicago. On Wednesday afternoon hundreds of people rode on the car at Cold Spring.

THE EDISON GENERAL ELECTRIC CO. made a most stupendous exhibit, in size and completeness, in three sections. In parlor G-H, at the hotel, outside the door, was an exquisite sign of light made of a number of small incandescent lamps, which formed the name of the company in letters of fire. Inside was a large United States map showing the location of the roads using the Edison system. It was draped in bronze red and illuminated by incandescent lamps. On the opposite side of their parlor was a picture of Mr. Edison, and two maps, one of St. Paul the other of Minneapolis, where 200 cars and a power plant of several thousand horse power is being installed by the Edison Company. Between the two entrances was a banner naming the Edison district offices, etc. Two small model cars, complete with the Edison motor truck, were shown. There was also a large, framed blue print of the Schenectady works, and a large number of maps and blue prints containing engineering data of the system, a well appointed buffet, and many other minor objects of interest.

Mr. Edward E. Higgins, special agent of the railway department of the Edison Co., was in charge. One of the most unique features of the convention was prepared by Mr. Higgins, when each delegate received a little cylindrical tube, labeled as follows: "This cylinder contains a letter from the Edison General Electric Co. to Mr. —— —— of the American Street Railway Associa-

tion, which may be reproduced at the Edison headquarters, parlors G–H, Iroquois Hotel, Oct. 15, 16 and 17, 1890, by courtesy of the New York Phonograph Co." On opening the end of this package the delegate, whose curiosity is now thoroughly awakened, finds a little pasteboard cylinder covered with a film of wax, on a portion of which is a dark stripe. He is particularly requested not to rub his finger over this stripe, as in that case it will be difficult to reproduce the matter contained therein. By taking this to the Edison headquarters he heard a letter of welcome addressed to him, the contents of which were of a highly interesting nature. The company was represented by J. Muir, E. E. Higgins, J. H. Vail, C. D. Shain, C. T. Hughes, F. R. Chinnock, C. E. Hewitt, A. D. Page and others.

THE WORCESTER FIRE APPLIANCE COMPANY, of Worcester, Mass., exhibited their chemical fire pail. These pails are well adapted for use in electric light and power stations. Mr. G. O. J. Clark is the Buffalo agent of the company.

MR. JAMES GOLDMARK, representing Wallace & Sons, the well-known copper magnates and pioneer wire manufacturers, was present and distributed a neat circular gotten up specially for the occasion calling attention to their hard drawn wire for overhead railway construction and their numerous other valuable specialties. This concern was established as far back as 1848 and, therefore, may be said to antedate all the great modern electrical industries except the telegraph. It has, however, kept to the front in a most remarkable manner and to-day is doing a larger business than ever in the electrical field. It is not generally known, but it is none the less a fact, that the development of electric light and power dates back directly to the experiments made by this house and to the encouragement given by its members to what seemed then and to others hazardous and almost hopeless inventions.

THE ELECTRIC CONSTRUCTION AND REPAIR COMPANY, of Chicago, were represented by Mr. Wm. Sharpe. This company, which is one of the prominent and recent electrical organizations of Chicago, make a specialty of constructing electric street railways and manufacturing devices for the same, and also do all kinds of electrical repair work. Mr. C. M. Barclay, of Chicago, is one of the prominent men in the company.

MR. M. E. BAIRD, the well-known representative of the Eddy Motor Co., of Windsor, Conn., was on hand looking after the interests of his company. He reports business as rushing and the Eddy motors are gaining in popularity all the time, orders for sizes of 20 and 25 h. p. being very numerous just now. The recent large motor plant sold by Mr. Baird, in Toronto, is running in the most successful and satisfactory manner, and serves as an excellent precedent.

MR. W. H. GORDON, of the rising young firm of W. H. Gordon & Co., 115 Broadway, this city, was early on the ground and lost no opportunity of putting in a word for Simplex wire and the many other specialties he is handling that are of interest to electric railway men. If our casual observation be correct, he left for home a complacent and well satisfied man.

THE STREET RAILWAY JOURNAL of New York city was out in force, being represented by J. H. McGraw, C. B. Fairchild, F. D. Russell, E. E. Wood, E. H. Chapin and F. L. Kenfield, members of the home staff. A large parlor was occupied on the dining room floor, and two or more of these gentlemen were constantly in attendance there, as well as a skilled typewriter and stenographer. During the convention, the *Journal* issued daily a really magnificent bulletin of no fewer than 40 or 50 pages, regular size, and with its regular style of typography. The covers were beautifully printed in colors, each day different, and the whole made a superb evidence of intelligent, brilliant enterprise. The contents were beyond criticism, constituting not only a complete record of the daily proceedings, but of everybody in attendance and of all the exhibits. There were moreover a series of editorials, all written, of course, on the spur of the moment, yet dealing ably with the questions brought up in the convention. We have never before seen a convention bulletin half so well handled, and have nothing for our contemporary but profound admiration as well as congratulations upon its success.

THE NEW YORK INSULATED WIRE CO. were represented by Mr. J. W. Godfrey, who has already managed to push some big wedges into the electric railway work and follows up every opening closely. As the Hotel Iroquois is wired with Grimshaw, Mr. Godfrey posted up a few modest placards emphasizing the fact, and he did not forget to display a few others touching on the company's various specialties. Mr. Godfrey also distributed samples and copies of their admirable price list.

MR. C. J. FIELD, of the Field Engineering Co., was naturally on the ground, having so much work on hand for the Buffalo Street Railway Co. The company has carried out some of the largest electric railway contracts in the country, including the recent work at Newark. In this week's issue, we describe one of his recent plants, that at Salem-Winston, N. C.

THE ELECTRICAL ENGINEER, owing to the attention it pays to electric railway questions, was greatly in demand by the delegates, many of whom called in to secure two and three copies. Thanks to the courtesy of Chadbourne & Hazleton, the headquarters of the journal were established in the ladies' parlor, at the head of the main staircase and adjoining the dining room. The ENGINEER was represented by Messrs. T. C. Martin and M. C. Sullivan, of the New York office, and Mr. W. F. Collins, the Western manager, of Chicago.

MR. L. GUY FLITZ represented F. J. Kuhne, of 18 Front street, New York, the well known expert and specialist in lubricating and illuminating oils. Mr. Kuhne, as a manufacturer in these lines, has been devoting his attention lately to the lubrication of electrical machinery, and Mr. Flitz found many opportunities of giving electric railway men advice and information on the subject.

A VERY PLEASANT RECEPTION was given on Tuesday evening by Messrs. Cargill and McCarty, of the Thomson-Houston Co., to all the "supply" representatives,—electric railway, wire, poles, &c.,—then arrived. There was a large muster around a punch bowl of generous proportions filled to the brim with a most astounding punch. The evening from 9 to 12 was passed with speeches and stories, and wound up with an enthusiastic toast to the "T.-H." and all its efficient corps of engineers, experts and agents.

THE HOSPITALITY of the Buffalo street railway people was of the most profuse and royal kind. Every want was anticipated, and the programme of excursions, drives, &c., was endless. Each delegate and visitor was furnished with a pretty guide book, having a pocket crammed with street car tickets, and the white or red button admitted one everywhere. After the banquet on Thursday night came a special excursion to Niagara, by special train, and including a lunch at the Cataract House. It would have been impossible to do the thing better or with a happier spirit of hospitality, and we desire, if only for ourselves personally, to thank President Watson and his colleagues for attentions and kindnesses innumerable.

DR. AUSTIN, the versatile editor and proprietor of *Practical Electricity*, was one of the most active journalists on the spot, having just launched another enterprise, to which he has given the name of the *Electric Railway Advertiser*. The Doctor has our heartiest good wishes.

JOURNALISTIC INTERESTS were well looked after at the Convention. Besides the papers and representatives named elsewhere, the *Western Electrician* was represented by Messrs. Temple and Dickinson; *Electric Power* by Messrs. Blanchard and Ferguson; *The Electrical Review* by Mr. C. W. Price and associate; *The Electrical World* by Dr. Bell and Mr. Hart; *The Electric Age* by Mr. Taltavall and *Power-Steam* by Mr. Swetland.

DORNER & DUTTON, of Cleveland, O., showed one of their trucks adapted for electric traction work.

THE PECKHAM STREET CAR WHEEL AND AXLE COMPANY made a most attractive display of their trucks outside the hotel. Mr. Peckham was on hand expounding the principles of his cantilever and improved electric motor truck and fibrous steel motor axles. His fine exhibit deserved and received the closest attention.

THE GOLD CAR HEATING CO., of New York, exhibited their heat storage system. The heater is charged with steam and retains its heat from three to four hours. Mr. Charles Parker had the exhibit in charge.

THE SHORT ELECTRIC RAILWAY CO.—An exhibit which attracted an immense amount of attention was the vestibule car shown by the Short Electric Railway Company. It is elegantly furnished and most beautifully appointed, the chairs being of the most luxurious description. The car is fitted with bevel plate glass windows, incandescent lights, etc., and is altogether most perfect in its equipment both mechanical and electrical. It is mounted on a Brill truck.

THE WENSTROM MOTOR, &C.—In the hotel rotunda the Wenstrom motor was shown and also the noiseless gears. The exhibit was made by Chadbourne, Hazelton & Co.

THE STEAM GAUGE AND LANTERN CO., of Syracuse, N. Y., showed their new Electric Street Car Head-Light. Mr. Sawyer was in charge.

THE LEWIS AND FOWLER MFG. CO., of Brooklyn, N. Y., made a beautiful exhibit of their alarm passenger registers and general railroad supplies. They manufacture street railroad cars and equipment of all kinds for street railway work. This company distinguished itself by running a special train for its friends from New York to Buffalo.

THE ELECTRIC MERCHANDISE COMPANY, of Chicago, made one of the most elegant exhibits in Parlor F of their electric street railway supplies, to which line they pay exclusive attention. The genial manager, Mr. Mason, assisted by Mr. Gustin, laid himself out to entertain and explain their valuable specialties to the many visitors to their fine quarters. It is safe to say that every street railroad man visited the rooms for information or to place orders for trolleys, switches, insulators, motor parts, etc.

THE STANDARD UNDERGROUND CABLE CO., represented by Mr. G. L. Wiley, the New York manager, showed samples of their well known wires and cables. The cables now being laid by the

Field Engineering Co. for the Buffalo Street Railway Co. are those manufactured by the Standard Underground Co. and comprise mains and feeders amounting to 20 miles of No. 0000 wire.

THE RAE ELECTRIC RAILWAY SYSTEM was exhibited by the Detroit Electrical Works, and Mr. C. Benton and Mr. Paul Bossart were busy showing the salient features of their system. The most striking feature is the use of a single motor, gearing to both axles. This system has given signal success wherever it has been introduced. The truck is absolutely rigid and will run around the shortest curves without difficulty. These trucks are built by the Sheffield Velocipede Car Co., of Three Rivers, Mich. The Rae system was described fully in THE ELECTRICAL ENGINEER last week, and the paper was in great demand at the company's exhibit.

CHADBOURNE, HAZELTON & CO., of Philadelphia, the general selling agents of the Wenstrom Consolidated Dynamo and Motor, had one of the most popular and novel exhibits of their street railway system in the Ladies' parlor, Iroquois Hotel. Mr. Chadbourne, Mr. Hazelton, Mr. E. L. Tunis, president of the Wenstrom Co., Mr. J. B. Groom, Mr. Beals of Buffalo, and Mr. Foote of Cleveland, Mr. P. A. Dowd and Mr. H. P. Broughton, were all on hand explaining the advantages and peculiarities of their excellent electric traction system. They showed some very complete and beautifully made models of their apparatus and numerous handsome photographs.

THE J. G. BRILL CO., in parlor E, made quite a display of their trucks by handsome models. These included the trucks in use on the Short vestibule car; and they also exhibited a couple of the trucks outside the hotel.

THE WESTINGHOUSE ELECTRIC AND MFG. CO'S. RAILWAY DEPT., were located in parlor 68, and represented by Mr. H. McL. Harding, Mr. J. L. Barclay, Mr. Osgood Mr. Steward and Mr. Atkinson. They showed their magnificent car built by the Pullman Co., in practical operation on the Cold Spring line. They had a framed illustrated description of their system hung up, taken from the columns of THE ELECTRICAL ENGINEER, and attracting much attention.

THE THOMSON-HOUSTON CO. were out in force for business, located in elegant quarters on the second floor of the hotel, the the rooms being those used by Mr. Woolley, the proprietor. They were represented by Mr. Winthrop Coffin, Mr. Mansfield, Mr. Stebbins, Mr. Barr, Mr. Glaiser and Mr. Cargill, the other general agents of the company. Mr. Clark, Mr. McCarty, Mr. Morse and the technical men, Lieut. Cohoon, Mr. Stebbins and Mr. Wiggin, were all present. The company made no display of parts of motors, but exhibited their sweeper and snow plough on the Cold Spring division of the Buffalo Street Railway line, on Wednesday. These unique devices have never before been exhibited at any convention and attracted great attention from their evident practicability and adaptability to the uses for which they were designed.

THE LEWIS & FOWLER MFG. CO. showed a sample of their girder rail in Parlor 56, in addition to their handsome exhibit in the hotel rotunda.

DR. A. F. MASON, of Simplex fame, was on hand. He made no exhibit, for, as he puts it, everybody knows him and his wire, and, in fact, on more than one occasion, he has found himself addressed as "Mr. Simplex." He interested numerous people in his well known goods. The Simplex wire will be used for the Buffalo work.

THE SHORT ELECTRIC RAILWAY CO., of Cleveland, O., in addition to their exhibit of their vestibule car, made a splendid display in their magnificent reception room on the ground-floor of the hotel. They showed their motor, running on a table, and the various other ingenious devices belonging to their system, which was recently illustrated in THE ELECTRICAL ENGINEER. Prof. Short, Mr. Frenyear and Mr. Kinzelback represented the company. Treasurer Potter, of the Brush Co., and Mr. Curtiss directed matters and held quite a levee.

EUROPEAN CORRESPONDENCE.

LONDON.

Electric Traction in Glasgow.—Woodhouse & Rawson.—Servian Telegraphs.—Lectures on Meters.—National Telephone Company.—Edinburgh Exhibition.—The Brush Company's Works.—Electric Lighting in Newcastle.—St. Pancras.—Killarney.—Jarman System of Electric Cars.—The Tramway Accident in Italy.—Electric Lighting in Leeds.—Electric Traction in Chelsea.—Crompton & Co.—Telegraph Clerks.

A DEPUTATION of the Glasgow City Council has recently visited the electric line at Barking, worked by the General Electric Traction Company. It is said, so pleased were they with the demonstrations, that experiments will be made on the tramway lines in the northern city. I may mention that the tramways are so extensive in Glasgow that the cars run something like 4,000,000 miles per annum, and carry over 40,000,000 passengers.

An exhaustive report has been issued by Messrs. Woodhouse & Rawson, United Limited. £61,065 stands to the credit of the company, out of which the directors have proposed to pay a dividend of 15 per cent. on the ordinary shares, and 8 per cent on the preference shares. As was to be expected, considerable space is devoted to the launching out of the International Okonite Co. and the Elmore Companies. In spite, however, of owning several factories, no account is given of the profits made by manufacturing.

I hear that a Franco-Russian Company is about to organize a new telegraphic agency in Servia and the other Balkan countries, the Servian government having declined to renew its connection with the Vienna Correspondence Bureau.

Professor Silvanus Thomson began a course of lectures on Electric Meters at Finsbury College, on Monday night. The lecture theatre was crowded with students. The Professor opened with a dissertation upon the form and working of the present ampere meters, illustrating his remarks by use of the instruments. The subject of voltmeters will be dealt with next week.

Stafford, an important town in the Midlands, was last week connected to the trunk lines of the National Telephone Co., which gives communication with Birmingham, the black country towns, Manchester, Liverpool and London. The directors have decided to reduce the rentals of telephones from £15 to £10, and are considering the question of giving special conditions, to the trunk line subscribers. It is quite time that subscribers did derive a little consideration. The National Telephone Company has a peculiar manner of dealing with its patrons. A short time ago Mr. Muirhead, of Glasgow, brought at the invitation of the company several telephones of the Ader and Berthon type from Paris, which were placed in the London and Glasgow offices. A few months went by and Mr. Muirhead received a note from the company complaining that the telephones were infringements, and that they must be sent back to France. This request was not complied with, and the telephone company fetched away their instruments from Mr. Muirhead's place. The matter was brought before the courts, but owing to a lost contract the case was decided against the subscriber.

A meeting of the London committee of the Edinburgh Exhibition was held a few days ago. It was stated that, although the attendance had not been up to the expectation, it had exceeded three millions. It is extremely doubtful, however, whether this figure would have been reached were it not for the fact that the Forth Bridge is in the neighborhood. The determination of the Executive Council not to award prizes to electrical exhibitors has caused dissatisfaction.

The Falcon Works, Loughborough, acquired by the Brush Company about a year ago, have undergone considerable alteration. £20,000 have been spent in the erection and fitting up of spacious machine shops and foundry. Here will be manufactured the whole plant required for central stations. A few electrical cars have been built, and in the event of any great development of electric traction this company will no doubt receive many orders. For some time the two local electric light companies of Newcastle, which have had areas alloted to them, have been busy laying mains, and completing their plant in other ways. It has been wisely ordained that the streets should be divided in such a manner that no one company could create a monopoly, a little healthy competition has been the result, and the work has been pushed rapidly on. The public has not been slow to appreciate the efforts, and many are the private installations which have ceased to run since the companies started work. Large users of artificial lights, such manufacturers as have adopted electricity, and the postal authorities in that town are introducing it into every part of the central office. The experiment of lighting the streets by arc lamps has been successful, and more lamps will be erected.

Work in St. Pancras, which, by the way, is the only local body in London who will supply electricity, is pushed on. The contracts have been accepted by Babcock & Wilcox for boilers, Williams & Robinson for dynamos, Electric Construction Company for switchboards, and Clark, Muirhead & Co. for conductors.

After many discussion, the Town Commissioners of Killarney, Ireland, have decided to apply to the Board of Trade for a provisional order to supply light under the Electric Lighting Acts.

Last week the Electric Tramcar Syndicate, Limited, the owners of the Jarman patents, ran one of their new cars on a section of line placed at their disposal by the London Tramway Company. So well did everything work that it is expected that the cars will be adopted very soon. The car was of the ordinary type with accommodations for 44 passengers. A double motor is employed with the two armatures placed on one spindle. The gearing is a singe set of mortise wheels and pinions. The mortise wheels are of special construction with vulcanized fibre teeth. The driving arrangement is contained in a vertical case enclosing a cylindrical switch. By this switch all the necessary manipulations are made. The battery of E. P. S. accumulators supplying the current to the motors consists of 52 double E cells, 19 plates in each cell—the whole coupled in series. The capacity is 140 ampere hours. This system is likely to be introduced into Spain.

The full particulars of the tramway accident at Fiesole, in Italy, which mentioned in a previous letter, are to hand. I will not trouble you with the sickening details of the accident, but touch upon the reputed cause. The conductor, it appears, was drunk. He

started the car above the normal rate, and on the passengers becoming frightened, he appears to have lost his head and turned off the current by which he would have been able to reverse the car. Of course no sooner this was done than the gravity of the vehicle impelled it at a terrific rate down the hill. It jumped the rails and finally crashed into a parapet, the whole thing being smashed to atoms, killing several outright and severely maiming over twenty. So strong was public feeling in the matter that numbers patrolled the line preventing further cars running. It will be years, it is thought, before this electric line will pay a dividend, or even be worked without loss. It appears the driver was paid at the rate of 1s. 8d. per day.

It has been decided by the Leeds County Council that the lighting of the borough of Leeds shall be left to private enterprise, and it is probable that the Yorkshire House-to-House Co. will apply for an order. The Chelsea Electricity Supply Company has applied to the vestry of Chelsea district for permission to lay down rails for the use of electric tram cars.

Messrs. Crompton are completing central stations for the local companies in Northampton and Southampton.

In spite of the agitation among the telegraph clerks for some months past, their position does not seem to have materially improved. They complain that increments were made in their salaries and recalled after a few weeks operation. A meeting was to be held on Saturday, when 10,000 clerks were expected to be present.

H. S.

LONDON, Oct. 8th, 1890.

CORRESPONDENCE.

BOSTON.

The New England Electric Exchange.—Boston Electric Light Co.—West End Railway Work.—Walworth Light and Power Company.

THE New England Electric Exchange held its regular quarterly meeting this week, with Mr. Alex. P. Wright presiding. The reports, which were read and accepted, showed an increasing interest in the licenses granted to candidates. The members voted to make electric welding one of the branches of electric science, efficiency in which would assist in procuring a license, and it now ranks on an equal footing with electric light and power. A committee composed of Messrs. A. P. Wright, J. R. Lovejoy and C. R. Burleigh was appointed to confer with a committee from the New England Insurance Exchange relative to the change in the rulings of the new code of wiring, &c. Mr. H. C. Spaulding resigned his position as secretary and treasurer of the Exchange, and Mr. T. W. Sprague was appointed in his place.

At a meeting of the board of Aldermen this week the Boston Electric Light Company asked for permit to erect a 600-horse-power engine at 853-857 Albany street. A remonstrance having been made, the matter was referred to the committee on steam engines, with instructions to give a public hearing.

The West End Street Railway Company are equipping their electric cars with lanterns, the glass in which will be lettered with the name and number of the route on which they run.

BOSTON, MASS., Oct. 18, 1890.

PITTSBURGH.

Troubles at McKeesport.—A Peculiar Fire.—Electric Railway Work.

A TELEGRAM from McKeesport, Pa., reached me to-day reading as follows :—" A great fight is in progress between the local electric light company and the Edison people, and one which promises to reach the courts. The light company a short time ago contracted with the National Tube Works Company and the Monongahela Furnace Company to furnish a large number of arc lamps to be placed in the yards of the companies. The light company people made preparations for enlarging their plant and sent on to New York to the Edison Company to furnish the desired material, but instead the order was countermanded. Last Tuesday night a meeting of stockholders was held to elect new directors; among those present was President Herrick, of the Edison system, which owns about half the stock in the local company. He made a statement to the effect, that it was thought best not to enlarge the plant and that he should have a voice in the election of certain directors. The local faction objected to any such a move and a great rumpus occurred, which resulted in no election being held and the meeting adjourned. Mr. Herrick has ten days in which to settle the matter and if it is not accomplished at the end of that time the local stockholders threaten to withdraw and organize a new company." I give the telegram just as I received it and I know nothing more particularly about the facts.

A peculiar fire occurred here yesterday, which ended in the destruction of a telegraph pole, a cable box and did a great deal of damage to the electric wire system of the town generally. The telegraph pole stood opposite the Union Depot in this city and at its top it contained a box with several hundred Western Union telegraph wires. It is supposed that one of these wires became crossed with an electric light wire and thus started a fire in the cable box. Immediately a flame emerged from the box and soon the pole was surrounded with a blaze giving the idea of a gigantic torch. An alarm was sent in to the fire department and in a few minutes the engines arrived on the spot. By this time the pole was sending flames ten feet in the air, but one stream of water soon extinguished the fire.

The Pleasant Valley Electric Railway Company in this city has issued a circular to the patrons of its line to the effect, that in the future no car will be allowed to carry more than 45 passengers at a time.

The authorities of the city of Allegheny have decided to increase the capacity of their electric light plant by adding 100 arc lamps. The Westinghouse Electric and Manufacturing Company has the contract for the electric apparatus.

PITTSBURGH, Oct. 17, 1890.

SOCIETY AND CLUB NOTES.

THE BROOKLYN INSTITUTE.

On Friday, Oct. 26, Dr. S. S. Wheeler, will deliver a lecture before the Department of Electricity, on "Certain Applications of Electricity." The lecture will be illustrated by experiments and the meeting will be held in the Lecture Room of the Brooklyn Y. M. C. A. Building, 502 Fulton St.

At the regular weekly meeting October 10, of the Electrical Department of the Brooklyn Institute, the following officers were elected for 1890-91 : James Hamblet, Supt. of the time service of the Western Union Telegraph system, president ; Prof. Samuel Sheldon, first vice-president ; J. P. Wintringham, second vice-president ; William H. Randall, secretary and R. W. Bayles, treasurer.

THE TELEGRAPHERS' BALL—PRESENTATION TO MISS STEPHENSON.

The second grand annual reception of the New York Telegraph Club was held at the Central Opera House, this city, on October 15. There was a large and brilliant gathering, and special interest was given to the occasion by the presentation to Miss Kittie B. Stephenson, the winner of the first prize, Ladies' Class, in the late Fast Sending Tournament, of a handsome silver cairngorm brooch, the gift of the Hon. James D. Reid, U. S. Consul to Dunfermline. After a few introductory remarks by President E. E. Brannin, of the Club, Mr. W. J. Dealy, the well-known manager of the Western Union operating department at "195," made the presentation. He read a letter from Mr. T. C. Martin, to whom Mr. Reid had forwarded the brooch, and the following cablegram :

"DUNFERMLINE, October 15.

"T. C. Martin, New York. With presentation of brooch, if deemed worthy of so formal a ceremony, please present my love and grateful memory to all present. My heart is in New York.

"J. D. REID."

Here the entire assemblage shouted in a mighty chorus, as a salute to Mr. Reid, the telegraphers' fraternal signal of good will, "73." This Mr. Dealy responded to with one of his eloquent and epigrammatic speeches. The acknowledgment, on behalf of Miss Stephenson, was made by Mr. E. C. Cockey, who said of the donor : "His memory will always be wreathed with the grateful and loving thoughts of every member of the craft. A thousand things he has done, ten thousand words he has uttered will spontaneously come back to us, and will make us feel how much better and richer we were because we knew him, and honored him and loved him. It is therefore not only with present pride but with loving care for the future that Miss Stephenson asks me to say that she shall guard the pin as her most precious possession." As Mr. Cockey finished his felicitous remarks a letter to Miss Stephenson was handed in from Mrs. M. E. Randolph, in which she said that the significance of this occasion seemed to call for a woman's voice, and spoke of Mr. Reid's work in opening to women the doors of telegraphy as a new and honorable profession

The brooch is a beautiful piece of work, being a deer's head, in the antlers of which is placed the stone. It is deservedly admired by all who have seen it. Miss Stephenson will ever prize it, remembering, too, Mr. Dealy's happy phrase, "This pin, set with Scotia's choicest stone—the cairngorm, brilliant gem—to crown your victory ; and happy design—the deer—emblem of the speed that won it."

REPORTS OF COMPANIES.

STOCKS AND BONDS.

SPRAGUE, WASH., is to be bonded for $35,000 for electric lights and water works.

THE SCHUYLER ELECTRIC CO.

At the annual meeting of the Schuyler Electric Company held at the office of the company in Middletown, on Thursday, October 9, 1890, the following gentlemen were chosen directors: S. H. Butler, John N. Camp, Walter B. Hubbard and C. E. Jackson, of Middletown, Conn., C. N. Wayland and C. L. Buckingham, of New York, and Chas. E. Dustin, of Hartford. A meeting of the board of directors was held immediately after, and officers for the ensuing year were elected, as follows: President, Chas. E. Dustin; vice-president, S. H. Butler; treasurer, Jos. T. Elliott; secretary, D. J. Glazier.

INVENTORS' RECORD.

Patents issued Oct. 14.

Alarms and Signals:—*Electric Signaling Apparatus*, T. A. Edison, 438,304. *Police-Patrol Signal-Box*, C. Plumb, 438,361. *Annunciator*, A. F. Stanley, 438,390.

Conductors, Conduits and Insulators:—*Method of Insulating Electrical Conductors*, T. A. Edison, 438,309. *Connector for Electrical Conductors*, G. J. Brennen, 438,400. *Insulating-Joint*, S. H. Short, 438,495. *Electric-Wire Distribution Box*, W. H. Eckert and W. H. Gregory, 438,592.

Distribution:—*System of Electrical Distribution*, T. A. Edison, 438,308.

Dynamos and Motors:—*Electric Motor*, E. Thomson, 438,204. *Commutator for Dynamo-Electric Machines*, T. A. Edison, 438,302. *Magneto-Generator*, N. B. Ginochio, 438,431.

Galvanic and Thermo-Electric Batteries:—*Composition of Matter for Making Cells or Retaining Vessels*, O. A. Enholm, 438,311. *Acid-Proof Retaining Vessel*, O. A. Enholm, 438,312. *Insulating Appliance for Electric Batteries*, S. C. C. Currie, 438,582. *Galvanic Battery*, R. E. Murphy, 438,586.

Lamps and Appurtenances:—*Electric-Arc Lamp*, A. Apps, 438,134. *Manufacture of Incandescent Electric Lamps*, T. A. Edison, 438,298. *Manufacture of Carbon Filaments*, T. A. Edison, 438,299. *Gauge for Testing Fibers for Incandescent-Lamp Carbons*, T. A. Edison, 438,300. *System of Electric Lighting*, T. A. Edison, 438,301. *Arc Lamp*, T. A. Edison, 438,303. *Manufacture of Incandescent Electric Lamps*, T. A. Edison, 438,307. *Lamp-Base*, T. A. Edison, 438,310. *Electric-Light Shield*, A. A. McCreary, 438,419. *Incandescent-Electric-Lamp Socket*, J. W. Collier, 438,431.

Measurement:—*Apparatus for Measuring the Strength of Electric Currents*, S. C. C. Currie, 438,226.

Metallurgical:—*Method and Apparatus for Magnetic Separation of Ores*, J. M. McMahon, 438,357.

Metal-Working:—*Method of Utilizing Electricity in the Formation of Sheet-Metal Articles*, M. W. Dewey, 438,406. *Apparatus for Forming or Shaping Sheet-Metal Articles Electrically*, M. W. Dewey, 438,407 and 438,408. *Method of Utilizing Electricity in the Formation of Metallic Cartridge Cases*, M. W. Dewey, 438,409. *Method of and Apparatus for Working Metals by Electricity*, G. D. Burton, 438,525.

Miscellaneous:—*Circuit-Closer*, T. Marcher, 438,167. *Coin-Actuated Box*, J. W. Patterson, 438,174. *Circuit-Closer*, J. Geary, 438,231. *Electric-Safe Lock*, W. H. Hollar, 438,236. *Electric Switch*, C. W. Smith and C. J. Lyons, 438,260. *Fuse-Block*, T. A. Edison, 438,305. *Automatic Cut-Out*, G. W. Richardson, 438,326. *Circuit-Interrupter*, N. Chaize and J. Chaize, 438,344. *Thermal Cut-Out*, W. R. White, 438,394. *Electric Means for Preventing Boiler Incrustations*, A. B. Faunce, 438,579. *Automatic Safety Cut-Out for Electric Circuits*, G. T. Woods, 438,590.

Railways and Appliances:—*Electric-Motor Car*, J. F. Shawhan, 438,192. *Gearing for Motor-Cars*, O. C. Smith, 438,127. *Support or Hanger for Trolley Wires*, H. C. Wirt, 438,211. *Trolley-Pole*, J. M. Andersen, 438,219. *Electric Railway Conduit System*, M. Wheless, 438,262. *Electric Railway System*, F. J. Sprague, 438,293. *Trolley-Wheel for Electrically-Propelled Vehicles*, L. Pfingst, 438,359. *Contact for Overhead Electric Railways*, A. H. Chadbourne, 438,404. *Electric Railway Brake*, C. J. Van Depoele, 438, 452. *Electric Railway*, H. E. Swift, 438,561.

Secondary Batteries:—*Regulation and Control of Storage Batteries*, S. C. C. Currie, 438,145.

Telegraphs:—*Telegraph Instrument*, J. Geary, 438,233. *Telegraph-Key*, C. H. Crockett and L. O. Dedrick, 438,530.

Telephones and Apparatus:—*Telephone*, T. A. Edison and E. T. Gilliland, 438,306.

FRANKLAND'S RESEARCHES ON THE CHEMISTRY OF STORAGE BATTERIES.[1]

THE chemical changes which take place during the charging and discharging of storage batteries have been the subject of considerable difference of opinion amongst chemists and physicists. Some authorities have maintained that the effects are dependent on the occlusion of oxygen and hydrogen gases on the plates, whilst others, regarding the question from another point of view, have held that lead sulphate plays an important part in the phenomena. That the differences of opinion amongst experts have been widely divergent may be recognized from the fact that scientists, who, apparently, are well competent to express their views, have asserted that no chemical change of the lead sulphate occurs either in the charging or discharging of the plates.

In order to test the accuracy of the former opinion, Dr. Frankland, some time ago, undertook a series of experiments, the results of which were communicated to the Royal Society (*vide* Proceedings Royal Society, XXXV., p. 67). Two plates of lead were twisted into a corkscrew form, the gutter of the screw being filled with red lead; these plates were immersed in dilute sulphuric acid and charged in the usual way. When these plates were subsequently heated and the gas evolved, collected and examined, it was found that mere traces of oxygen and hydrogen were expelled, whereas, if the theory had been correct, there should have been a copious evolution. Hence, it was concluded, that the important agent in the cell is not constituted by the occluded gases.

With regard to the lead sulphate, Dr. Frankland observed that in charging a storage cell, a considerable amount of sulphuric acid disappears, and is accompanied by a certain deposition of lead sulphate, but that the deposit formed is inadequate to account for the total acid which has disappeared.

The strength of the acid ceases to diminish and afterwards increases as the charging of the cell proceeds; this change continues until the maximum charge has been reached, and oxygen and hydrogen gasses are evolved from the positive and negative plates respectively.

When the cell is discharged, the phenomena above described are reversed, the specific gravity of the acid decreasing from the point from which it began to increase on the charging of the cell.

From these experiments and the observations made upon them, Dr. Frankland deduced the following results, representing the changes which occur in *charging* a storage battery, viz.:

1. The electrolysis of hexabasic sulphuric acid (*i.e.*, $H_6\,SO_6$) according to the equation

$$H_6\,SO_6 = \underbrace{SO_3 + 3O}_{\text{on + plate}} + \underbrace{3\,H_2}_{\text{on − plate}}$$

2. The reconversion of the evolved sulphuric anhydride (SO_3) into the corresponding acid ($H_2\,SO_4$).

3. Chemical action on the coating of the positive plate according to the equation

$$PbSO_4 + O + 3\,H_2O = PbO_2 + H_6\,SO_6.$$

4. Chemical action on the coating of the negative plate according to the equation

$$PbSO_4 + H_2 + 2\,H_2O = Pb + H_6SO_6.$$

When the storage battery is *discharged*, the first two changes observed in charging the battery are repeated. Further, on the coating of the positive, formerly the negative electrode, the chemical change which takes place is represented by the equation

$$PbO_2 + H_2 = PbO + H_2\,O$$

on the coating of the negative. Finally, the positive electrode, the change occurring is represented by the equation

$$Pb + O + H_6\,SO_6 = Pb\,SO_4 + 3\,H_2\,O.$$

Hence Dr. Frankland formed the opinion that the formation of the cell consists in the more or less thorough decomposition of those portions of the lead sulphate comparatively removed from the conducting metallic nucleus of the lead. Lead sulphate possesses a low specific conducting power, whilst lead peroxide, and especially spongy lead, offer comparatively little resistance to the current, which is thus enabled to bring the outlying portions of the coating under its influence.

Since these results were published Dr. Frankland has been pursuing his researches in the same direction. He undertook a series of experiments with a view to ascertaining what lead compounds actually take part in the chemical reaction in charging and then discharging secondary batteries.

A quantity of lead oxide (PbO_2) reduced to a fine powder was treated successively with portions of dilute sulphuric acid until the liquid became permanently acid. On being allowed to stand, a buff-colored precipitate separated from the mixture and was found by analysis to possess the formula $Pb_5\,S_3\,O_{14}$.

1. London *Electrical Review*.

When finely powdered red lead (Pb_3O_4) was treated in the same way with dilute sulphuric acid, the powder which settled on standing was brownish-red in color, and was found on analysis to have the constitution $Pb_3\,S_2\,O_{10}$.

Dr. Frankland considers that these hitherto unknown or undescribed salts constitute the original active material of storage cells, and that the following equations accurately represent the reactions which take place on the surface of the plates on charging and discharging the battery.

A. If the buff-colored salt is the active material used, then

I. on charging—

(1) Positive plate, $Pb_5\,S_2\,O_{14} + 3\,H_2\,O + 5\,O = 5\,PbO_2 + 3H_2\,SO_4$.

(2) Negative plate, $Pb_5\,S_2\,O_4 + 5\,H_2\,O = 5\,Pb + 3\,H_2SO_4 + 2\,H_2\,O$.

II. on discharging—

(1) Positive plate, $5\,PbO_2 + 3\,H_2\,SO_4 + 5\,H_2 = Pb_5\,S_2\,O_{14} + 8\,H_2\,O$.

(2) Negative plate, $5\,Pb + 3\,H_2\,SO_4 + 5\,O = Pb_5\,S_2\,O_{14} + 8\,H_2\,O$.

B. If the brownish-red colored salt is the active material used, then

I. on charging—

(1) Positive plate, $2\,Pb_3\,S_2\,O_{10} + 2\,O_2 + 4\,H_2\,O = 6\,PbO_2 + 4\,H_2\,SO_4$.

(2) Negative plate, $Pb_3\,S_2\,O_{10} + 4\,H_2 = 3\,Pb + 2\,H_2\,SO_4 + 2\,H_2\,O$.

II. on discharging—

(1) Positive plate, $6\,PbO_2 + 4\,H_2\,SO_4 + 4\,H_2 = 2\,Pb_3\,S_2\,O_{10} + 8\,H_2\,O$.

(2) Negative plate, $3\,Pb + 2\,H_2\,SO_4 + 2\,O_2 = Pb_3\,S_2\,O_{10} + 2\,H_2\,O$.

It is worthy of remark that in practice only half as much material seems to be necessary for the negative as for the positive plates, and this is evidence in favor of the latter alternative, B, being correct.

We cannot assume, however, that there is nothing more to be discovered concerning the chemical action of storage batteries. The subject is full of complications, and it is to be hoped that electricians will receive further and large assistance from chemists who alone, perhaps, are able to throw the necessary light upon these obscure matters.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT

MAKING ALUMINUM IN PITTSBURGH.

THERE is probably no other metal the usefulness of which is so extensive as aluminum and yet its practical utility has only been very recently successfully demonstrated. Of course, the metal was known long ago, and its advantages were at once realized, but the great cost of its production prevented it always from becoming a competitor of other metals.

That this obstacle has now been overcome and that aluminum bids fair to eclipse even iron and steel in many instances, as a commercial commodity, is mainly due to electricity. Owing to the fact that electricity has the faculty of separating pure aluminum from its surrounding impurities and that it helps to reduce the expense of production, the metal has now become useful in many ways.

There are, however, still but very few aluminum factories in the world and among them the Pittsburgh Reduction Company is one of the largest.

Since the electric current plays a very important part in the manufacture of the metal, a visit was paid to the works a few days ago, in order to get an idea as to the manner in which electricity is applied in the process of producing aluminium.

Aluminum exists in nature in the form of an oxide so refractory in its character as to make reduction in any ordinary furnace impossible, the only means which have been found available for its reduction on a commercial scale being by electrolysis. It is this method which has been perfected by the Pittsburg Reduction Company.

The company's power plant consists of several Babcock and Wilcox boilers and the engines are three in number, two being of 200 h. p. of the Westinghouse compound type and one a Westinghouse automatic engine of 125 h. p.

The electric plant consists of four direct current dynamos made by the Westinghouse Electric and M'f'g Co. and the U. S. Electric Lighting Co., of Newark, N. J. The armatures of these dynamos are shunt wound and all of them furnish the current for the reducing pots. Two of these dynamos are immense machines, they are wound to generate a current of 2,500 amperes at a pressure of fifty volts, running at a speed of 325 r. p. m. These two dynamos are probably the largest in the country, and they have been especially made to do the work in this factory. The other two machines furnish a current of 1,000 amperes each, at a pressure of 25 volts, running at 1,000 r. p. m.

The two larger dynamos are connected in parallel, as well as the two smaller ones, though on an independent and separate circuit. The arrangements for transmitting the 5,000 ampere current from the two large dynamos are striking and somewhat novel in the way of electric current conductors, two copper bars, each six inches by one-half inch, having a total area of cross section of six square inches, being used. For the 2,000 ampere current from the small dynamos, a similarly shaped bar, four inches by one-half inch, is used. Fortunately, it is necessary to carry the current but a very short distance on such expensive conductors as these.

Since the works of the Pittsburgh Reduction Company have been operated, their production of this valuable metal has been constantly on the increase and the demand is now so great that the company is contemplating an enlargement of its plant in order to make the producing capacity greater than it is at present. The Pittsburgh company also operates a similar plant in Manchester, England.

J. ELLIOTT SHAW & CO.

The above well-known Philadelphia house announce that on November 1, they will remove to their new store and factory, 623 Arch street, that city, where they will have far better facilities to meet the demands made upon them for reliable goods. They are, in fact, driven to make this change by the growing demand for such specialties as their Norway iron frame bells, &c.

THE NATIONAL ELECTRIC SYSTEM.

The National Electric Manufacturing Co., of Eau Claire, Wis., is crowded with orders for its lighting apparatus, and finds it well nigh impossible to keep within hailing distance of its new contracts for plant. This is, of course, a pleasing state of affairs, and the company hope to catch up soon by an increase of its facilities.

NEW ENGLAND TRADE NOTES.

ROLAND T. OAKES & COMPANY are installing a 120 ampere Perret dynamo, in the factory of Messrs. B. B. Webber & Co., of Holyoke, Mass., which will furnish current for 110 16 c. p. incandescent lights, and 12 Ward arc lamps of 1800 candle power.

THE GOULD & WATSON CO., of Boston, the well-known manufacturers of moulded mica insulators, and dealers in mica, have published a very attractive and complete catalogue of their specialties for electric railways and other work. The book embraces, trolley line insulators, pull over or curve brackets, strain insulators, line insulators, pole insulators, insulated line hooks, and many other insulating devices. The Gould & Watson Co. have done a very successful business in these goods, having over 65,000 of their trolley line insulators in use, and they are constantly making new applications of their material for various insulating purposes. The catalogues will well repay a careful perusal.

THE ROBINSON RADIAL CAR TRUCK CO., of Boston, have printed and are issuing a special circular giving comparison of weight, seating capacity, power required, and cost to propel and earning capacity, between their car and any form of eight-wheeled car. The circular claims a net total gain in favor of the Radial car of 36¾ per cent. and should be carefully studied by every electric railroad engineer.

THE EASTERN ELECTRIC SUPPLY CO., of Boston, have recentla sold quite a large amount of goods to a Paris house, including y large number of Burnley dry batteries. Mr. Henry F. Kellogg, a gentleman well and favorably known among the electrical fraternity, has connected himself with this company, and is at present traveling in New England in their interests. The following officers of the company have been elected :—Mr. Maybin W. Brown, president; Albert Otis Smith, treasurer; Messrs. C. F. Hutchinson, of Everett, Mass., L. A. Dean, Boston, Samuel R. Moseley, Hyde Park, and the two first mentioned gentlemen as directors. Mr. James E. Cook has been appointed attorney for the company.

RUSSELL ELECTRIC LAMP CO.—Mr. E. C. Russell, the inventor of the Russell lamp, and Mr. Abram Hoffecker, have sold their Canadian rights to the Craig Russell Electric Company, of Montreal, which lights five Canadian cities, for the sum of $60,000.

THE
Electrical Engineer.

VOL. X. OCTOBER 29, 1890. No. 130.

AN ELECTRIC TIME AND DATE STAMP.

AT the present day, when the exigences of business require an accurate record of the time and date at which transactions are effected, it is quite obvious to everyone that a convenient piece of mechanism which will automatically and continuously record the time of day, as well as the day of the month and year, must evidently be of great convenience

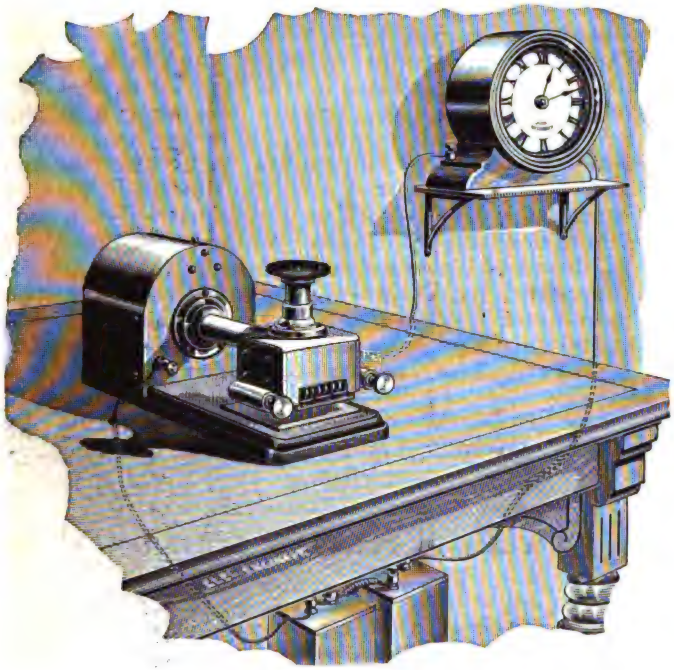

FIG. 1.—A NEW ELECTRIC TIME STAMP.

and value. Among the numerous cases in which such a record is not only highly desirable, but frequently indispensable, we may mention the transactions on the stock exchange, the recording of fire and police signals, the delivery and reception of telegraph and cable messages, the recording of all legal documents, and of many amusements such as billiards, boating, etc., the cost of which is based upon time; and in general business life a convenient time record is evidently a desirable addition to the office equipment.

To afford the means of obtaining such a record the New York Electrical Device Co., of this city, have just brought out a number of time and date stamps in which, by the use of electricity, some of the defects of the purely mechanical stamps heretofore in vogue have been removed. This has been accomplished by making the clock which gives the time, entirely independent of the stamping mechanism, and thus avoiding the shocks and jars to which it would otherwise be subjected.

The accompanying engraving, Fig. 1, shows the swinging arm model of the recorder, one of which has lately been put in successful operation on the New York Stock Exchange, to record the departure and arrival of messengers. The apparatus consists simply of a stamp, the variable characters of which are mounted as type wheels at the end of a swinging arm. These wheels are connected in a simple manner with the armature of an electro-magnet placed at the other end of the arm and actuated by electric impulses controlled by the clock shown. The latter is arranged to close the circuit for a fraction of a second at the beginning of each minute, the result being that the type wheels are correspondingly revolved to accord with the indications of the clock. Two cells of an open circuit battery is all that is required as the electric energy.

Another model of this apparatus has been designed, in which the type wheels are revolved and the recording, as well, is effected electrically. This instrument, which is illustrated in the engraving, Fig. 2, is made with a wide-lipped slot so as to allow of the insertion of a large sheet, and is connected to the clock in the same manner as the instrument just described. When it is desired to stamp the time it is only necessary to press the button at the front of the case. This energizes the electro-magnet, the movable armature of which gives the desired impression.

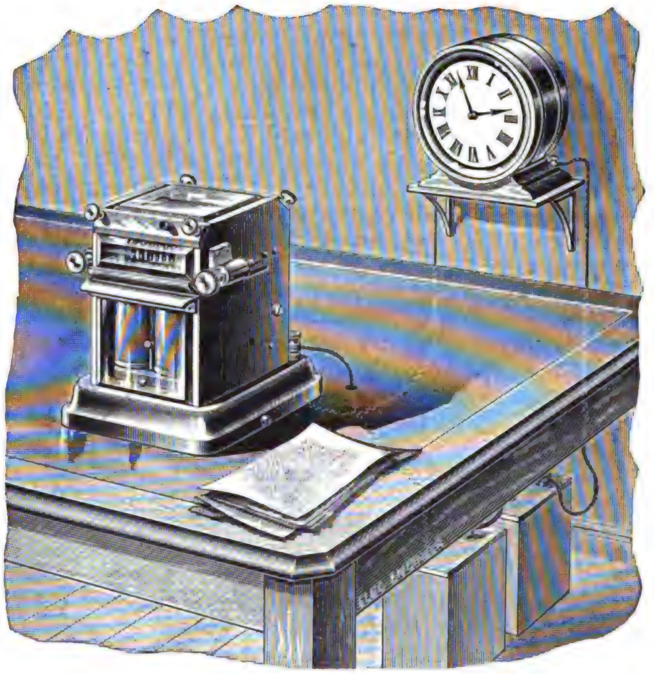

FIG. 2.—A NEW ELECTRIC TIME STAMP.

The apparatus is so constructed that it prints face up on top of the paper. As the clock is entirely independent it is evident that any number of stamps can receive their time impulses from a single central clock, which is very desirable in many cases, as, for instance, in the issuance and reception of railroad orders, where an entire section of a road could be controlled by a single time wire.

A modification of the model just described has been specially adapted for stamping time upon a continuous paper

tape such as is employed in the reception of cable or automatic telegraph messages and fire and police signals. One of these has been placed in the office of one of the Atlantic cable companies, where its accurate work has elicited much commendation.

OVERHEAD AND TRACK WIRING FOR ELECTRIC RAILWAYS.

BY W. H. CULL, SUPT. ALBANY CITY RAILWAY.

It has been said that constant vigilance and absolute cleanliness are the two requisite elements to the successful operation of electrical apparatus. It is certainly true when applied to an electric railway. Too much attention cannot be given to the overhead construction and track wiring. Iron poles are probably the most desirable for many reasons, and should be set at intervals of 125 feet, six feet deep, in a rich bed of concrete, surrounding the pole from 12 to 15 inches, and should be of sufficient strength to show a deflection of not more than four and one-half inches at the top of the pole when put under a direct strain of 800 pounds, and to stand a strain of 2000 pounds without bending them beyond their elastic limit. The top should be provided with a device admitting of the most perfect insulation for the suspension wires, and if guard wires are to be put up, with an extension for the guard suspension wires, at least 10 inches above the trolley suspension wire. The trolley wire should not be smaller than No. 0, hard drawn copper wire, supported by suspension wires of galvanized steel wire of a size not smaller than No. 5 American gauge; the hangers, or ear bodies, should be of sufficient strength to stand any sudden strain without breaking and still be as light as possible. The hangers should be provided with an insulation capable of eliminating moisture. From recent tests made we have found that mica or glass gives the best satisfaction. It is well to imagine that no insulation is good enough when insulation is desired. Utmost care should be taken in wiring curves; instead of building a trolley wire directly over the centre of the track it should be placed directly over a point to be determined by the radius of the curve between the centre of the track and the out-side rail and should be as high as the tension on the trolley pole will permit. If a speed exceeding three miles an hour is prohibited on curves constructed in this manner, the trolley wheel will rarely, if ever, run off. Trolley wires put up in sections are absolutely indispensable to the good working of an electric railway. The trolley wires should be divided in sections of sufficient numbers to permit of trouble on the line being located easily and rapidly and also to enable a large portion of the road to be operated while the disabled portion is being repaired. The frequency of these divisions must depend largely on the peculiarities and situation of the different roads.

On roads where it is practicable, an independent and separate feeder wire connected to each section of trolley wire and provided with a circuit switch at the power station would give a road a most complete system of sectional trolley wiring. In the event of trouble being noticed, it would enable the attendant at the power house to ascertain what section the trouble was on in two or three minutes, and also, to keep the uninterrupted portion of the road in operation.

The entire line should be constantly patrolled by linemen trimming trees, examining insulators, and especially curve wiring. All insulators should be treated to a coat of some insulating paint as often as once in three weeks.

Track wiring and ground connections are the most important factors in the operation of an electric road. The supplementary or return wire ought not to be smaller than No. 0 wire connected to each rail twice by a wire not smaller than No. 6. All joints should be well soldered and wiped as plumbers joint a lead pipe. In selecting a device to connect the bond wires with the rail, care should be taken to get the one having the least number of connections and making the most perfect contact. The fewer the electrical connections and the better the electrical contact the more perfect will be the electrical efficiency of the plant.

In Albany we have a most extensive system of track wiring and track ground connections, with which, together with metallic stringers under some of our rails, we have succeeded in getting a return circuit of so low a resistance that our current does not leak to telephone circuits, and consequently does not interfere with telephone service. We have placed copper ground plates, having a surface of about 36 square feet, at intervals of 1000 feet and of sufficient depth to insure their being in permanent moisture.

The Albany Railway, with a few exceptions, have carried out the suggestions set forth in this paper, and as a result they are enabled to take their cars up the heavy grades of their three lines, developing an average of only nine indicated electrical h. p. per car.

Perhaps the best proof that we have secured a good ground connection, and that we are receiving benefits therefrom, is the fact that we require no metallic connection in the return circuit between our power station and that portion of road now operated by electricity, a distance of about one mile.

When the road was first equipped by the Thomson-Houston Co. no ground connection was made, but two No. 0 American Gauge copper wires were strung overhead over this section for the purpose of carrying the current back to the generator. Tests made by us after we had connected our ground connection to the supplementary wire and track proved that we were deriving no benefit from these overhead return wires; we therefore, abandoned one of them and intend to make a feeder wire of the other.

The writer recommends perfect ground connections with the track and supplementary wire, and believes that it should be the aim of electricans to return the current to the generator in a path as direct and having as little resistance as possible. By the lower resistance encountered in the return portion, the total resistance to the current is very materially reduced, and economy of power, and efficiency of service in motors are gained.

A SIMPLE POLARITY TESTER.

BY ARTHUR J. NEWELL.

Having obtained, after considerable experimenting, a very convenient and cheap polarity indicator, the writer thought it might be of interest to some of your readers to know the results of the experiments.

If blue litmus paper, which can be bought in book form, for five cents, of any druggist, be immersed in a saturated solution of sodium sulphate, enough will be absorbed so that when the wires to be tested are brought into contact with the paper, the sodium sulphate will be decomposed. The alkali formed at the negative pole will produce no effect on the litmus, while the acid at the positive pole turns the blue litmus red. Therefore the rule for the use of this paper would be: The wire leaving a red spot is the positive pole of the circuit. If, however, an excess of acid should have caused the entire paper to become red, the converse of this rule would be true, viz., the wire leaving a blue spot is the negative pole.

After the paper has been immersed a short time it can be dried and carried about in the pocket. All that is necessary to again prepare it for use is simply to wet it.

One volt is enough to effect a decomposition, and leave a spot upon the paper, and the writer has tested it on circuits of 125 volts, and there is no reason why it could not be used on any voltage, if only a small portion of the wires be allowed to touch the paper and they are separated a sufficient distance.

The writer is confident that all who try this method will find it both convenient and reliable, as it avoids the use of any apparatus or dangerous chemicals.

NEW ELECTRIC ELEVATORS AND HOIST.

THE compactness and simplicity, as well as the economy of the electric motor when applied to the operation of elevators and hoists seems destined to lead to its general adoption for such purposes. In seeking to utilize the electric motor for this class of work, the American Electric Elevator Co., of this city, have recently brought out several designs which embody a number of novel and valuable features.

As the entire machinery occupies a floor space of only 4x6 feet, and stands only 4 feet high, it permits of being placed with equal readiness either at the bottom or at the top of the elevator shaft. The arrangements adopted in both these cases are shown in the engravings, Figs. 1 and 2.

The entire apparatus comprises merely the motor that drives a drum through the medium of a worm gear. To this is added the proper regulating and safety devices, consisting of a reversing switch and rheostat combined, an automatic electric brake, and an automatic stop device for stopping the elevator at the top or bottom of the lift, thus making it impossible for the elevator car to travel too far in either direction. The armature shaft of the motor is coupled direct to the worm shaft, and this coupling is also a brake wheel, to which the brake is applied automatically when the current is cut off. The brake shoes, it will be noted, are connected to the core of a solenoid, mounted directly above the shaft. When current is on, the solenoid is energized and the brake shoes are released. But a stoppage of the current from any cause, drops the core and applies the brake. This not only serves the purpose of overcoming the momentum of the armature when stopping, but also serves to hold the car stationary, if through accident at the generating station, or from any other cause, the current should be cut off.

The worm actuates the worm gear which is attached to the drum shaft. The wheel to which is attached the operating rope, and the movement of which starts, reverses or stops the car at the will of the operator, is also mounted on, but not fixed rigidly to the drum shaft. The end of the drum shaft has a screw thread cut on it, upon which there travels back and forth a nut provided with wings; hence, the nut, when it meets with any obstruction, turns with the drum shaft, and is so attached to the operating wheel by means of the wings, that it turns the wheel just enough to stop the motor. The necessary obstructions to the travel of the nut are in the form of collars which are fastened to the shaft at just the right place to stop the machine at the top and bottom of the lift. The worm, which is one piece with the worm shaft, is made of hard machinery steel, and

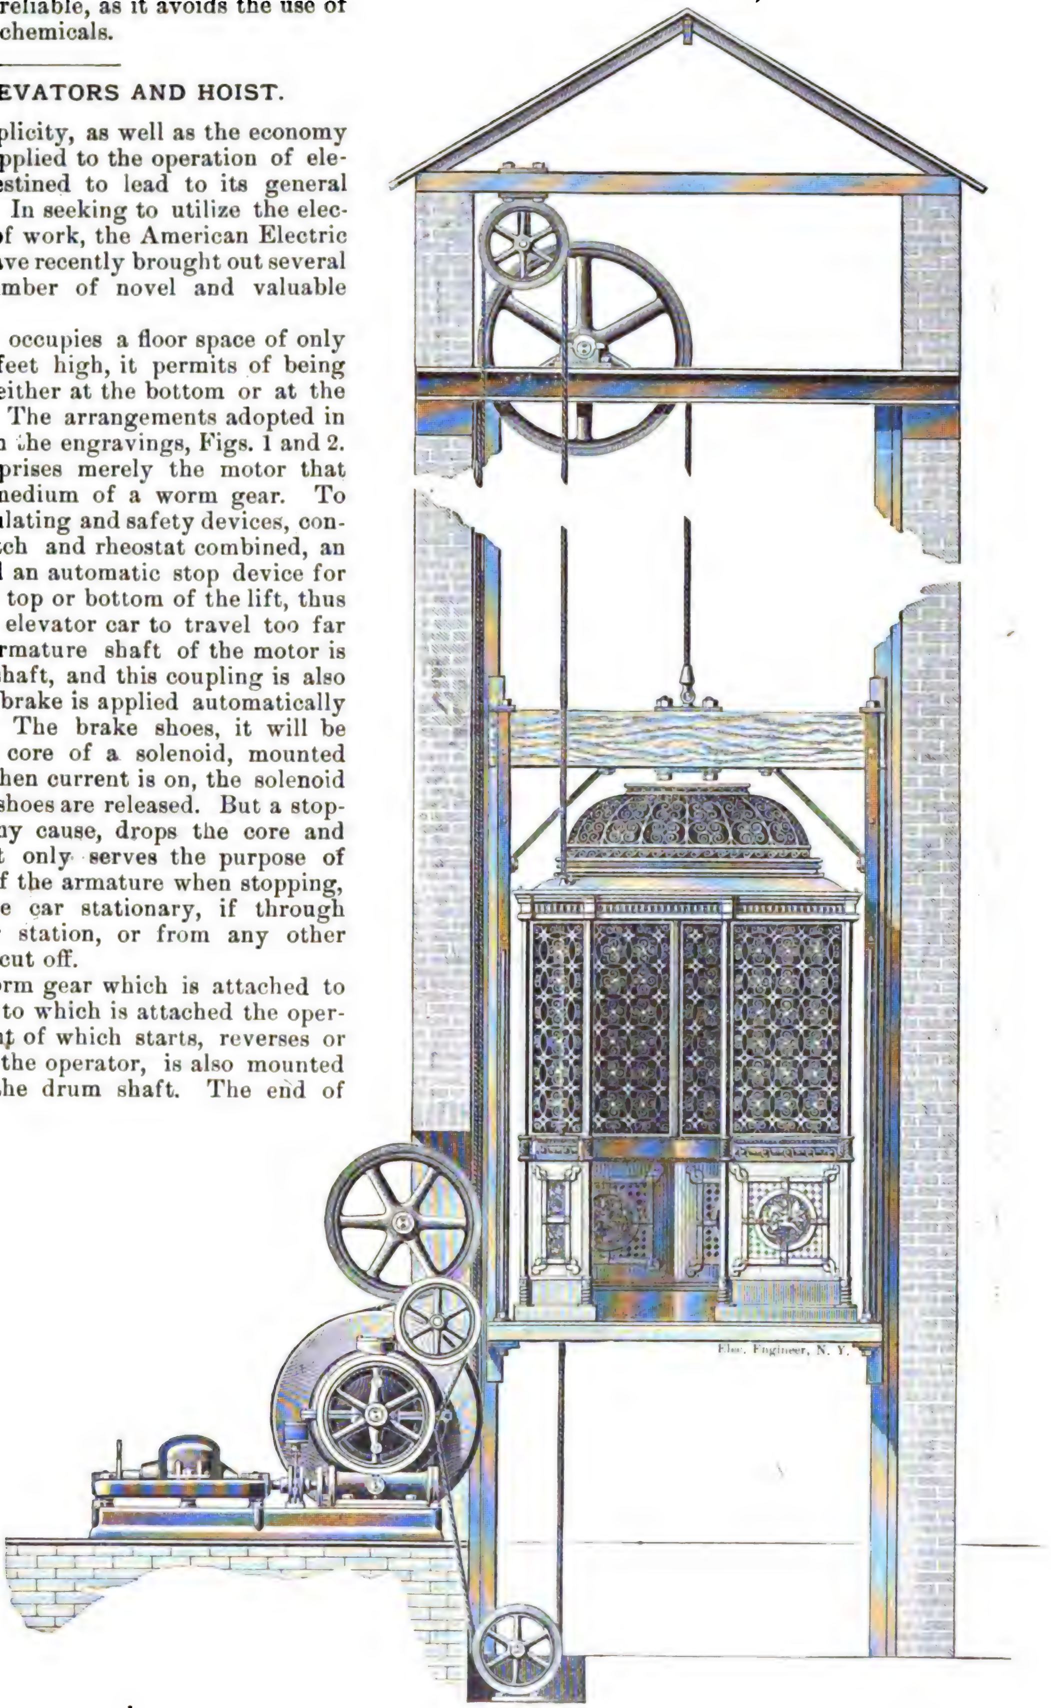

FIG. 1.—"AMERICAN" ELECTRIC ELEVATOR—MOTOR AT BOTTOM OF SHAFT.

the worm gear is a bronze composition ring which is securely fastened on a cast iron web, both being run in oil.

The whole machinery is assembled on one bed plate, and

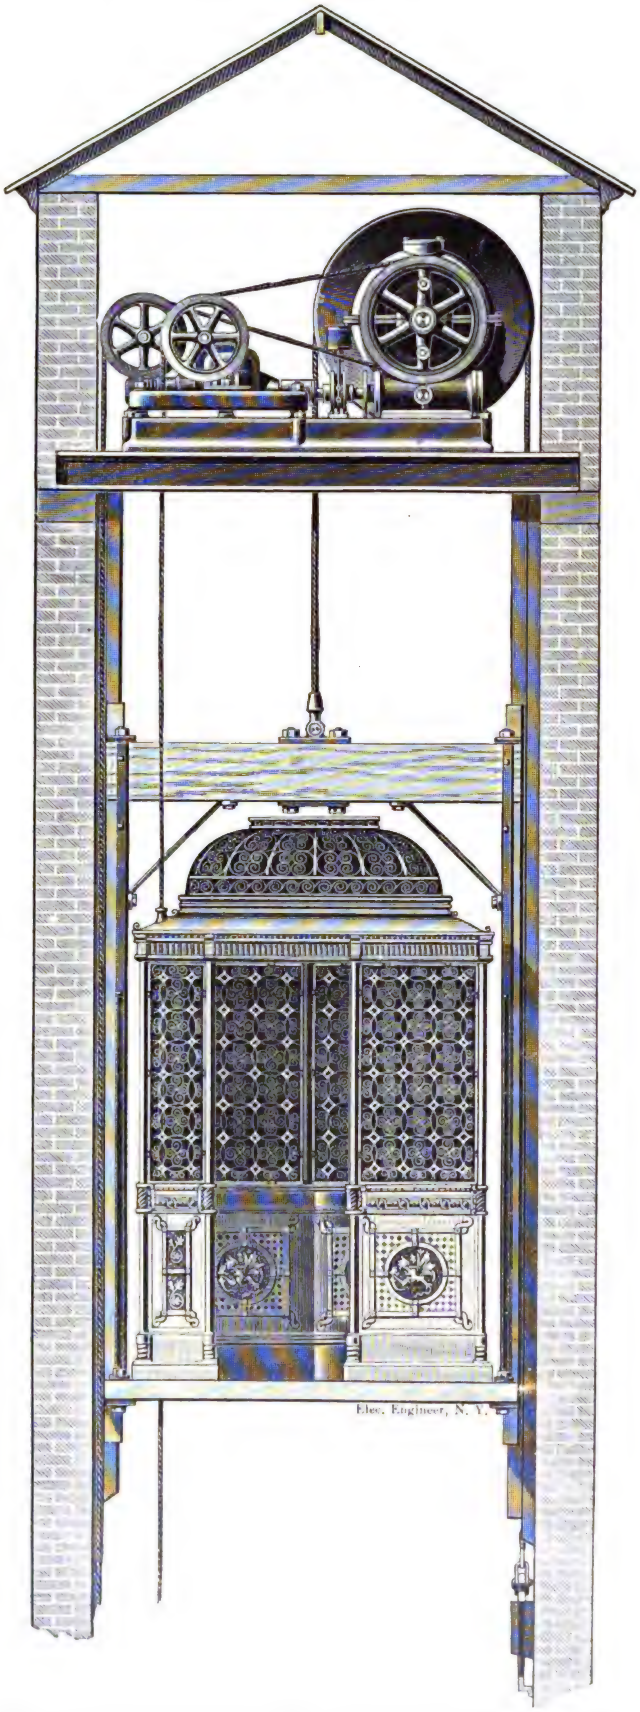

FIG. 2.—"AMERICAN" ELECTRIC ELEVATOR—MOTOR AT TOP OF SHAFT.

hence its erection and fitting in place can be effected with the least amount of difficulty and in the shortest possible time.

In carrying out the application of the electric motor to the handling and lifting of freight, the same company have brought out a new dock and ship hoist, which has some decidedly interesting features. The 10 h. p. hoist, which is illustrated in perspective in the accompanying engraving, Fig. 3, is assembled upon a bed plate 5 ft. 10½ in. by 2ft. 9½ in., and from the bottom of the bed plate to the highest point on the machine (the switch lever when in a vertical position) is but 3 ft. 7½ in. On account of its great compactness it may be placed on an overhead platform if desired, so that it occupies no dock or deck room whatever.

The engravings, Figs. 4 and 5, show the hoist in plan and side elevation, and Fig. 6 shows a section through the drum shaft.

The apparatus consists of an electric motor A, coupled direct to the armature shaft of which is a worm shaft C, which, with the worm, is one solid steel forging. This worm actuates a bronze worm gear D, and cast iron friction clutch E, which is attached to a solid steel shaft F. To one end of this shaft is attached a hauling drum or winch-head G, and on the other end there is cut a thread. On this thread is mounted a cast iron nut and handwheel H, which is supplied with steel handles on the inside of the

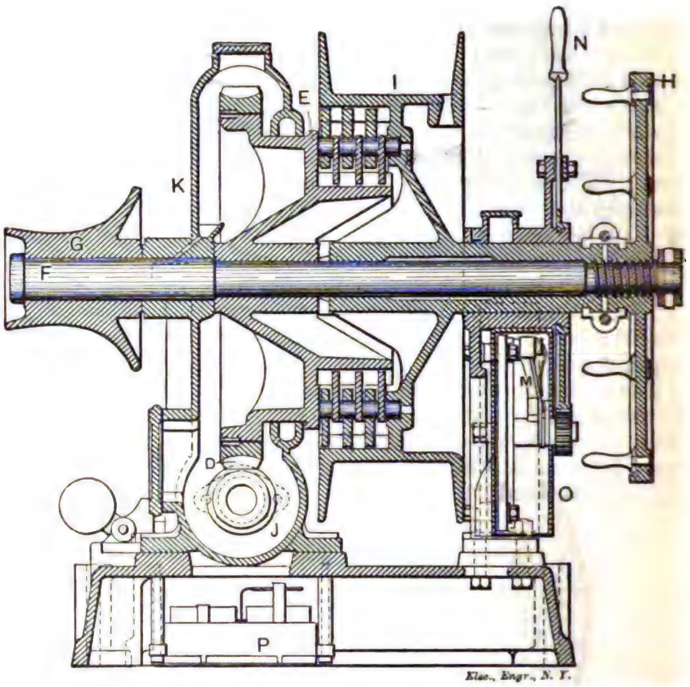

FIG. 6.—NEW ELECTRIC DOCK HOIST—SECTION.

rim; these are so placed in order that they will not catch in the clothing of, or strike, the operator. The movement of this handwheel-nut forces the loose drum I, into contact with the friction clutch E, or withdraws it, at the will of the operator.

The worm runs in an oil cylinder J, and the worm gear is enclosed in a cast iron casing K, which forms a bearing for the drum shaft F. The standard L which carries the other end of the drum shaft, also carries the switch M and the switch lever N. The switch is completely inclosed in a cast iron box O, which excludes all dust and dirt, and prevents bodily contact with it. The rheostat or resistance box P, is placed inside the bed plate, and the connections are so made that there are no wires in sight, and injury to the wires is, therefore, entirely avoided.

The manner in which the hoist is operated will now be plain. The operator moves the switch handle N to the left, which completes the electrical circuit and starts the motor; and as he continues to move the lever to the left he cuts out more resistance until full speed or the speed desired is attained. The drum shaft, winch-head and handwheel-nut are now in motion, but the drum is still at rest.

The winch-head G, alone may now be used; but if it is desired to use the hoisting drum F, the operator places his hand upon the hand-wheel H, and holds it stationary, which has the effect of screwing the wheel against the hub of the drum I, and thus forcing it into contact with the friction clutch E. When the pressure is sufficiently great to enable the drum to hoist the load, the operator is no longer able to hold the wheel, which then turns with the drum until the load is lifted to the desired height; the machine is then stopped by throwing the switch lever back to a vertical position, thus breaking the circuit and stopping the motor. The worm gear now holds the shaft with the friction clutch stationary, and the possibility of the worm being driven by the load is prevented by an automatic brake Q, Fig. 4, on the worm shaft. The handwheel H is connected with the hub of the drum I in such a manner that while each can turn independently of the other, the drum is moved back and forth on the shaft, as the wheel is turned on the thread.

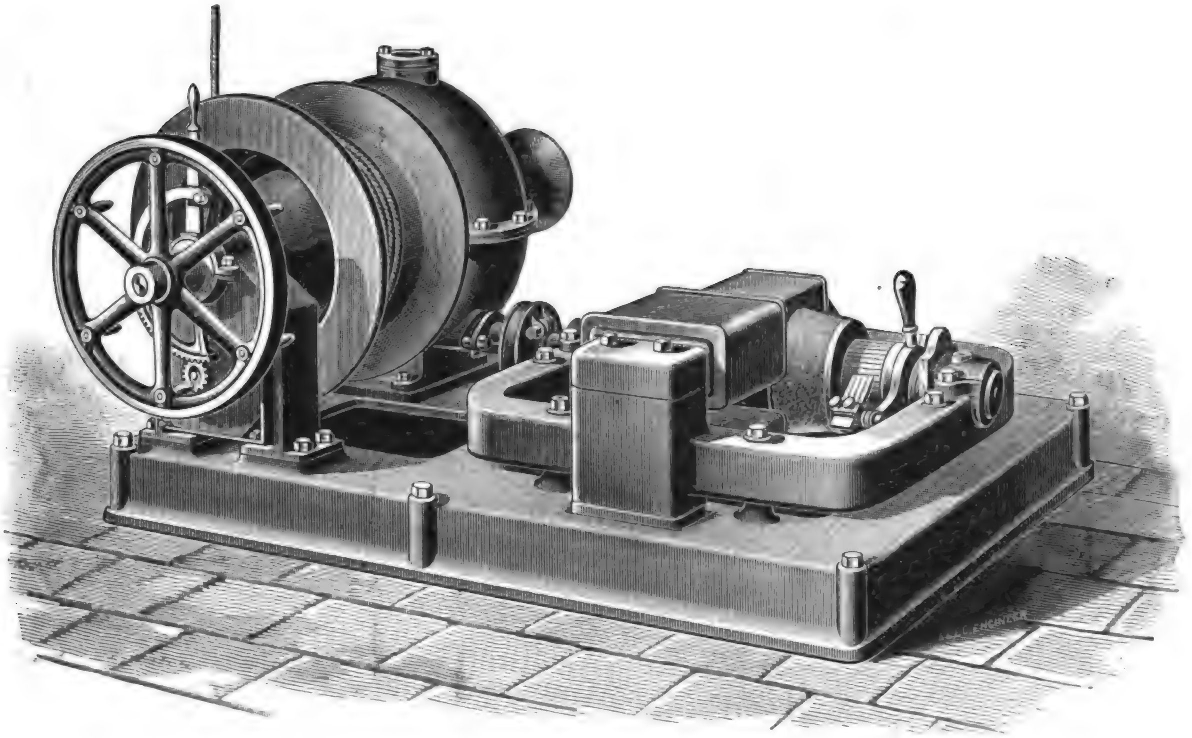

FIG. 3.—NEW "AMERICAN" ELECTRIC DOCK HOIST.

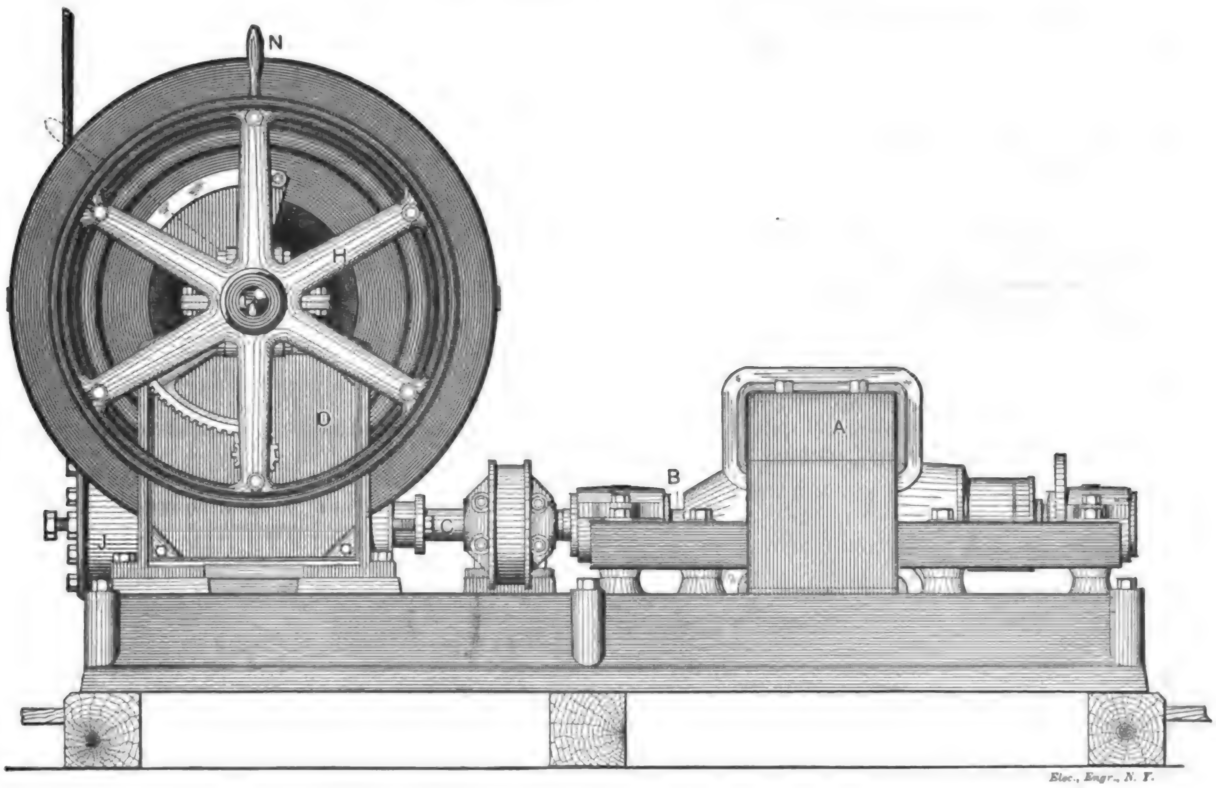

FIG. 5.—NEW ELECTRIC DOCK HOIST—ELEVATION.

To lower the load the operator moves the wheel H so as

to withdraw the drum I from the friction clutch E until the load begins to descend by gravity, and the speed of the descent is governed to a nicety by the handwheel. The positive connection between the handwheel and the drum is pointed out as an improvement over the more common one of having the drum forced out of contact by means of a powerful spring, for with the latter arrangement, there is always a possibility that the spring will fail to work; besides which the operator always has the spring working against him in applying the friction.

In addition to the apparatus described above, the American Electric Elevator Co. have a variety of others adapted to the numerous special cases which are met with in this class of work. Our readers will also be interested in the fact that the entire electrical work of the company is carried out by the Thomson-Houston Co., who, indeed, have practically turned over this entire department of their motor work to the Elevator Co.. All the non-electrical equipment is constructed by the Trenton Iron Works.

The Elevator Co. expect shortly to bring out a complete set of electric pumps to be used in connection with hydraulic elevators. We may add that Mr. G. H. Reynolds, the well known designer of the Reynolds-Corliss engine, is the general manager of the new company.

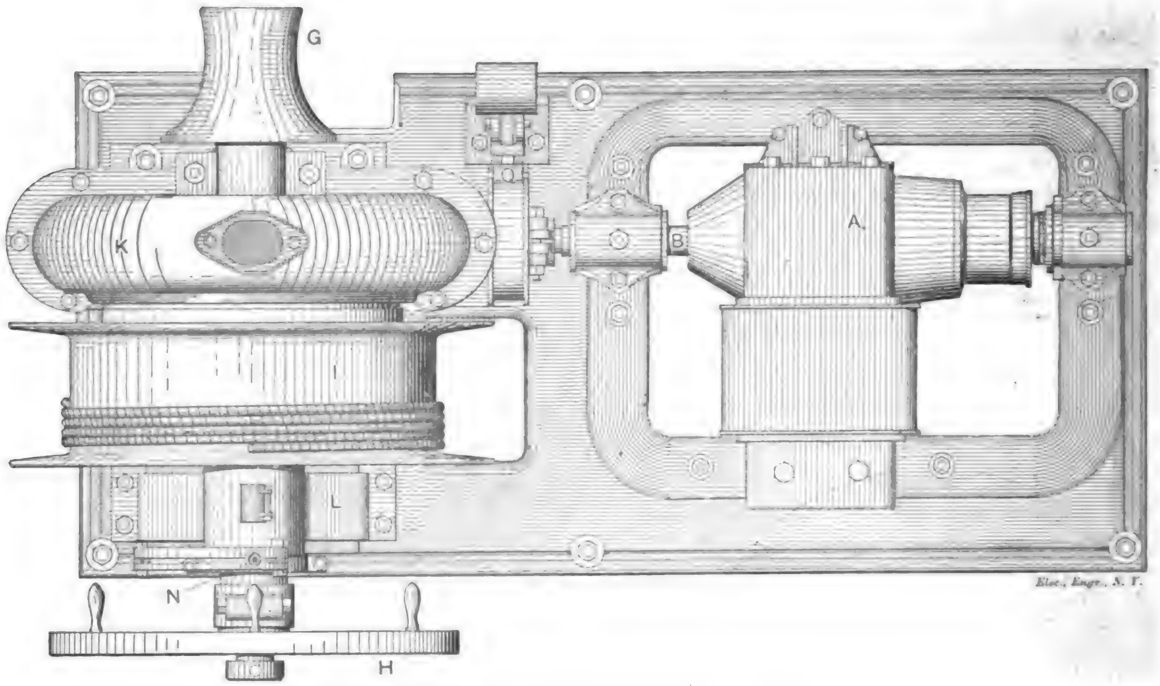

FIG. 4.—NEW ELECTRIC DOCK HOIST—PLAN.

THE JARMAN ACCUMULATOR.

IN connection with his system of storage traction, Mr. Jarman, of London, intends shortly to bring out a new storage cell. The active material is made of a mixture of hyposulphide of lead, acetate of lead, and a small quantity of litharge. This is cast in blocks and cut by a saw into squares. The carrier is made of an aluminum-lead alloy, cast round sets of suitably arranged blocks of the active material. This accumulator, he thinks, will be able to be made at half the cost of the present cells. The solution for the accumulator is an acid solution of alum—the double sulphide of alumina and potash.

Mr. Jarman has also perfected a connection lag which will not burn out. For this he takes a thick solid piece of copper rod, tinned on the exterior and tapped at both ends. This, when the ends are bent up, is cast round with lead and thoroughly embedded therein. The two ends form a double contact, on which nuts can be screwed down on the connecting piece with a lead washer so as to be secure even if one end fails.

SOME PRACTICAL METHODS FOR THE DETERMINATION OF INDUCTIVE RESISTANCES AND SELF-INDUCTION OF ALTERNATE-CURRENT INSTRUMENTS.—I.

BY CHAS. STEINMETZ.

SINCE the system of distributing electricity by alternating currents and transformers has found such manifold applications, terms formerly rarely used, such as self-induction, retardation, etc., have come into general use, and determinations of inductive resistances, and of coefficients of self-induction of measuring instruments, will soon be carried on as every-day work.

Now, the instrument mostly used for the determination of self-induction and mutual induction is the ballistic galvanometer. But not only is this instrument generally too delicate for the unstable floor of an electric factory, but it has the disadvantage that its readings very often cannot directly be applied for the alternating currents of our machines.

Another but more simple method for the determination of self-induction I shall give in the following, being a method which requires no other apparatus but an alternate-current voltmeter and ammeter—instruments available in any electric factory which is building alternate-current apparatus.

This method will be specially adapted and convenient when the self-induction is of a similar value, or even greater, than the true electric resistance.

A.—DETERMINATION OF THE COEFFICIENT OF SELF-INDUCTION OF AN INDUCTIVE RESISTANCE.

To find the coefficient of self-induction of an inductive resistance (induction coil, transformer, etc.) I connect the inductive resistance to be determined, in series with an alternating current ammeter, and connect an alternate current voltmeter in shunt to ammeter and inductive resistance.

Let $r =$ the electric resistance of the ammeter;
$l =$ the coefficient of self-induction of the ammeter;
$R =$ the true electric resistance of the induction coil, the coefficient of self-induction of which is to be determined;
$X =$ the coefficient of self-induction.

Now, in sending an alternating current of known num-

ber of periods through this circuit, the current in the inductive resistance, read by the ammeter, may $= c$, and the difference of potential around inductive resistance and ammeter, read by the voltmeter in the shunt circuit, may $= p$.

Then the E. M. F., or potential, lost in overcoming the resistance of the ammeter, is: $e = r\,c$; the potential, lost in the resistance of the induction coil: $E = R\,c$.

Therefore, the E. M. F., or potential, lost in overcoming the whole electric resistance of this branch-circuit,

$$e + E = (r + R)\,c. \tag{1}$$

The E. M. F., due to self-induction in the ammeter, is

$$e^1 = \frac{2\,\pi\,l}{T}\,c,$$

as well known; and in the inductive resistance:

$$E^1 = \frac{2\,\pi\,X}{T}\,c,$$

where T = time of one full period. Therefore, the whole E. M. F. of self-induction in this circuit:

$$e^1 + E^1 = \frac{2\,\pi\,(l + X)}{T}\,c. \tag{2}$$

The impressed E. M. F., p, measured by the voltmeter, is the resultant of these two E. M. F.'s: $(e + E)$ and $(e^1 + E^1)$. But, $e + E$ has the same phase as the current c. $e^1 + E^1$ lags behind c by a difference of phase of exactly 90°.

Therefore, the resulting E. M. F. of $e + E$ and $e^1 + E^1$ is found by the law of the parallelogram of E. M. F.'s as the hypothenuse of a rectangular triangle, of which the cathets are $e + E$ and $e^1 + E^1$.

Therefore,

$$p = \sqrt{(e + E)^2 + (e^1 + E^1)}.$$

Or, substituting (1) and (2),

$$p = c\sqrt{(r + R)^2 + \frac{4\,\pi^2}{T^2}(l + X)^2}, \tag{3}$$

Therefrom we get the coefficient of self-induction of the inductive resistance:

$$X = \frac{T}{2\,\pi}\sqrt{\left(\frac{p}{c}\right)^2 - (r + R)^2} - l; \tag{4}$$

and the angle ω of shifting of phase by this inductive resistance:

$$\tan\omega = \frac{E^1}{E}.$$

Or, from (1) and (2),

$$\tan\omega = \sqrt{\left(\frac{p}{c\,R}\right)^2 - \left(\frac{r + R}{R}\right)^2} - \frac{2\,\pi\,l}{T\,R}. \tag{5}$$

When we can assume the approximation, $r = 0$, we get:

$$X = \frac{T}{2\,\pi}\sqrt{\left(\frac{p}{c}\right)^2 - R^2} - l. \tag{4a}$$

$$\tan\omega = \sqrt{\left(\frac{p}{c\,R}\right)^2 - 1} - \frac{2\,\pi\,l}{T\,R}. \tag{5a}$$

And when $R = 0$, too,

$$X = \frac{T\,p}{2\,\pi\,c} - l; \tag{4b}$$

$$\tan\omega = \frac{p}{c\,R} - \frac{2\,\pi\,l}{T\,R}. \tag{5b}$$

And, if the self-induction l of the ammeter can be neglected also:

$$X = \frac{T\,p}{2\,\pi\,c}, \tag{4c}$$

$$\tan\omega = \frac{p}{c\,R}. \tag{5c}$$

which formula will be found sufficiently exact in very many cases.

Therefore, for approximate determination of the coefficient of self-induction, if r and R are small, it is not necessary to know the electric resistance at all, and the current in the alternating circuit is almost entirely independent of the electric resistance, depending only on the impressed E. M. F. and the self-induction. But the energy absorbed by this circuit will nevertheless be proportional to the true electric resistance, *i. e.*,

$$W = c^2\,(r + R).$$

For the determination of small electric resistances, I consider as the most reliable method, to send a continuous current through them and measure current strength and potential.

Let the continuous current in the circuit of ammeter and inductive resistance $= c_0$, the potential difference $= p_0$.

Then we have:

$$p_0 = (r + R)\,c_0; \tag{6}$$

and by substituting this in formulas (4) and (5), the coefficient of self-induction:

$$X = \frac{T}{2\,\pi}\sqrt{\left(\frac{p}{c}\right)^2 - \left(\frac{p_0}{c_0}\right)^2} - l; \tag{7}$$

and the shifting of phase by it;

$$\tan\omega = \frac{1}{R}\sqrt{\left(\frac{p}{c}\right)^2 - \left(\frac{p_0}{c_0}\right)^2} - \frac{2\,\pi\,l}{T\,R}; \tag{8}$$

or, if r and l can be neglected:

$$X = \frac{T}{2\,\pi}\sqrt{\left(\frac{p}{c}\right)^2 - \left(\frac{p_0}{c_0}\right)^2}. \tag{7a}$$

$$\tan\omega = \sqrt{\left(\frac{p}{c}\cdot\frac{c_0}{p_0}\right)^2 - 1}. \tag{8a}$$

This method has the feature of eliminating the resistance of the connecting wires, which, when the main-resistance is small, cannot well be neglected.

As an instance I shall give the following test made by me some time ago on an inductive resistance.

The resistance of the ammeter, an electro-dynamometer, with one turn as the movable circuit, was,

$$r = .01 \text{ ohm};$$

its coefficient of self-induction,

$$l = .000066 \text{ henry}.$$

The alternate current was produced by a small Westinghouse dynamo, giving 100 complete periods per second; therefore,

$$T = .01 \text{ second}.$$

The continuous current was derived from an Eickemeyer storage battery. Another storage battery was feeding the field of the alternator.

The readings were:

Continuous current:

$c_0 = 26.40$ amperes; potential: $p_0 = 1.742$ volt.

Alternate current:

$c = 16.62$ amperes; potential: $p = 31.01$ volts.

Therefore, the coefficient of self-induction, by formula (7):

$$X = .002902 \text{ henry};$$

and the electric resistance:

$$r + R = \frac{p_0}{c_0} = .066 \text{ ohm};$$

and since

$$r = .01 \text{ ohm},$$

therefore,

$$R = .056 \text{ ohm}.$$

The angle of shifting of phase, by formula (5), was:

$$\text{angle } \omega = 88.15 \text{ degrees}.$$

Formula (4*b*) gives,

$$X = .002904 \text{ henry}.$$

And (4*c*),

$$X = .002970 \text{ henry}.$$

In considering that the exactness of the test was limited by the inconstancy of the speed of the alternator, which, driven by an ordinary steam-engine, fluctuated by more than 2 per cent., the approximate figure, .002904 henry, and even .002970 henry, could be considered exact enough for most purposes.

THE NEW LAW CABLE HEAD.

The general introduction of underground cable work for telegraph and telephone purposes in our large cities has taxed the ingenuity of electricians to the utmost to devise not only suitable conduits but many minor devices

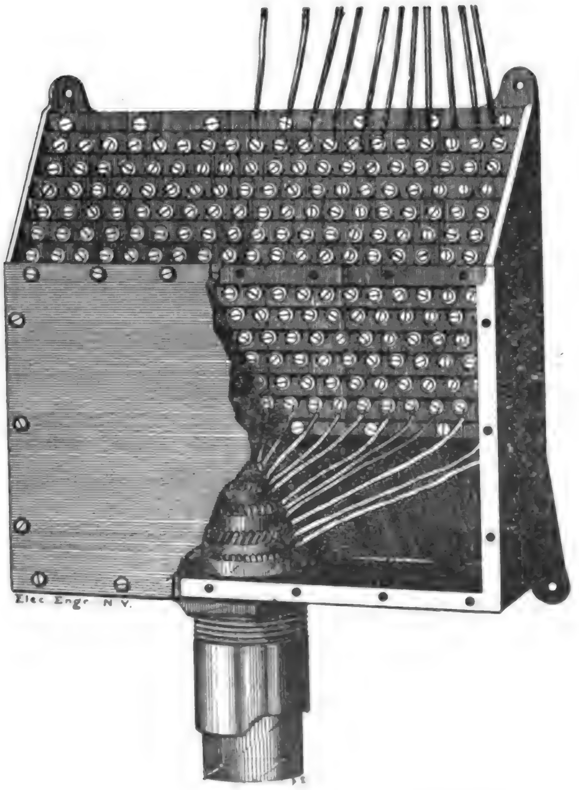

Fig. 1.—New Law Telephone Cable Head.

upon which the successful working of underground conductors depends.

In the case of telephone circuits, for instance, these are, as a rule, run underground in various lengths and distributed from poles. This requires the cable to be led from the conduit up the side to the top of the pole. Or, again, on entering the exchange from the conduits the cables are brought in and then carried to the distributing board. In either case, it is important that the arrangement be such that while the wires constituting the cable shall be easily accessible for making connections, the end of the cable proper shall be sealed so that moisture is entirely excluded.

Past experience has shown that the entrance of moisture for but a few feet from the end of a cable reduces the insulation enormously, and may completely vitiate good service which might otherwise be obtained from the same cable in proper condition.

The effort to obtain a device which shall afford ready

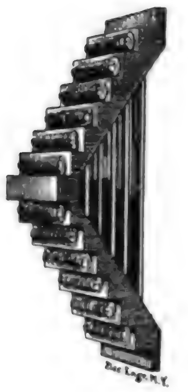

Fig. 2.—Interior View of Law Cable Head.

access to the conductors and leave the cable intact has resulted in a variety of what are known as "cable-heads." A recent departure in this direction, and one which merits attention on account of its simple and ingenious construction is that invented by Mr. W. H. Balsby, of the Bell Telephone Co., of Philadelphia, now being made by the Law Telephone Company, of this city. A large number of these heads are being installed in connection with the "Law" switchboard in Philadelphia.

The cable head, which is illustrated in perspective in the engraving, Fig. 1, consists of a cast iron box, the back of which is extended beyond the sides. Mounted upon this back is a hard rubber frame upon which the terminals are fixed, each set being raised a short distance above the other and sloping away from each other, as clearly shown in Fig. 2. It will also be noted that each terminal on one side of the slope is connected by a brass strip with a corresponding terminal on the other slope.

By the construction adopted one set of these terminals is enclosed by the sides of the box into which the cable leads and to which the cable conductors are attached.

After the connections with the cable conductors are made, the box is sealed by a cast iron cover and screwed down upon a rubber gasket making a perfect joint. In this way all moisture is excluded. This leaves the upper tiers of terminals free for connection to the distributing wires.

The hard rubber frame upon which the terminals are mounted evidently leaves an air space between it and the rear wall of the box, and to prevent the entrance and accumulation of moisture, as well as to thoroughly insulate the brass connecting strips from one another, the entire space is filled up with black "battery wax." This is applied by pouring it in while hot through a hole in the rear of the cast iron box.

The cable head illustrated is designed for 119 circuits and is exceedingly compact while at the same time so constructed that the wires can be easily got at.

NUMBER OF TELEPHONE SUBSCRIBERS ABROAD.

In Germany the telephone subscribers are estimated to number 31,325; in France, 9,487; in Great Britain, 20,426; in Russia, 7,585; in Italy, 9,183; in Austro-Hungary, 4,200; in Spain, 2,218; in Portugal, 890; in Switzerland, 6,570; in Belgium, 4,674; in Netherlands, 2,872; in Denmark, 1,837; in Sweden, 12,864; in Norway, 8,390.

ELECTRICAL ENGINEERS.

FRANCIS R. UPTON.

THE subject of this biographical sketch was born July 26, 1852, at Peabody, Mass., of an ancestry and stock New England in every branch for over 200 years. His father, a leading business man in that place, was a friend of Peter Cooper and George Peabody, and his mother is a public spirited woman, for many years at the head of various local charities. Mr. Upton's education began in Phillips Academy, and Chauncey Hall, Boston, and continued in Bowdoin College, where he was very active in undergraduate matters, being editor of the college paper, commodore of the Boat Club, etc. A speech delivered at the time of his graduation attracted notice and was quoted in several newspapers. His education, so far as American training went, was completed at Princeton, where he took the degree of M. S.

Being devoted to Physics, and feeling the need of supplemental work, Mr. Upton then went to Germany and spent a year studying in the laboratory at Berlin, under Helmholtz. While there, he earned money for the first time in a somewhat singular and striking manner. When going to lunch in the middle of the day, he noticed the Emperor William's carriage being driven away rapidly from a fast gathering crowd. Then policemen came out of the throng dragging the man Hodel, who had attempted to take the life of the Emperor. Young Upton naturally made inquiries about the matter and soon picked up enough information to satisfy him that he had happened upon a very important piece of news. Possessing himself of the facts, he jumped into a vehicle and rushed off to the Central Telegraph office, writing a telegram to the *New York Herald* as he went. Of course there were difficulties in the transmission of political intelligence, but by golden persuasion the telegram was put through. It was the first news out of Berlin of the occurrence, and the first to reach America. Mr. Upton made $90 over expenses by this little display of his ability to earn a living as a newspaper man.

Francis R. Upton.

On returning to America, Mr. Upton at once sought out practical work, and in 1878 entered the employ of the Gold & Stock Telegraph Company, to learn the telephone business. Through the friendship of Howard R. Butler, to whom the position had been offered, he became associated with Mr. Edison, as his mathematician, to calculate various electrical problems, and thus entered an entirely new field of work, in which not only mathematics but every other accomplishment and quality were needed. He was with Mr. Edison during the memorable experiments in electric lighting at Menlo Park, worked hard day and night, and, together with Mr. Charles Batchelor, became interested with Mr. Edison in his inventions on the basis of a percentage of the profits. It was about this time also that Mr. Upton contributed to the old *Scribner's Monthly* that highly interesting article on the electric light, which has since become historical and has perhaps been more often reprinted and referred to in litigation proceedings than any other article of the same kind. It is worthy of note that the first carbon filament lamp burned outside the laboratory was lighted in Mr. Upton's house at Menlo Park, as, by luck, the line to his house was the first to be finished. It also fell to Mr. Upton's lot to place the first two of the present type of high resistance lamps in multiple arc across the circuit from a low resistance armature. This showed that either lamp could be lighted without making the other flicker appreciably.

In 1881, Mr. Upton took charge of the Edison Lamp Factory, and he has remained in direction of that important branch of the Edison industries down to the present time, witnessing an enormous development of the business, and initiating and superintending many changes looking to the perfection and cheapening of processes. Mr. Upton has in the meantime been interested in electrical and business enterprises and has himself brought out various inventions.

Owing to the pressing nature of his professional engagements, Mr. Upton has had little time for public engagements, but he has served actively as Vice-president of the American Institute of Electrical Engineers, and been invited to stand for election as President.

ELECTRIC TRACTION IN BUDAPEST.

THE Budapest Electric Railway, which was built by Messrs. Siemens and Halske, on the underground-conductor system, has proved a decided commercial success. Some 20 cars run on the line, the length of which is 7.9 kilometres. The line passes through the most fashionable streets of the town. During the month of April, 337,200 passengers were carried, being at the rate of 42,684 per kilometre of line, and 16,860 per car. The horse lines in the same town, which have a total length of 45.6 kilometres, and 329 cars, carried in the same month only 33,074 passengers per kilometre, and 4,854 per car. The earnings for the month were, for each electric car, $500; for each horse car, $175. Since the date of this return, it is said that the differences in favor of the electric lines have been still further increased. The greater speed attained by the electric cars (11 miles per hour, as against 5) is no doubt responsible to a great extent for this flourishing state of affairs. The Town Council has also recently given permission for the building of a small electric line on the Zipernowsky single track system. An experimental length of 3 kilometres, from Messrs. Ganz's factory to Steinbruch, is at present being laid down. In spite of the disaster at Florence, caused by the drunken driver, and the general slowness in adopting electricity, there seems reason to believe that, overhead systems being in disfavor, the conduit and storage methods are about to enjoy a large measure of prosperity in Europe, although it may be doubted whether electric railway development there can catch up to that already seen in America.

The science of electrical engineering is now recognised as one of the most necessary practical sciences of the world.—Lieut. B. A. Fiske, U. S. N.

ELECTRICAL ENGINEERING AND ELECTRICAL INVESTMENT.

MORE emphatic testimony to the pecuniary value of good electrical engineering has not been given anywhere than will be found in Mr. B. E. Sunny's thoughtful and suggestive paper, read before the Chicago Electric Club and printed in our columns this week, on the central lighting station as an investment. The financial questions connected with electric lighting are well worthy of consideration by themselves, and have their own aspects; yet, after all is said and done, it is striking how they narrow down generally to points that interest very directly the electrical engineer.

Who can deny, for example, Mr. Sunny's assertion that "the face of the earth is dotted with lighting properties which were poorly planned, badly built, and indifferently managed;" and that "we can all point out a long list of stations located in cellars, basements, abandoned barns, and cheap wooden structures," with an equipment cheaper, if possible, than the buildings they run in? It is only too true; and it is equally true that in every one of these instances the electrical engineer was conspicuous by the contempt in which he was held whenever he ventured to propose an improvement.

Another class of stations referred to by Mr. Sunny is that in which it has been necessary almost from the start to launch out in a series of extensions to keep pace with the business, until at last the station with its varied equipment has come to resemble an electrical museum, a place where the absence of "system" is shown by the presence of too many of them. Here again the low regard of the practical layman for the electrical engineer is evident, for while the engineer has short-comings of his own, he is generally influenced by his training in favor of doing a thing largely, broadly and well, and against practices that prevent him from detecting just where undue expenses arise, or from operating with the best economy. No one will be quicker than the electrical engineer to endorse Mr. Sunny's remark that "the whole secret of dividend paying enterprises is in their ability to run reliably, every day and every year, without subjecting the machinery to excessive and abnormal demands and in the avoidance of rebuilding or abandoning the original investment."

One thought that comes up on reading Mr. Sunny's paper is that the central station as an investment in many places will yield better returns than it has by being given all the work it can do, so that its load line is a pretty straight one the day and night through. To establish a number of little stations in a small, or even a large town is a mistake. The labor item is among the heaviest, so that the distribution of this charge over a variety of services by operating them all under one management is distinctly in the direction of higher profit. There is a point at which the cost of management of such a combined plant again cuts down the saving, but in hundreds of instances it would pay to throw all the electrical services of lighting, stationary motors, and railway work into one set of hands.

We have just mentioned stationary motors. Here is a means of increasing the return on the central station investment that, to our certain knowledge, has not even been touched by large numbers of managers and superintendents. Few of them have, so far, made a systematic canvass of their territory to discover how much power current they could sell, and how many motors they could place. Yet these motors, all the year round, are a source of income, and in summer time, when lighting patronage drops off, they come in as an admirable means of keeping the income up to a decent average. The study of ways for increasing the earning capacity of a station has not yet been reduced to a fine art.

Then, stations ought to have more measuring instruments than they now possess. So long as a station is simply running some arc lamps, strung along on a clothes line, the necessity of ammeters and voltmeters may appear small; but the moment a station begins to discharge its mission and live up to all its opportunities, its managers must know its exact output, just as they check its exact income. It seems the easy way to sell current on a flat rate, but there is more money in getting a definite price for definite service. As Prof. John Trowbridge once said: "The difference between the scientific man and the unscientific man is, that one makes accurate measurements, while the other is satisfied with general knowledge, and does not ask 'How much.'" The odds are all in favor of the station that weighs its coal by the scale and sells its current by the meter.

PRACTICAL EXPERIENCE WITH ELECTRIC CARS.

The report on electric motive power made by Dr. W. L. Allen, at the Street Railway Convention, and printed in our last issue, deserves attention as coming from those who have had practical experience with both horse and electric railway work, and because the report is written with an evident spirit of fairness. The hints which are thrown out as to the direction in which improvements are desirable concern the mechanical as well as the electrical engineer. While the electric railway operator may learn, and has learnt, much from the electric light station operator, the former's work differs in many important respects from that of the latter and especially with regard to the character of the load. The extremely violent fluctuations in load met with in railway work make the choice of a proper type of engine one of considerable difficulty. In the matter of the present modes of construction the report points out some changes which are desirable in the material employed in effecting a good ground return, galvanized iron rail bonds and return wire being suggested in place of the copper at present employed. We think the experience which has dictated this suggestion sufficient to warrant its general adoption, so far, at least, as bare copper wire is concerned. On the subject of repairs to motors and gear generally it cannot be denied that these appear to be heavier than seems necessary, and their reduction is the most important problem which confronts the electric railway engineer to-day. Some of the means by which this can be effected have already been pointed out by us; it will be noted as significant, however, that the number of cars disabled electrically was far less than those mechanically incapacitated. In spite of these short-comings, however, which are destined to be remedied in a short time, the report is an unqualified endorsement of electric motive power; and it may be added that the testimony of many present went to show that the general average for repairs is enormously below Dr. Allen's figure on a pioneer plant.

LOWER PRICES FOR INCANDESCENT LAMPS.

In commenting recently upon the relative positions occupied by the metals in the electric arts at the present day, as compared with but comparatively few years ago, attention was drawn to the fact that the cost of one item alone in the manufacture of the incandescent lamp, namely, that of the platinum leading-in wires, had increased from 3 cents to 8½ cents. It might by some be supposed, therefore, that on the whole the cost of manufacture of incandescent lamps had been materially increased; but a glance at the past history of the ruling prices for incandescent lamps will show that, on the contrary, the increased number of lamps made and used during the past few years has brought about a constant reduction in the price. Many of our readers will remember that when the incandescent lamp was first introduced the price ranged in the neighborhood of $1, and remained so up to 1887. In that year a reduction was made bringing the cost to consumers down to 85 cents. This was again reduced during 1889 to 75 cents and somewhat below that even; but we are free to say that few would have anticipated that the present year would see 16 c. p. incandescent lamps selling at 44 cents. Yet such is now actually the case.

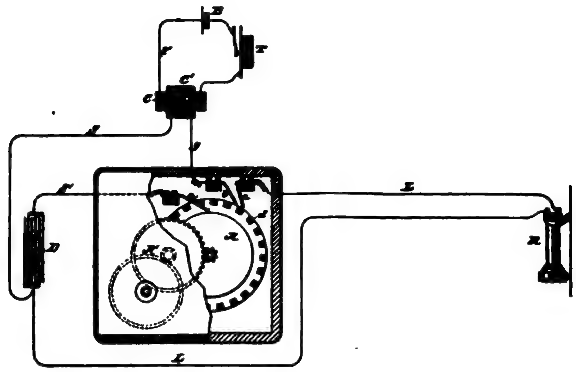
The question might naturally be asked, how such a considerable reduction is possible, and whether it still leaves a fair profit to the manufacturer. It is safe to answer the latter question in the affirmative, and if we seek for the causes which have made this reduction in the price possible, we must look to the improvements which result from experience in the manufacture of any article in large quantities. Thus as time has passed since the beginning of the art, probably the most expensive part of the lamp, if we may be allowed to use the expression, the vacuum, has been largely reduced in cost of production by improvements in exhausting apparatus, pumps, etc. Again, the introduction of machinery for cementing the filaments to the leading-in wires and for other purposes has not only reduced the cost of manufacture directly but indirectly, on account of the reduced amount of breakage, which, with the old methods, involved a considerable percentage of loss. There can be no question that this considerable reduction in the price of incandescent lamps will lead to the manufacture and consumption of an increased number of lamps. It will without doubt also be followed by a notable change in the methods of operation of many central stations and perhaps private plants. With the cheaper lamp, it is evident that the life is not as important a factor in the cost of operation as formerly; so that lamps may be run at a higher candle power and be more economical in the use of current than was desirable in the past. There is, therefore, every reason to believe that the lowering of the price of incandescent lamps will not only give us more of them, but will tend to brighten them, and this again will lead to greater demand for them. Such reasons were doubtless the determining ones with the manufacturers in making such an appreciable reduction in price at a moment when almost everything has an upward tendencyin the market as the result of the new tariff.

The U. S. Electrical Corps.

Some months ago, Mr. Frank Stockton, in one of his characteristic stories, told how a great sea war waged by this country was carried on and won almost wholly by novel electrical apparatus and appliances. Wild as his fiction seemed to many people, the novelist did but mildly exaggerate the rapidity with which electricity is coming to the front as an agency in warfare. The fact is, the modern army or navy officer who is not as expert in electricity as in navigation or in military tactics is only half trained. This truth has been seen by Lieut. Bradley A. Fiske, who, in his excellent paper read last week before the New York Electrical Society, advocated not only that the electrical education of officers should be thorough and complete but that an electrical corps should be formed which could be called upon in case of the outbreak of a war to assist in handling ships and forts with the electrical devices and machinery already so indispensable and multiplying daily. The idea is a good one, and meets a condition of things that, unless dealt with in some such manner, might result in all the injustice and reproach recorded in the history of the U. S. Military Telegraph Corps. That body, a purely voluntary one, rendered great services during the war, yet it has never met with any recognition, even of a merely formal nature.

McDONOUGH'S NEW TELEPHONE SYSTEM.

Mr. J. W. McDonough, one of the early inventors in the field of telephony, has just received a patent for an elaborate and ingenious method of transmission. He has sought to produce an effective transmitter, particularly applicable to long-distance lines, employing a continuous undulatory current in the local or primary circuit, includ-



McDonough's New Telephone.

ing the usual induction coil, and an intermittent current in the line leading to the receiver. The accompanying diagram illustrates the principle and method of operation of Mr. McDonough's method of transmission; L, L, representing a main line connected to an ordinary receiving telephone R. T is a transmitter acting on the usual microphone principle, with induction coil and battery in the local circuit.

The peculiar feature of the system consists in the use made of a condenser D and the metal disc A included in the secondary or line circuit. The periphery of the wheel or disc, which is rapidly rotated by a train of wheels or other mechanism, is serrated, having insulating blocks between the teeth. Two contact-springs *b c* bear upon the periphery of the wheel, and a third contact-spring *a* bears upon the side of the disc or upon the circular shoulder, in the manner illustrated. The contacts *b* and *c* are never in contact with the metal at the same time, but the spring *a* being always in contact with the disc, is brought alternately into connection with the springs *b* and *c*. One end of the circuit S, including the secondary C′ of the induction-coil, is connected to one of the contact-springs, *b*, and the other end to one of the terminals of a condenser D. Similarly the ends of the circuit L are connected, respectively, to the same condenser terminal and to the other contact-spring *c*. S′ connects the opposite terminal of the condenser with the contact-spring *a*.

In operation, the disc A is set in rapid uniform rotation. The secondary currents from the induction coil do not pass to the receiver, but flow into the condenser whenever the spring *b* is in contact with the metal teeth of the disc. When the spring *c* comes in contact with one of the metal teeth, the condenser is discharged into the main line.

According to Mr. McDonough, the time occupied in charging the condenser is that required for one of the metal teeth of the disc to pass under the spring *b*, and the strength of any charge will depend upon the character of the movement taking place in the instrument T; but the time required to discharge the condenser is much less than that occupied in charging it; the discharge being practically instantaneous whatever the strength of the charge, while the charging is gradual and consumes an appreciable period of time. It would follow that the current in line L would be made up of a succession of sharp, quick, and absolutely-distinct impulses formed by the condenser-discharges. At the same time it is found to reproduce in the receiver R the words or sounds directed into the transmitting instrument T.

A PRESSURE REGULATOR FOR STORAGE BATTERY PLANTS.

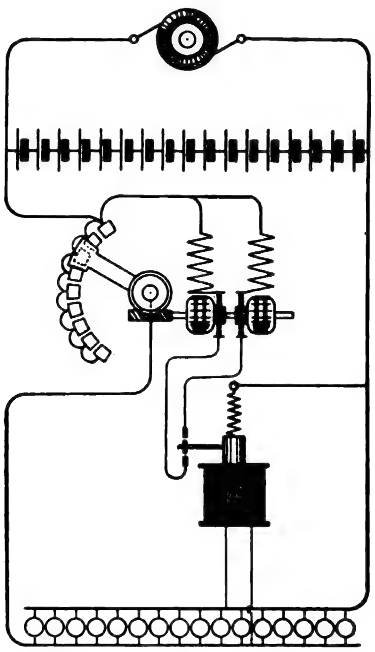
BY E. T. BIRDSALL, M. E.

In the October 1 issue of The Electrical Engineer there was described a method of regulating the pressure on the lamps in a storage battery plant. As the method somewhat resembles one devised by me, I give below a description of the latter. In the drawing, everything is shown diagrammatically; in the actual machine I would use a large high resistance relay operating mercury cup contacts.

Two motors are shown, but the contacts can be arranged to operate the rheostat with one motor. The rheostat contact arm should also break the respective motor circuits when the pressure, by any accident, cannot be controlled by the range of the rheostat.

It will be seen that this is a much modified form of the Goolden and Trotter governor, the motor or motors furnishing the power for operating the rheostat instead of the shaft usually employed, but which in private plants is seldom available. In the present case, the apparatus was designed for the engine and batteries, which were located several hundred feet from the lamps and rheostat and in separate buildings.

It will be seen that when the pressure on the lamp mains is at the proper point neither motor is in circuit. If the pressure for any reason increases, or diminishes, the



Birdsall's Method of Regulating Accumulators.

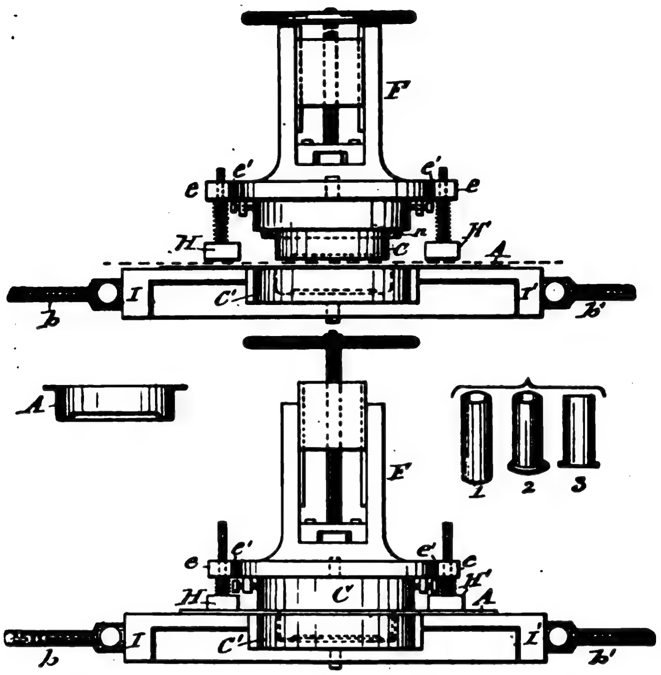
corresponding motor is put in circuit and the arm of the rheostat moved until the pressure on the lamp mains is once more at the proper point. It will be noticed that this arrangement requires no auxilliary batteries.

A RADIOMETER PHOTOMETER.

The well-known radiometer of Mr. Crookes has been adopted as a photometer by MM. Seguy and Verschaffel. The rotating disc is not pivoted, as in the Crookes apparatus, but suspended by a silk fibre and fitted with a scale and needle, after the manner of Coulomb's torsion balance. A glass containing a solution of alum is placed between the light to be measured and the rotating disc, so as to cut off the heat rays. The light rays in falling on the disc cause it to turn round through a certain angle depending on their intensity. Thus one light can be measured after another. The apparatus is stated to be so sensitive as to indicate the one-hundredth of a standard candle.

DEWEY'S ELECTRICAL SHEET METAL FORMER.

The introduction of electrical welding has served to direct the attention of inventors to the employment of electricity in other departments of metal-working. Among others, Mr. Mark W. Dewey, of Syracuse, N. Y., has produced a number of inventions in this line. One of his latest is an apparatus for forming or shaping sheet metal, which is shown in the accompanying illustration.



DEWEY'S METHOD OF FORMING METALS BY ELECTRIC HEAT.

The machine is applicable to the forming of metal objects from sheets when heat is required to soften the metal, and particularly when successive and graduated pressings are necessary. In such cases, when ordinary presses are used, the metal becomes hardened after each pressure, and requires removal for successive heatings and annealings. In many classes of work the entire operation can be completed by Mr. Dewey's method without removing the sheet of metal, or the blank, from the press till the article is finished.

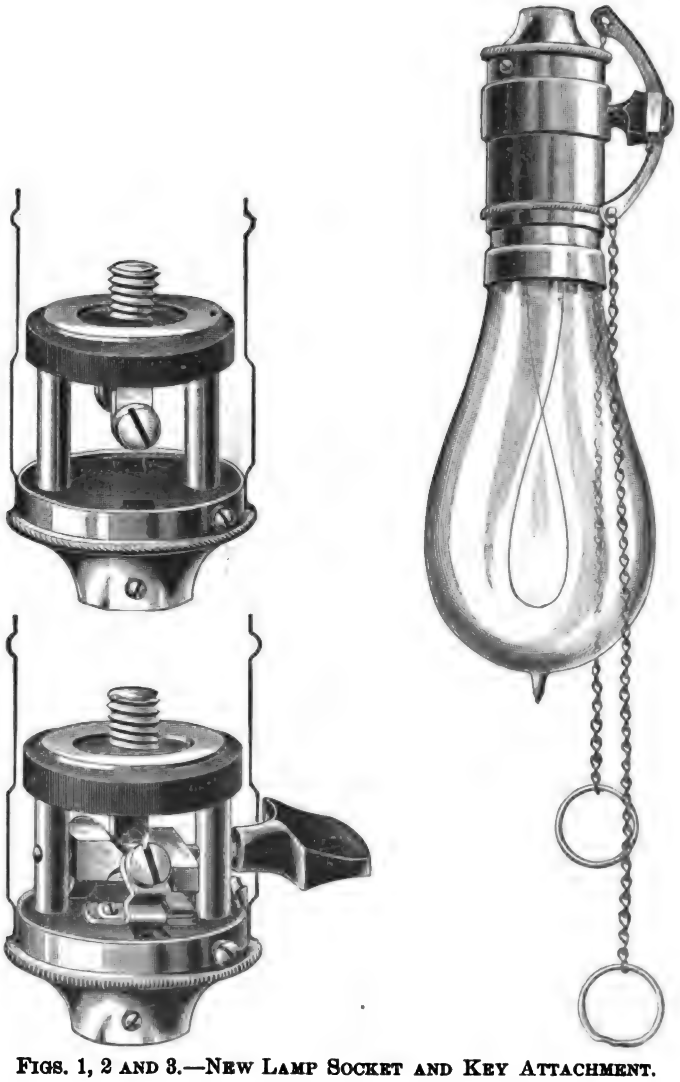
The method is here shown as applied to a hand press, but it is obviously equally applicable to machine presses. F F represent a screw press in two positions, with die and mold C and C'. A is a sheet of metal or a blank to be treated. When in operation, the yielding clamps, H and H', carried by the follower of the die C descend with it and press the sheet or blank firmly against terminals I and I' of the conductors *b* and *b'*. The current thus allowed to flow through the blank heats and softens it to the degree required to produce, under the proper pressure, an even distribution of the metal between the die and mold.

The clamps are either faced with non-conducting material, or the supporting bars E are insulated from the plunger at E'. The base of the press is insulated from the terminals. Mr. Dewey deems it advisable to face the die and mold with non-conducting material, or to make them entirely of such material. It will be seen that with suitable current regulation the sheet or blank operated upon may be kept at any desired temperature during the entire operation, or that the temperature may be varied or graduated for different stages of the work.

BROOKLYN, N. Y.—There has been filed in the county clerk's office, Kings County, the consent of 13,203 shares (out of a total of 15,000 shares) of the stock of the Edison Electric Illuminating Co., of Brooklyn, for the purpose of effecting a mortgage of the company's property for the sum of $2,000,000 to the Franklin Trust Co., Brooklyn.

NEW LAMP SOCKET AND SOCKET KEY ATTACHMENT.

We illustrate in the two accompanying engravings, Figs. 1 and 2, the new form of lamp socket now being manufactured by the Bryant Electric Company, of Bridgeport, Conn., a company which has become well known as the manufacturer of the Bryant switch. The cuts show a keyless socket, which requires no explanation, and the key-socket, which has been designed with especial reference to durability, simplicity of parts, good contact and quick make and break. The key is rectangular in section, and, as shown in the cut, the current is shut off, but when turned a quarter round comes into rubbing contact with the spring piece, forming one terminal, on the base of the socket. The action of the key is positive, the upright spring at the back pressing on the square surface preventing the key turning too far or not far enough. We illustrate also in Fig. 3 the Lewis attachment, manufactured by the same company, a very useful contrivance, where lamps are suspended too high to reach by hand conveniently. The attachment is the invention of Mr. Fred. Lewis, electrician of the New Haven Electric Company.



FIGS. 1, 2 AND 3.—NEW LAMP SOCKET AND KEY ATTACHMENT.

STARTING THE "SHORT" CARS IN ROCHESTER.

A very successful start was made on the lines of the Rochester Railway Co., a few days ago, of the Short electric system. The cars are very handsome and run extremely well. There will be 18 cars on the Lake Avenue line. The Sophia street line will be the next to be operated by electricity; then St. Paul street and then Main street.

THE LINEFF ELECTRIC TRAMWAY.[1]

BY GISBERT KAPP, M. I. E. E.

When we have to convey current to the car by means of a conductor, this conductor must run along the line either above or below ground. In the former case it may be a wire suspended along poles, or a rail resting on insulating supports close to the ground, or it may be formed by the tram-rails themselves. All these arrangements have been tried, but it is needless to say that they are inadmissible for urban and suburban lines in this country. With such lines the first condition must necessarily be to place the conductor underground. As usually carried out, this system involves the adoption of a slot in the road through which passes a slipper or contact-shoe attached to the car, and which establishes electrical connection between the conductor underground and the motor on the car. The system is, as experience shows, practically workable; though the slot, which must admit dirt and moisture into the underground channel and may to a certain extent inconvenience other traffic, is a disadvantage. This disadvantage may, perhaps, not be very great, considered from a purely technical point of view, but such as it is, it has to be taken into account. If we consider the question from the point of view which will naturally be taken by the local authorities and the public whom they represent, we shall come to the conclusion that the slot is a great disadvantage to the general traffic, and that its abolition is highly desirable. How to abolish the slot and yet retain electrical connection between the underground conductor and the motor on the car is the problem which has been solved in the system of electric tramway I am about to describe.

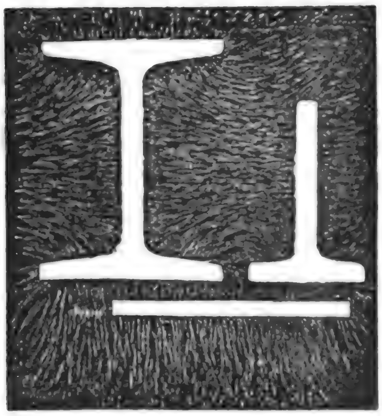


Fig. 1.—Magnetic Circuit, Lineff Railway System.

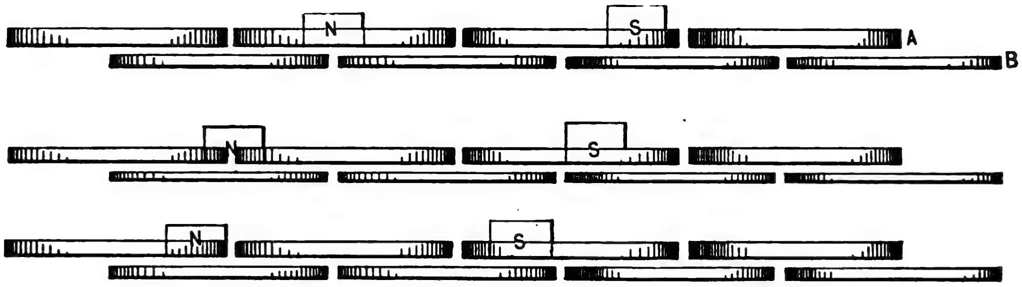
The conductor consists of bare copper strip or cable, and of iron strip. The latter is galvanized so as to protect it from rusting. It lies on the copper conductor, and both are enclosed in a sealed channel formed of asphalt. The copper conductor rests upon the bottom of a trough made of a succession of glazed tiles, and the cover to this trough is formed by the lower flanges of iron rails arranged in short sections so as to be insulated from each other. The head of one rail reaches up to the surface of the road; the head of the other is cut off, and this rail is, therefore, completely buried in the asphalt. The surface rail, which may be arranged alongside one of the ordinary tram rails, or in the centre of the track, is in electric and magnetic contact with an electro-magnet carried under the car. This magnet runs upon the surface rail on wheels, which form its north and south poles. The distance of the wheels is greater than the length of a section of insulated rail, so that successive sections become oppositely magnetized. This causes the iron strip immediately below the magnetized region to be attracted upwards and thus come into contact for a length of several feet with the under side of the two sectional rails. At the same time the iron strip to both sides of this region remains in contact with the copper conductor, and forms thus an electrical connecting link between the copper conductor and a few sections of insulated rail under the car. The current passes from the surface rail through the body of the electro-magnet (which is insulated from the body of the car) into the motor, and finally into the ordinary tram rails and earth in the usual manner. The electro-magnet is energized by a shunt current obtained from the main conductor, but to provide for the possibility of dropping the strip from some unforeseen cause there is placed on the electro-magnet a third thick wire coil, which can at all times be energized by two storage cells carried on the car, and thus the strip can be picked up and the main circuit again established if it should have been accidentally interrupted. I may, however, at once state that during some tests which I made on an experimental line of this kind, and which lasted over several days, there has been no need for the picking-up battery, as the current was never lost. I shall say a few words about the results of these tests presently; but before entering upon the practical results I would draw your attention to a question of both practical and theoretical importance—namely, the way in which Mr. Lineff makes use of magnetic lines of force to effect the attraction of the iron strip. It might, perhaps, be thought that the most direct, and therefore the best, way of utilizing the lines of force would be by one single line of sectional rail through which there would be longitudinal magnetic flux corresponding with the fore and aft position of the poles and attraction of the strip at every gap between two sections. Experiment has, however, shown that this apparently direct way is by no means the best way, and that far more satisfactory results can be obtained by arranging a more roundabout course for the lines of force. This is attained by the employment of the subsidiary or buried rail, the gaps in which do not exactly correspond with those in the main or surface rail, but are shifted forward by a certain amount. In consequence of this arrangement, the buried rail acts as a kind of magnetic bridge (*see* Fig. 1) to successive portions of the surface rail, and this action takes place in two ways, one direct and the other indirect. The direct way is longitudinal, and does not affect the strip at all. The indirect way is both longitudinal and transverse, the latter passing several times through the strip. The buried rail is a rather imperfect bridge to the lines of force traversing it longitudinally, because its magnetic resistance in that direction is great, but this rail forms a very efficient bridge for lines passing through it transversely, owing to its lower magnetic resistance in that direction, which includes the strip. This flow of magnetic force transversely is, therefore, that which effects the attraction of the strip, and may be represented as a series of magnetic stitches passing to and fro between the two sets of rails and the strip.

This action will be understood by reference to the diagrams Figs. 2 to 4, which represent the magnetic condition of the rails for three positions of the electro-magnet. A represents the surface rail, and B the buried rail. The energy provided to attract the strip is only 180 watts, or equivalent to that consumed by three glow lamps; and this I have found sufficient under all circumstances. Fig. 6 is a cross-section, Fig. 5 a plan, and Fig. 7 a longitudinal section of the line and electro-magnet.

The experiments to which I have referred were undertaken to see whether the whole system is practically workable. The first question which presented itself was whether the wave in the strip running along at the speed of the car was likely to induce subsidiary waves either in front or behind the car, whereby exposed sections of the surface rail might become charged and be a danger to ordinary traffic. To investigate this matter a pilot brush was fitted to the car at different distances

1. Abstract of a paper read before the British Association in Section G, Leeds, September, 1890.

from its centre, and connected with an electric bell. The pilot brush was so placed as to slide over the surface rail, and if on a charged section the bell would sound. It was found that the charged region was at all speeds considerably shorter than the length of an ordinary car. Contact tests were also made over the whole line at greater dis-



Figs. 2 to 4.—Diagrams of the magnetic condition of the rails for three positions of the Electro-magnet

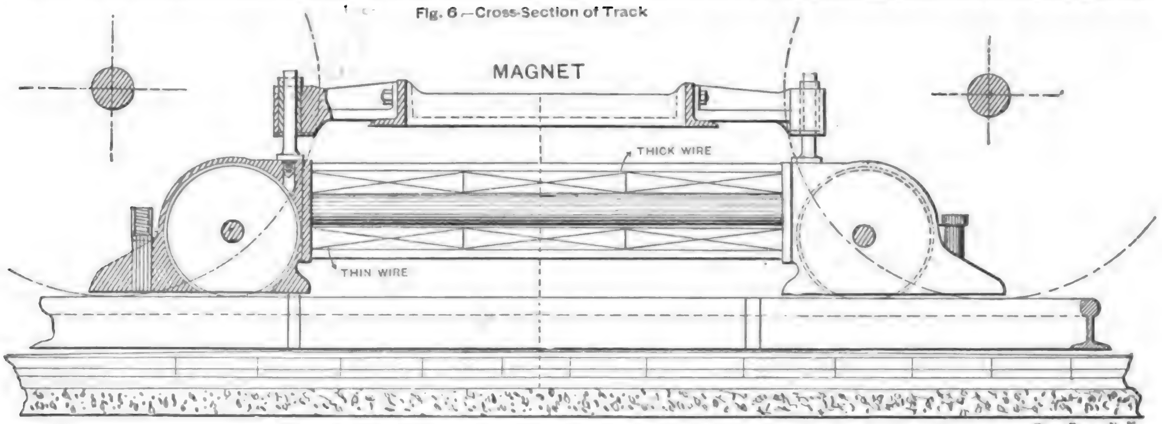

Fig. 7 Longitudinal Section of the Line and Electro magnet.

Elec., Engr., N. Y.

The Lineff Electric Railway Conduit System.

tances from the car than the pilot brush could reach, and in no case have I found an exposed section of rail charged. There was, further, the danger that with a dry and dirty line the collection of current might be accompanied by sparking, which would frighten horses; but this difficulty was overcome by fitting wire brushes to the pole-shoes of the electro-magnet.

An important point in all conductor systems of electric tramway is the energy spent in collecting the current. With the overhead wire system this is very small and practically inappreciable. With an underground system it is naturally larger. In the first system elaborated by Mr. Lineff, the flexible underground shoe with its trailing rope required from 20 to 48 lbs. for its propulsion. In the series system the "arrow" rubbing through the "spring jacks" must necessarily also require the application of considerable force; but I have no figures on this point. In the new Lineff system the electro magnet rolls on the surface rail, and the propelling energy is consequently small. I am informed by Mr. Lineff that he has succeeded in reducing it

to 210 watts with the magnet energized. The whole power spent in collection of current is therefore about half a horse power.

The insulation resistance of the conductor was tested both by the bridge method (48 Leclanché cells, Post Office pattern bridge, and mirror galvanometer), and by passing the leakage current through a voltmeter, and the two methods gave fairly accordant results. The highest reading I recorded by the voltmeter test, when the full pressure of 230 volts was on the conductor, was 5,400 ohms, and the lowest 3,550 ohms. From these figures it appears that the average insulation is 186 ohms per mile.

To ascertain the surface leakage I also applied the voltmeter test and found the following insulation resistances of three charged sections of magnetic rail. With the line clear and moist, 4,183 ohms; with the line very wet and covered with mud and horse droppings, 980 ohms. Taking 2,000 ohms as an average, the loss of power at 300 volts by surface leakage per car amounts to 45 watts.

The mechanical strength of the line was tested by running a steam roller over it in various directions, under which treatment the line suffered no damage whatever.

THE CIVILIAN ELECTRICIAN IN MODERN WAR.[1]

BY LIEUT. BRADLEY A. FISKE, U. S. N.

I BEG to propose for your consideration this evening a plan by which, in time of war, all the electrical resources of New York, both in supplies and in men, will become at once available for the defense of the country and the city.

It is well known to all here that electricity has come into use as one of the great factors in warfare, both on sea and shore, not as an adjunct merely, as for lighting ships and forts, but as a vital element in the handling of weapons in actual battle, and in the construction of new instruments which accomplish things heretofore impossible.

I desire to recall to your recollection a few of the most important uses to which electricity is now put in warfare, to indicate some of the probable paths of future development to show that it would be impossible for our regular navy and army to adequately handle the vast electrical work that would have to be instantly done in time of sudden war, and to suggest a plan for coming to their assistance.

The science of electrical engineering is now recognized as one of the most necessary of the practical sciences of the world. It stands out as distinct and defined as the science of medicine, or the science of astronomy. It enters into thousands of the departments of daily life, but into no other department is it used in so various and important ways as in warfare. This is so much the case that the prophecy is sometimes ventured that in the near future nations will fight by electricity. Though this, like all extreme statements, requires modification, yet the number of ways in which electricity has come to be applied within the last eight years, is calculated to inspire the liveliest anticipations as to the developments of the next eight years. No vessel pretending to modern equipment goes to sea without a complete electric plant for furnishing light. This light is so much more suited to ship life than any other light that we now wonder that we ever went to sea without it. The electric motor is coming into use for ventilating ships, and it is beginning to be used for training guns and the hoisting to the deck of shot and shell. The best and the most accurate results at target practice are attained when the guns are fired by electricity. Range finders give the gunner constant knowledge of what he must know, *i. e.*, the distance of the enemy. The best means of night signalling, and the one adopted in nearly every navy in the world, is by means of incandescent lights. The electrical search light is almost as much a feature of the equipment of a modern war ship as are her guns and her torpedoes. In the actual use of the Whitehead and Howell torpedoes electricity plays an important part. The telephone is now coming into use for ship work, and will unquestionably supplant the speaking tube, which is acknowledged in all navies to be unsatisfactory. In fact, we find all through modern war ships an increasing use of electricity. The reason is clear. The modern war ship is the most intricate, tremendous and powerful machine existing. In no other equal space can be found so many, so various, and so important kinds of apparatus. Everything must be done which will put her absolutely within the grasp of the captain. She must respond at once to his command, and her whole strength and power must be his, as though she were a part of him. Ensconced in his armored conning tower he must be the brain of the gigantic body. Electric wires must convey instant tidings to him from her innermost recesses, and electric wires flash back from him the inevitable command. In this way only can a modern ship, no matter how large, how strong, how heavily armored, or how swift, completely fulfill her mission and be a perfect fighting machine.

What is true of ships is equally true of forts. The power of ships' guns has so increased that it has become necessary to protect shore batteries by iron and steel instead of masonry, as in the days not long gone by, and, in addition, to use disappearing carriages wherever it can be done. Disappearing carriages, as is well known, are so arranged that the gun disappears below the parapet of the fort when the gun is fired, and remains out of sight and safe during the operation of loading, so that it is exposed only for a short time when it is raised to fire. Now, without the aid of electricity, a very considerable time would elapse, even after the gun was raised, before it could be fired; because the gun would have to be trained in the proper direction and be elevated to the proper degree for propelling its projectile over the distance between it and the enemy. To estimate this distance and make the proper adjustments would entail delay, and would be absolutely impossible if smoke obscured the target, as would be the case a great portion of the time. But electricity, acting through the medium of the position finder, gives the gunners continuous information of the distance and direction of the enemy, no matter how thick the smoke, so that they know exactly what to do before the gun is raised to fire.

Electricity, furthermore, gives the commanding officer complete control of all the different groups of guns and mortars in his fort. Noting the progress of the action from a station aloof from the smoke and noise, he can direct the concentration of as many batteries as he thinks best on one ship, or can disperse the fire as much as circumstances from time to time dictate.

For the handling of the monster apparatus used in forts, the guns, the carriages, the ammunition, electricity is rapidly coming to the front. Some power must be used, since the muscles of men are too weak. Hydraulic power has been used hitherto; but for many purposes electricity has the same advantages over hydraulics that have caused its unprecedented advance in the other departments of engineering throughout the world; while for repelling a night attack from ships, the search light has been found by repeated trials in the naval manoeuvres abroad to be simply indispensable to the land defense.

For military service in the field there is not an army in the civilized world that has not its military telegraph service. One great cause of the suddenness and completeness of the German victory in 1870, was the rapid mobilization of the Prussian army, and its appearance on the frontier ready for battle. Now the splendid efficiency of the telegraph service in the hands of the military authorities made this possible. Nothing is more important in warfare than despatch in moving the enormous bodies of men, of which modern armies are composed, with all their ammunition, equipments and numberless accessories. To move a quarter of a million men to the frontier in a single day, means a good deal; and to manœuvre so large a body of men with such precision and rapidity that no one division shall have to wait for any other division, simply cannot be done without electricity.

But the most immediate and important use of electricity in the defence of a coast is in the submarine mine or ground torpedo. Defending a harbor with submarine mines is simply carrying out with more or less elaboration a system by which a large number of water-tight tanks, each holding from 100 to 1,000 lbs. of gun cotton, or other explosive, are anchored in carefully defined positions, and connected by armored electric cables with protected operating rooms, in which are batteries, measuring instruments, etc. The more complete mines have usually floating above them automatic circuit-closers, in which two contact points are joined together by a passing ship, and thus afford a passage for the electric current to the fuse in the torpedo.

Now these mines are some of them exceedingly large and heavy, and the electrical apparatus, while simple to the mind of a trained electrician, yet must be made and adjusted with great care. The torpedoes as a system must be constructed, laid down, and connected to the operating rooms on shore by long and heavy armored cables. The operation of practically planting and connecting the necessary submarine mines for New York would be a stupendous undertaking. Kindly bear this in mind until I recur to it again.

We have now seen, after a rough survey of the subject, that electricity has already acquired an acknowledged position in the art of war, and that the uses to which it is put are not trivial ones. Electricity is not used in warfare as a convenience, nor is it a fad of theorists; it fires the guns, it discloses the stealthy approach of the torpedo boat at night, it directs the proper elevation of the guns; in fact, it does good, honest, practical work. But note this point also: in every one of these applications of electricity we have to pay, in one way, for what we get, by studying the ways in which electricity will work for us. We cannot expect electricity to work for us unless we treat her properly. We cannot handle electrical apparatus with carelessness and ignorance, and expect that it will work when we need it. In other words, we find in warfare, as in everything else, to which electricity is applied, that electricians are useful. This remark doubtless seems absurdly commonplace, but it is intended to suggest that, in war

1. A paper read before the N. Y. Electrical Society, Oct. 23, 1890.

time, electricians, even civilian electricians, may suddenly become very useful to the Government. A captain of a fine ship might lose an action from simply a lack of knowledge as to some electrical appliance on his part, or on the part of some subordinate; some small accident might break a circuit just at a critical juncture, which might prevent the communication of an order, the receiving of information or the firing of a torpedo, at a crisis; and yet the cause might be such, that a man with even a very slight knowledge could remedy the difficulty in a second by the mere pressure of his finger; but that pressure not being given, the action might be lost, and from that cause alone.

Let us now glance at some of the other uses of electricity to which it would probably be put in case of an attack upon New York. There can be no reasonable doubt that Lay torpedoes, Patrick torpedoes, Sims-Edison torpedoes, and Halpine-Savage torpedoes would come to the front at once. The enemy's fleet being daily expected off Sandy Hook, we should see the advocates of these systems, under authority of the general government, preparing stations at Coney Island, Sandy Hook, and elsewhere, for the launching of their dreadful missiles against his ironclads. The question of ballooning, both for observation and for the dropping of explosives on his decks, would be taken up at once, and the electrical world would be agitated anew over the question of balloon propulsion by electricity. Electric launches, ranged to carry torpedoes would be fitted out, to noiselessly steal out at night on their errands of destruction. Electric picket boats of smaller size perhaps, would scout the waters in pursuit of information or to convey despatches; electric submarine boats would spring into being by the dozen, and, filled with adventurous spirits, would seek the enemy, secure from detection below the surface of the sea, and carrying enough explosives to utterly destroy the proudest war ship of the world.

It will now be apparent, that in the case of a sudden war (and most wars are sudden), there will be an immense amount of work to be done in the electrical line alone. Could our regular Army and Navy do all this work in the time allowed? It is probably known to all here that our regular Army and Navy are simply a nucleus around which fighting forces could be formed. They are so small as regards both officers and men that they can barely carry on the work in time of peace, and would be wholly inadequate in time of war. We should not have enough battle ships, monitors, cruisers or torpedo boats; we should not have enough forts; we should not have enough sailors; we should not have enough infantry; we should not have enough artillery; we should not have enough electricians. Take the single matter of laying out and connecting up the submarine mines in New York harbor. This is an area covering many square miles, in parts of which the mines would be placed at frequent intervals; every mine being accurately secured in its designated place and connected by cable to the operating room, perhaps miles away. The mere labor of constructing, fitting and filling one mine, and afterwards taking it out into the harbor and lowering it into place, with all its connections, is no small task; and what can be said of the task of doing this with hundreds of submarine mines? Then the work of properly arranging the various cable connections, testing apparatus, firing apparatus, etc., necessary for the efficient action of the mines would follow. The Board on Ordnance and Fortifications have designed all the torpedo defences, but they will not be in practical operation, probably, for many years, and a war may come meanwhile. But it is certain that on the outbreak of any war an immense amount of this work would have to be immediately done, because we will never keep the submarine defenses of New York harbor on a war footing in time of peace.

The Navy Department would be even more hurried. We should certainly be called upon to commission a great many war ships, and to equip as commerce destroyers a great many merchant steamships; we should have to do all the things that we did on the outbreak of our last war, and in addition, we should be confronted with the necessity of fitting all kinds of fine apparatus, the necessity of fitting electrical appliances of all descriptions, besides securing gun-circles in place with mathematical precision, and of accomplishing all the manifold fine work that is required with the ordnance, navigation and engineering equipment of a war ship of the present day. And as to fitting on merchant ships, who is going to fit them out? This operation requires technical knowledge. Who has it? How many of the merchant steamship captains would be able to install and manage a battery of even Hotchkiss or Driggs-Schroeder guns, or could remedy an accident to either gun or ammunition?

It being apparent that the regular Army and Navy in event of a sudden war would be unable to handle all the electrical work that would certainly be thrown upon them, I will propose the formation of a corps of naval and military electricians to assist the regular Army and Navy in its work. Such a corps might exist in every principal seaport town on the coast; the principal one, of course, being the corps with headquarters in New York. Electricity being now a recognized factor in both naval and military war, and requiring expert electricians for its full development, there would seem to be just as much reason for an electrical corps in the National Guard of the State of New York as for infantry, artillery or cavalry. While the members of this corps would be men of technical knowledge, and while its sphere of usefulness in war would be because of that technical knowledge, it is obvious that the organization should be a military one, and that with some modifications it should be governed by the same principles as govern all military bodies. Being a military body under the Governor of the State, it could at once become available on the outbreak of war.

It would seem that this corps, like all other corps, should be composed of men of various ranks, subject to various duties. Many kinds of work would have to be done in war, and many kinds of men would be required to do them. On the outbreak of war, certain members would naturally elect duty in the Navy; others in the Army. The most obvious and immediate employment would doubtless be in the torpedo defence of the harbor, under the direction of the general commanding. And who can doubt the gratification which that general would feel, when suddenly ordered to defend New York harbor, on finding added to his list of subordinates a hundred or more capable electrical engineers, young, enterprising, accustomed to difficult electrical work, familiar not only with electricity in its technical features, but also acquainted with the electrical people of New York, with its factories, its places of business, and its methods of business. These men would become available in a day, and could be at once set to work in carrying out the details of the vast and complicated system. Their work need not be confined to that purely electrical in character, because every electrical engineer is, by training and of necessity, a mechanician, and every sort of apparatus would be readily understood by him, and a very slight training will make him master of it. Those members volunteering for naval work would be equally useful. The ordnance officer at the Navy Yard would suddenly find himself overwhelmed with a mass of work which he would be utterly unable to carry out without the assistance of some such sort as this. And for the reason that electrical engineers are of necessity mechanicians, a great deal of technical work could be entrusted to them; such as the arrangement and fitting of gun carriages, the storage of ammunition, the assembling of guns, etc. Their more immediate and obvious field, however, would be the installation and fitting of electric lights, motors, telegraphs, telephones, and other electrical appliances on board the vessels of war suddenly called into requisition. In the matter of fitting out merchant steamships their usefulness would be at once apparent. The number of regular officers would be found utterly out of proportion to the number of ships; the whole Navy would have to undergo an expansion. Only a very few regular officers could be assigned to each vessel; so that the majority of officers would have to be volunteer officers, as was the case in our Civil War. During the first part of the war the command of the different vessels would naturally be intrusted to regular officers leaving the other positions to be filled by volunteers. Now, as the commander of a ship is head of all the departments of a ship, he cannot give much personal attention to one special department. Therefore, the general arrangement and fitting out of all vessels, both regular war ships and merchant steamships, would have to be largely entrusted to volunteers in all that relates to the electric and ordnance equipments. Now, as the work of fitting out ships with electric and ordnance equipments calls for technical knowledge and experience of a high character, it is obvious that a corps of well-trained technical men, such as here suggested, would be more than useful, they would be necessary. A further field for employment of such a corps in time of war is suggested by the fact that the genius of our people tends towards constant invention and improvement of all sorts of machinery and apparatus, and our history has shown that every war has brought into being many inventions in weapons of defence and offence. Can it be doubted, then, that any future war would produce more such inventions? And in view of the great progress of electrical science since the last war, and in further view of the large number of electricians in New York, can it be doubted that many of these inventions would be electrical in character? Under the stimulus of a national peril, and with the resources of New York at command, it is certain that important and novel warlike applications of electricity would at once spring into being. And while our regular forces of both Army and Navy were employed on their specific duties, what more natural than that some new Ericsson should arise, and some new "Monitor," or other craft, startle the nations of the world? Therefore, besides the obvious uses to which such a corps as this might be placed, there are other uses, no less important, of inventing, constructing and using weapons of defence, the nature of which we cannot as yet even faintly conceive. And as few heroes of our late war go down to history with more glory than has Ericsson, so, perhaps, our next war may produce some electrician now unknown, whose fame will outlive the ages.

It would seem as if such a corps as this could be formed under existing laws, and that there would be no difficulty in enlisting members. The attractions of the Naval Reserve and of the National Guard seem sufficient to induce a large membership in the different regiments, and there is no reason why membership in an electric regiment should not be equally desirable and confer equal distinction. The qualifications for entrance as regards education and intelligence, would be greater than those for any other regi-

ment, corps or battalion. Its military and naval usefulness would be acknowledged, and its position in all respects would be one of dignity. The larger the membership, the better; provided, of course, that due care be observed in excluding undesirable persons. The whole electrical influence of New York and of the country would be at its back, with all its millions of dollars and its men of world-wide fame; and there is no reason why it should not acquire a national influence. The course of instruction could be readily carried out, embracing the naval and military applications of the purely technical science, with which the members are already familiar, instruction being given by regular Navy and Army officers detailed for the purpose. This instruction would naturally embrace the construction and care of apparatus. It being presupposed that there are different ranks in this corps, the system of instruction will naturally differ with the different ranks. With the higher ranks, it would naturally embrace the theory and practice of gunnery, navigation, including compasses, and seamanship. Steam engineering would probably not need to be taught, it being assumed that the members require very little instruction in that branch. For the lower ranks the scheme of instruction need not include much more than the handling and care of the different apparatus. On the outbreak of war the members volunteering for the different services could be subjected to certain examinations, and their rank determined by the proficiency exhibited. As to the details of organization, uniform, etc., these need not be entered into here, as they can obviously be settled at any future time. My only purpose now is to propose to you a plan for meeting an emergency, which may some day arise. I would hazard the suggestion that the corps or battalion should at first include about 250 members, and that it should be officered, uniformed and drilled in much the same ways as the other corps of the National Guard. I would even advocate a certain amount of infantry drill as a means of instilling the military idea. Occasional runs in the torpedo boat "Cushing," and frequent short trips out to sea for target practice in modern war ships, would be essential. There would be considerable work, but there would be many compensating social and other advantages. I have ventured with much diffidence to put forward this idea, but earnestly hope that you will think it worthy of earnest consideration. My only excuse for broaching it is that it has been in my mind for many years, that it has been commended by every man to whom I have spoken about it, and that I have been urged to bring it to the attention of the electricians of New York.

THE CENTRAL LIGHTING STATION AS AN INVESTMENT.[1]

BY B. E. SUNNY.

The central lighting station has been the subject of many lectures. It has been discussed from an electrical, mechanical and geographical standpoint, until there is not much left to say about it.

Everybody knows now what kind of apparatus to use; what steam plant to put in, and where he had better locate his central station. If he don't know, all that he need do is to tell the editor of his newspaper that he is thinking about embarking in the electric lighting business, with strict injunctions as to secrecy, and before he knows what has happened, he will be surrounded with a galaxy of dapper young electricians from the nearest big city, all brimming with wise suggestions and advice. If he escape them,—well, there is no use of discussing improbabilities.

Central stations, from an investor's standpoint, have not been discussed to any extent, however, and as I have had the opportunity of knowing the financial side of many of them, I may be able to make a few suggestions of interest.

While both the arc and incandescent light are young, they are old enough to give an account of themselves as money makers. They are not in their "infancy," as so many suggest, but are almost ten years old, and should stand or fall by the record that they have made during that period.

It may not be amiss to refer at this time, and in a brief way, to the introduction of these two forms of light to commercial and domestic use.

The arc lamp found a clear field, with practically no competition for out door and store lighting, and was immediately installed in all large cities, to permanently replace the gas and oil lamps that for so many years had quite indifferently performed the service. The additional cost at that time charged for arc lights as compared with gas was very great, but only in proportion, however, to the increased amount of light. Price was of secondary importance, as compared with the great demand for a means of making the stores and thoroughfares as bright by night as they were by day. The arc lamp became at once a popular and permanent adjunct in the service of the community, and, as years have come and gone, it has become more firmly intrenched, so that it is now indispensable. While there are a few small towns in the country that have escaped the vigilance or resisted the wiles of the electric light man, history fails to record a single instance where the arc lamp has been discarded, and the old methods of lighting substituted.

When we consider what the arc lamp is, it is obvious beyond all doubt that it is the best light that has ever been known. Brilliant, steady, noiseless; absolutely reliable, and at the same time cheap; it is permanent, and notwithstanding the inventive age in which we live, it will shine on for years into the future. There is no possible substitute for it as it is used now, and while we hear of the prospective betterment of this thing and that, how seldom we hear anybody suggest that there is soon to be a better light than the first-class arc lamp of to-day. The experimental stage has been passed, except as to minor details, and what we have now will stand the scrutiny, and defy the inventive genius of the next decade.

The incandescent light has had a hard fight for a position in the commercial and domestic world. Coming after the arc light, it has met the latter in competition for store lighting, and has felt the opposition of cheap gas and cheaper oil, in many instances difficult to overcome—especially in house lighting in a community where a small difference in price determined the choice of illuminants. Notwithstanding the fierce competition, the incandescent light has become a fixed factor, with a future before it that its most enthusiastic admirer is more than likely to underestimate. Safe, clean, beautiful, and above all, free from the injurious effects to health that are induced by the use of gas and oil as illuminants, there is only the incidental competition of gas and oil, that will be less and less as years go by, to retard it in its march to supremacy in the lighting world.

It seems an inflexible and unvarying rule of the universe that we shall suffer, to a greater or less extent, injury to persons and property through the imperfections of several great agencies in the service of the community. Every means by which a large mass of people are benefited, calls for tribute in the shape of annoyance, loss and injury, because of its failure to do that for which it is designed, uninterruptedly, reliably and perfectly. If we will go over the list of public corporations, and analyze the advantages and disadvantages growing out of the service they perform, we will find this true in every instance.

The water-works is a priceless boon—an indispensable public servant, but how often is the water, so generously distributed, so contaminated with impurities that it causes epidemics and frightful mortality. It is only a short time since that the water furnished in this city was the subject of bitter complaint by the press and the people—notwithstanding we have the greatest sheet of pure water in the world, by our side.

The gas works perform a service of equal importance with the water-works, but its imperfections are evidenced in the blackened walls and ceilings—the vitiated atmosphere, the suffocating of ignorant or careless users and the dangers of fire.

The sewerage system, so vitally necessary and important, frequently fails in its work of doing good always, and turns its attention to decimating the population.

The telegraph and telephone, the great time savers in this age where time is precious, vex us to the soul with their shortcomings, that seem to be beyond the power of man to prevent or cure.

The steam railway, performing the greatest public service, furnishes a column of disasters in the daily papers, and even the slow-going street car, with plenty of time to be perfect in the performance of its duty, is imperfect, in that it kills so much time in doing its work. If its sanguinary exploits ended in killing time alone, it would not be so bad, but it occasionally extends its field of operations to children and old ladies.

So it goes through the whole list, and we can contemplate with the greatest satisfaction the almost perfect service of the electric light, and its greater freedom from the annoyances and losses to those whom it serves than the agencies enumerated. True, it has contributed to a small extent, in comparison with its large work, to the fatalities and losses that the community must suffer for employing these public servants, but the circumstances in each case of injury or mortality have invariably been of an extraordinary character, and capable of permanent correction.

In connection with the success and permanency of the electric light, it can be said that no one recognizes the future of electric lighting more than our friends in the gas companies, more than 300 of whom are operating electric lights in connection with their gas works. The *Gas Directory* says that the gas companies are operating 32,000 arc lights and 140,000 incandescent. If it could be known in how many instances the individual owners of the gas property are also the owners of the electric light plant, it would be found that the number of electric lights in control of the gas companies is double the number shown.

In one year—from March, 1889, to 1890—the gas companies increased their ownership in electric lights to the extent of almost fifty per cent., indicating their faith in a most gratifying way in the earning power and permanency of the electric light.

If statistics showing the growth of the gas business during the past five years were available, I think it could be shown that the increase in gas consumption is nominal as compared with the growth in population, and that aside from the large cities, where

1. A paper read before the Chicago Electric Club Meeting, Monday, Oct. 20th, 1890.

the difficulty in stringing wires has retarded the electric light, the gas business has only changed with respect to the adoption of cheaper methods of manufacture, so as to compete with electricity. In the smaller cities, towns and villages, the electric light is available for every store and home, however remote, because of the inexpensive means that can be used for complete distribution.

The number of electric light companies operating in the United States is, according to recent reports, 1,483 against 968 gas plants. This great difference is owing to the large original outlay for a gas company as compared with an electric lighting plant. The former, with its heavy iron pipes buried in the earth, subject to heavy leakage and frequent expenditures for repairs, can only cover a limited territory, and yet calls for an investment five-fold greater than the electric plant. The electric plant, because of the great saving in the original investment, is invariably given the preference by investors, as is also the case with the electric railway as compared with the cable railway. Recent figures show 288 electric railways as against 44 cable railways in operation in the United States, while the latter has been in practical operation 16 years, and the electric railway half that time.

It is a self-evident fact, therefore, that the electric light is an absolutely permanent and growing investment; that it has taken its place, in the large cities, side by side with the great public corporations, contributing its quota to the general service and comfort.

By the excellent methods developed with such speed and skill the individual is served with light or power, regardless of quantity—little or much, and just as his convenience may dictate. It is under perfect control; is readily adaptable to the varying conditions of the demands, and on the whole, calls for no extraordinary skill to operate.

Above all, the price at which it can be produced, and that at which it can be sold, leave a margin of profit that ought to be satisfactory.

So far then, we find that the electric light is: First, a commercial success; second, that it is permanently installed in the service of the public; third, that its imperfections are less than those attached to any other public service.

I have gone over the condition of the business quite fully for the purpose of impressing you with the fact of its indisputable permanency. It is firmly lodged among the commercial enterprises, and has been for seven or more years. Now, the important thing to get at is, How does its record read from the investor's standpoint? Does it rank with the water-works, the gas works, the telegraph and the steam railway as a producer of dividends? Unquestionably it does. All who are familiar with the operations of lighting plants can bear testimony to the fact, notwithstanding the grave mistakes that have been made in planning for, and furnishing, the service, and which have materially lessened the net financial results. With the one possible exception of the telephone, the future of no business has been more greatly underestimated than the electric light. The telephone people—and I was with them for several years—blundered on the growth of the business with the greatest unanimity, and built everything too small. The electric light people did the same thing, and now the face of the earth is dotted with lighting properties, which were poorly planned, badly built, and indifferently managed. I have classed the lighting station with the water-works, the gas plant and other quasi public institutions, in the importance of the service rendered, and as to financial results; but in the matter of construction, I am sorry to say, that the average lighting station is inferior. Where do we ever find a pumping station in other than a neat, substantial brick building, rather than in a frame shell, covered with tar paper, or tin? True, there are many lighting stations expensively and durably constructed, but we can all point out a long list, located in cellars, basements, abandoned barns and cheap wooden structures, with the usual and customary trimmings of second-hand boilers, an engine too old for service in a saw-mill, and underwriters' wire. Of course such a plant is a cheap one, and it is within the means of almost any man to start one, but with what results? Excessive running expenses, and a succession of break-downs and repair bills, until the profits are eaten up, and there is nothing left for the owners but to abandon the property or sell out to some one who will reconstruct the plant on a proper basis.

This is one type of non-dividend paying lighting station. Another is the station that is well built, of brick or stone, with good steam plant and electrical apparatus, and starts off on its career with the applause of its projectors and patrons. It is a great success, and the patrons increase, until the fact is brought home to the owners that they have left no room for more boilers; more engines and electrical apparatus, and that to meet the additional wants, they must add to the building, and machinery; put up another stack and reinforce their pole line. Then begins the work that ends in the central station becoming an exhibition of engineering gymnastics. Engines of various makes are crowded in spaces too small for them; high speed and low speed; big boilers and little ones, until the station takes on so many peculiarities that a change of engineers is apt to shut it down, until the new man can unravel the awful mystery. The remarkable thing about such a station is that it generally pays good dividends, for the reason that every boiler, engine and dynamo is worked to its fullest capacity, and consequently under economical conditions. So long as the machinery stands the strain, the stockholders will have cause to rejoice, and it is at this juncture that they would be glad to have the demand for lights cease. In the nature of things, however, it is just at this point where the demand becomes particularly pressing, and the stockholders are confronted with the necessity of rebuilding in its entirety a station but two or three years old, too small for the reasonable demands made upon it. The rebuilding means the throwing away of the old station, in many instances; the selling off at a great sacrifice the smaller engines and boilers to make room for larger types, and the absolute loss of the labor and material in foundation setting, steam fittings, etc. The shares of stock representing the cost of the property abandoned continue, however, to be an obligation upon which dividends must be paid. Then during the transition period, while part of the work is being performed from the old station and part from the new, the increase in the operating expenses caused by two sets of men, and the disorganized condition of affairs, is very marked. It generally happens, too, that in their desire to make the new one a model station, the manager or superintendent devotes all of his time and attention to that work, and leaves the old station to the boys to run, with the usual results.

This is the type of station that changes from a good dividend payer to one that, for a time at least, quits paying, and then resumes; or if its capital is increased to take care of the rebuilding, it can continue its dividends during rebuilding, but on a smaller basis, because of the additional number of shares. There are but few central stations in the country that have not already, or must within a short time, go through such an experience.

The remedy is old, and naturally occurs to any one of moderate experience. It involves at the outset the selection of a larger lot, and the construction of a larger building than we can at the time see any possible use for. There seems to be no reasonable limit to the demands that may be made for facilities, so that reasonable methods of planning do not seem applicable. A larger lot and building does not call for an excessive increase in cost over what a smaller property would cost. In fact, the real estate and building are generally the smaller items in the original expenditure. If then, the boiler room, engine and dynamo rooms are planned for indefinite extension, according to the generous proportions of the building, not with reference to the growth of the next three or four years, but of the next 15 or 20 years, and the machinery selected be of a standard type and capable of duplication from year to year, the sacrificing of original investment would stop. There are some who calculate the depreciation on the machinery of a lighting station at 10 per cent. but many will agree that the estimate is excessive. There is no reason why boilers, engines and dynamos, with reasonable care, and the occasional renewal of parts subjected to heavy wear, should not last twenty years. I refer to standard apparatus, of course, and do not include experimental types, that are, or ought to be, thrown out after a brief use because of their inefficiency. Now if we start out right, with plenty of room, with standard machinery, and the territory that we have is good, the increase is sure to come, and can be cared for gradually, by the addition of a boiler, an engine, or a dynamo, without throwing away any part of the original investment until it is worn out. The whole secret of dividend-paying enterprises is in their ability to run reliably, every day and every year, without subjecting the machinery to excessive and abnormal demands, and in the avoidance of rebuilding or abandoning original investments. There is no lighting property to-day that cannot pay a regular dividend, and earn enough above it to add to the plant as the demand may require.

There is no fixed rule as to the dimensions of a station building that will serve the wants of its patrons, present and prospective. The growth of the business has heretofore been beyond the calculations of the most enthusiastic. The same statement is true with the telegraph and telephone. The Western Union officials are building additions on their already mammoth structure in New York that will increase the facilities four-fold. The great telephone building on Cortlandt street, designed four years ago to furnish all the service below Canal street, is inadequate to meet the demands. The telephone building in Chicago, but three years old, is badly crowded, while in the electric light branch of the service, the Arc Light Co. and the Edison Co. in Chicago have, after two years' operations, exhausted their facilities for extending in their present quarters. Rebuilding is in process, or under consideration at Omaha, Denver, Milwaukee and other cities in the West.

We cannot complain of this most prosperous condition of affairs. Rather do we congratulate ourselves on the increasing growth in population, which does not come to the large cities only, but to the small ones, and to the towns and villages all over the greatest Nation that the world ever knew.

With the increased number of people, comes the increased demand for everything, and what, more than light,—and the electric light at that! Is it not wise, therefore, to pattern after the most substantial and permanent institutions of the time, and build, not for the present and the immediate future, but for twenty-five or

more years ahead of us? What is now standard may be obsolete ten years hence, but at the same time, standards are slow to change, and with the economical and efficient boilers, engines and electrical apparatus of to-day, we are safe to embark in great and important investments, and leave the almost impossible task of improving on what we now have to take care of itself.

GENERAL INSTRUCTIONS FOR OVERHEAD LINE CONSTRUCTION FOR ELECTRIC RAILWAYS.

THE large amount of overhead railway work now in course of construction and the large number of roads which will undoubtedly be constructed in the future makes it desirable to have some clearly defined rules for the construction of overhead work, as well as that relating to the ground conductor. Our readers will therefore be interested in the admirable general instructions relating to this part of railway work, which have been issued by the Westinghouse Electric and Mfg. Co., and which if carried out faithfully cannot fail to result in a substantial and lasting conductor system, with the least possible annoyance to the public.

Franchises, Permits, Etc.—The owners of the railway must secure all necessary franchises and permits from public authorities, or private individuals, for properly carrying on the work of construction, including permission to set poles in the most advantageous positions, and to run guys where necessary. They shall also do all necessary removal or trimming of trees, and shall be responsible for all necessary removal of existing wires or poles or other impediments.

Contractors.—The contractors shall comply strictly with the local laws governing their work, and are responsible for all unlawful damage done by their employés in the progress of their work. They are required to do all the carting and storing of material, to furnish all horses, wagons, men and material for carrying on work.

Completion of Work.—Each branch of the work must be pushed rapidly to completion as taken up, all re-sodding, paving, etc., promptly done, and all debris and material removed. All break downs, or deteriorations of the work, which shall occur before the final completion and acceptance of the whole, shall be repaired and made good by the contractors at their own expense.

Inspection and Acceptance of Work.—The Electric Company may appoint an inspector, who shall have authority to decide and direct how every branch of the work shall be done and what

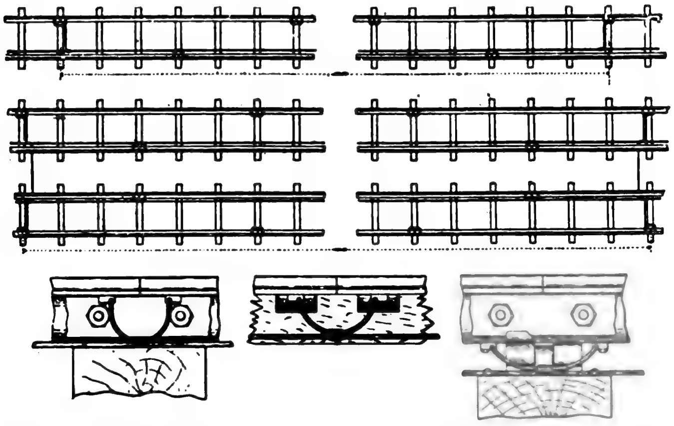

FIG. 1.—METHOD OF CONNECTING GROUND WIRE, SINGLE AND DOUBLE TRACK.

material shall be used. He may at any time order such changes and removals as he may see fit. If the inspector orders any work done or materials used which are not properly included in, or covered by, the contract, he shall give a written order to the contractors, specifying, as nearly as possible, the amount of labor and material involved. The inspector will give a written acceptance to the contractors when he considers their work properly completed.

TRACK AND GROUND CONNECTIONS.

On all roads where the size and material of the continuous ground wire are not particularly specified, No. 0 B. & S. galvanized iron wire shall be used. All joints in it shall be soldered. It shall be stretched taut, and secured to cross-ties or stringers with galvanized staples. It must be so deep in the ground that it cannot be reached by wheels, etc. It must be run close to one rail and connected to each rail bond it passes by a wrapped soldered joint. Every 150 feet a branch of No. 0 B. & S. wire shall be soldered to the continuous ground wire and to a rail bond on the other side of the track. Where there is a double track, there must be a cross wire every 150 feet, which is soldered to bonds or ground wire on all four lines of rail, and is the only cross connection required. It must be of No. 0 B. & S. (See Fig. 1.)

Between the ends of all consecutive rails, of whatever form, a rail bond, the Electric Company's standard pattern, shall be used. This bond is shown in Fig. 1. The holes in brass or copper block must be bored to fit rivet and wire, not punched. The end of wire must be put through block, and upset so that it cannot pull out, and the whole bond must be covered with half and half solder. The rivet must be Norway iron, $\frac{5}{8}$ inches in diameter, and of just sufficient length to pass through flange or web of rail and be riveted.

The best place for rivet holes in different kinds of rails depends to a great extent on paving and other conditions. The rivet must always pass through the rail, and be upset into a counter-sinking at the end of hole. No part of the bond must be exposed or

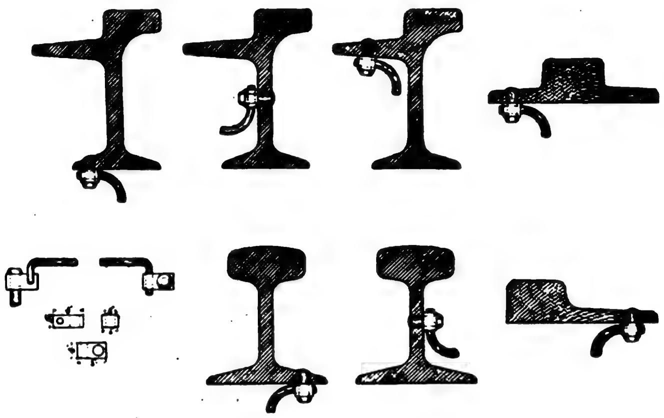

FIG. 2.—METHOD OF CONNECTING GROUND WIRE TO RAIL.

placed in such a manner that it can be touched by wheels or that the movements of the rail will tend to break the wire. The admissible positions for rail bond rivets in girder, T and tram rails are shown. (Fig. 2.) No rail bond may be less than 10 inches in length, and the bonds must be slack when in place, but as short as the conditions will permit. Where short pieces or castings, such as switches, frogs, or curve castings, occur in track, the pieces must be connected up in the same manner as consecutive rails, and each bond soldered to the continuous ground wire.

In steam railway crossings, each piece of rail must be connected to the continuous ground wire. Where a draw bridge is crossed, the rails on either side should be connected by a No. 0 B. & S. copper wire, weighted to the bottom of water, with such connection as is necessary for rails on draw.

Cables or wire leading from rails to dynamos must be soldered to continuous ground wires and bonds on all lines of rails, and must be connected to the positive terminal of dynamos. When ground feeders are run, they must be insulated in the same way as line feeders, but must, if possible, not be run on the same line of poles, and in no case must they be run on the same insulated pole tops.

POLES.

Wooden Poles.—Must be 30 feet long, and, for use on straight lines must not be less than 7 or more that 8 inches in diameter at top when finished, and they must not be less than 10 inches in diameter 5 feet from the butt. They must be of sound chestnut, cedar or Georgia pine, may be sawed or natural round, but in both cases must be dressed smooth and coned at top, cones having two coats of paint.

Poles for Corners.—At curves, and for the ends of line, or which in any way bear part of the pull of the trolley or feed wires, must be not less than 8 inches in diameter at top and not less than 12 inches at a point 5 feet from the butt. All poles must be straight and uniform and free from shakes, checks or large knots.

Iron or Steel Poles.—Of whatever form shall be of a strength and stiffness at least equal to the wooden poles specified. A pole made of three sections of extra heavy pipe, top section 3-inch pipe 5 feet long; middle section 4-inch pipe 6 feet long, and bottom 5-inch pipe 16 feet long (these lengths do not include the lap in joints), is sufficient for light work. All joints must be made perfectly rigid and as strong as the adjoining pipe, with proper provisions against telescoping.

All iron poles must have a thoroughly insulated iron top, to which wires are secured. This should be mounted in a hard wood plug in pole top, boiled in paraffine. The top must protect the plug entirely from water; it must have a deep petticoat extending at least 1 inch below pole top, and standing at least 1

inch clear of it on all sides. This top must be fitted with fixtures for securing span wires and insulators for feed wires, etc.

For Curves.—Angles of feed wire, and ends of line, etc., extra strong poles must be used. There is nothing in the work of building a line so essential to its durability and good working as is the perfect rigidity of corner poles. The top section of curve poles should in no case be less than 5-inch extra heavy pipe, and of course special insulated tops must be provided for them. Corner poles must be fitted with strong eye-bolts below the wooden plug for fastening guys.

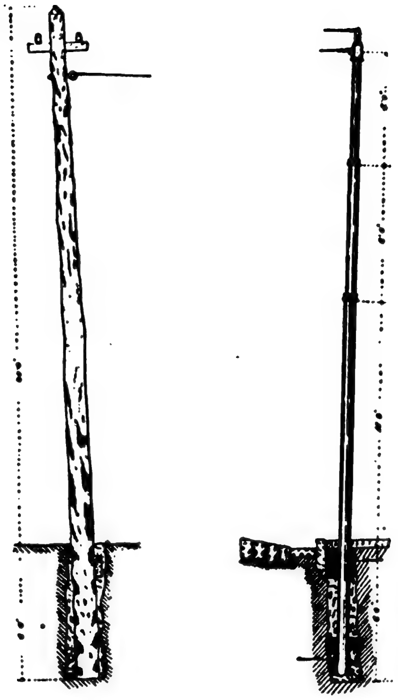

FIG. 3.—METHOD OF PLANTING WOOD POLE AND IRON POLE.

Pole Setting.—All poles on straight line work shall be set 6 feet in the ground. Large stones shall be tamped hard against butt of pole on side away from rails. Where practicable, pole should bear at surface of ground against curb stone, or have the space between it and curb stone filled by another stone or stones. Where there is no curb stone, a timber not less than 4x8 inches and 3 feet long shall be laid against the rail side of pole, 6 inches below the surface of the ground. A large stone, at least 2 feet long and 1 foot wide, should be used in place of timber when practicable. All poles shall be tamped solidly. (Fig. 3.)

In setting iron poles, good cement concrete must be used. The quality of the concrete should in all cases be good at the top and bottom of holes, and large stones may be used at these points to advantage. The hole in which an iron pole is set should be at least 20 inches in diameter, and filled with concrete, which should be given ample time to set before any strain is put on it. Poles of wood or iron for straight line work should have about 3 per cent. of rake away from street. (Fig. 3.) Wherever possible, the line of the tops of poles should be at a uniform height from rails, and the ground around poles should be graded to give the pole the proper depth of setting.

Poles which support part of the strain of curves or bends of trolley or feed wires must, in all cases where it is possible, be thoroughly head guyed. When this can be properly done, no extra precautions need be taken in setting, and poles should be set nearly vertical. The same applies to poles which support ends of lines.

Guy stubs must be anchored 5 feet in ground, and their tops must be 6 feet above ground; the stubs must be at least 8 inches in diameter, and must rake well towards pole top or point directly towards it. Guys must make no metallic contact with insulated pole tops or with any other wires which lead from the pole. Guys must be made of twisted (doubled) No. 6 galvanized wire or something equally strong and durable. (Fig. 4.) When guys cannot be used on the poles above mentioned, they must be set 7 feet deep in a hole 30 inches in diameter and built in solid with stone and concrete. Poles shall not be more than 125 feet apart, except where a greater distance is unavoidable.

In all cases where the character of the soil or the nature of the strains make the ordinary method of setting poles inadequate, precautions must be taken to make poles sufficiently firm, and whenever poles yield under the strain put upon them, the Electric Company's inspector may have them re-set at the contractor's expense. This may also be done when poles are displaced by undue strains imposed by contractors in building line, etc.

When the poles are not set by contractors who put up the wires, the latter must assume responsibility for the rigidity of curve and terminal poles, and their work can in no case be made acceptable unless these poles are thoroughly strong and firm or properly guyed.

FIXTURES.

All insulator pins and pin brackets shall be of the best oak or locust. Pin brackets shall be secured to pole with one 5-inch and one 7-inch lag screw.

Cross Arms.—Shall be of the best pine, 3¾x4¼ inches, painted with two coats Indian red. They must be secured in perfectly fitted gains with two 7-inch lag screws. Insulators must be extra heavy, such as are made for the largest sizes of wire. Where sharp turns are made with heavy wires, two or four cross arms must be used, and where necessary, iron pins and large paraffined wooden insulators may be used.

WIRE CONSTRUCTION.

Span Wires.—Are to be of stranded wire, $\frac{5}{16}$ inches in diameter made of 7 wires without a core. They must be secured to eye-bolts which pass through pole and have a nut on the opposite side. These bolts to be of ⅝-inch galvanized iron. With iron pole a suitable eye must be provided for span wire. The height of eye-bolts from the rail must be uniform on streets of equal width, and must be such as to hold the trolley wire at a height of 19 feet from the ground. A span wire must be allowed to sag about 3 per cent. of its length. When first put up, span wires must be left with one temporary connection, and must be carefully pulled up to uniform angle after trolley wire is run. They must in no case be connected so that slack cannot be readily taken in.

Span wires proper are only to be used where the line is perfectly straight. Where there is any lateral strain on trolley wire, double pull-off brackets must be used, with wires of the same material as span wires, leading to opposite sides of street.

Trolley Wire.—Must be put up in as long lengths as can conveniently be handled. The ends must be secured to a long V made of double $\frac{5}{16}$ stranded wire and led from securely guyed poles; it must be connected to this V by an insulator of suitable strength. Trolley wire must be drawn to a moderate tension only, allowing about 18 inches of sag in 125 feet. In hot weather it should be drawn slightly tighter. It must be run off large reels, on which it is carefully wound; it must not be bent, kinked or scratched. The practice of temporarily securing long lengths of trolley wire and allowing by guess-work for each curve is not approved, as it is sure to cause inequalities of tension in line or improper position of curves. Curves should either be completed as they are reached by the trolley wire, or should be built successively after the wire is up, an ample amount of slack being provided and carried ahead as the curves are completed, the line

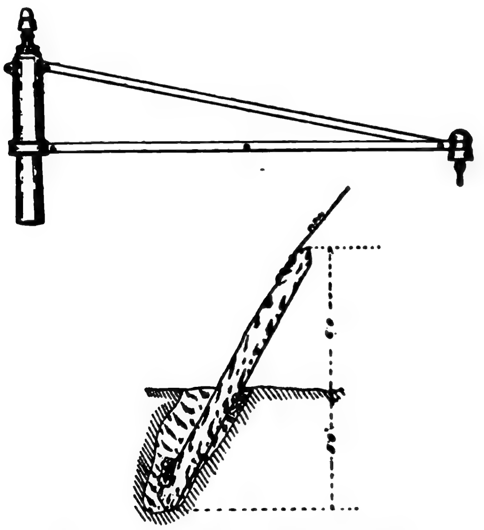

FIG. 4.—GUY STUB AND OUTRIGGER.

being permanently drawn to the proper tension and bridled as each is reached.

The hanging line insulators which support the trolley wire shall be clamped on (not soldered) after the line is accurately in place and all curves completed.

Joints in trolley wire shall be made in suitable brass tubes with tapered sides; they must be soldered by pouring, must be wiped smooth and must bear a strain equal to the strength of the wire itself. Joints shall not occur in, or near, curves.

Construction of Curves.—The positions of poles near curves should be carefully selected, and the poles must be permanently guyed, or otherwise properly strengthened, before work of running trolley wire begins. At the beginning and end of each curve the line must be bridled to the corner pole and one on the opposite side of the street. The fixtures for these bridles serve as the first and last pull-off brackets. They must be carefully swetted to the wire. Not more than five pull-off brackets shall be used between these bridle fixtures on a 90 per cent. curve, except where the curve is very long.

Pull-off Brackets.—The pull-off brackets shall be at equal intervals and soldered to the wire. They must be so placed that the trolley is exactly in line with the wire as it passes them. To accomplish this the bracket must be more or less inside of line vertically over the centre of the track, the height of the wire and the radius of the curve determining the position.

Pull-off wires shall be of the same material specified for span wires. They may be secured either directly to eye-bolt on pole or to a stout galvanized iron ring at a suitable distance from pole. On double curves, etc., insulators shall be used only on wires which run to poles. Where short wires are used to connect pull-off brackets (for instance, those which lead to the brackets on the inner curve) no insulators shall be used.

The weight of curves must be supported by double pull-off brackets, with wires leading to opposite side of street. Fig. 5 shows a sample curve. On all curve construction the greatest neatness and strength will be insisted on; the minimum possible number of wires and insulators must be used; the angling of wires must be advantageous; every wire must be made to serve as many purposes as possible.

Switches, crossings, circuit breakers, lightning arresters, etc., etc., shall be used when and in the manner specially directed.

All Material and Fixtures.—For line work shall be of the form supplied or specified by the Electric Company. All joints and connections in insulated wires shall be covered with three layers of the best weather-proof tape. All ungalvanized iron work and wooden insulators shall be thoroughly and neatly painted with P. & B. paint. Joints in feed wire must be of a neat, strong and approved form, thoroughly soldered. No telegraph joints will be allowed in wires larger than No. 0 B. & S.

Feed Wires.—These must be put up to gauge specified and must be 97 per cent. of the conductivity of pure copper. They must be put up without kinks or injury to the insulation and in lengths of not less than 500 feet. Feed wires must be led into the power station through suitable rubber or porcelain insulators. Every connection to the trolley wire must be made through one of the span wires, which must be fitted with an insulator at each end, and connected to the feed wire by an insulated jumper of No. 6 B. & S. wire, soldered to both. Connection to the trolley wire must be made by an insulated hanger, similar in appearance to the regular insulators. These span feed wires must be of the same material as regular span wires, but covered with the best weather-proof insulation. Where feed wires have to be led under water, the best armored cables must be used and suitable terminal fixtures.

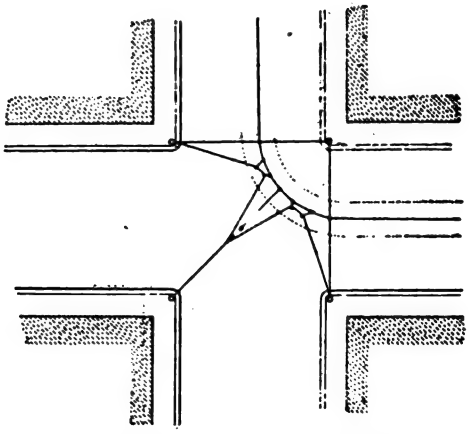

Fig. 5.—Method of Constructing Overhead Curve.

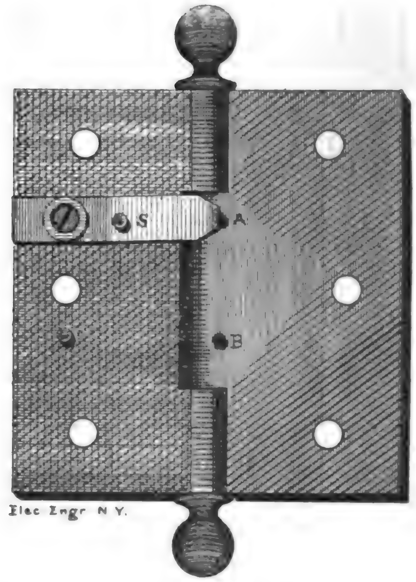
Guard Wires.—Wherever there is great danger of crosses with telephone, telegraph or other wires, through their falling on the trolley wire, guard wires must be used. They must be of No. 8 B. & S. galvanized iron wire, and must be hung to span wire of the same material as the ordinary span wires. Guard wire must be 18 inches or more above the trolley wire. They must be insulated from the span wires, and the span wires must be insulated from the pole tops. Porcelain insulators may be used, but must have no sharp edges.

On single track work, guard wires must be four feet apart, with the trolley wire midway between them. On double track work, three wires will be used, one two feet outside of each trolley wire and one in the centre. Guard wires should not be used except where the need for them is very positive and where their construction can be made simple and effective. A complication of guard wires will always be a source of trouble.

Outriggers.—When the trolley wire is hung to outriggers instead of span wires, the insulators must be so constructed that they will bear the lateral strain from the wire where the line is not straight. The outrigger arm must be insulated from the pole when the latter is of iron. (See Fig. 4.)

BLEAKLEY'S BURGLAR ALARM DOOR HINGE.

The accompanying engraving illustrates a very simple hinge designed by Mr. Wm. M. Bleakley, of Verplanck, N. Y., with the object of affording a ready means of connecting doors with burglar alarm systems. As these systems are operated, according to the requirements, both on the open and closed circuit plans, the inventor has so designed the hinge that it can readily be applied to both. As will be seen, the hinge has mounted upon it a spring which is insulated from the metal of the hinge, and has a terminal, S, to which one side of the circuit is attached. On the other leaf of the hinge there is fixed a small knob, A, of hard rubber, so placed that, when the door is closed the knob pushes the end of the spring out of contact with the other leaf, and thus breaks the circuit. Now, the slightest movement made to open the door moves the knob, A, from under the spring, allows it to come down on the opposite leaf and closes the circuit, which rings the alarm.



Bleakley's Burglar Alarm Door Hinge.

Where the closed circuit method is employed the spring is removed to the lower part of the hinge and then comes in contact with the metal knob, B, so as to close the circuit when the door is shut. Upon opening the door the spring falls away from the metal knob, but, without touching the leaf, remains with its end free, thus leaving the circuit open.

The device is evidently very simple and meets both kinds of service.

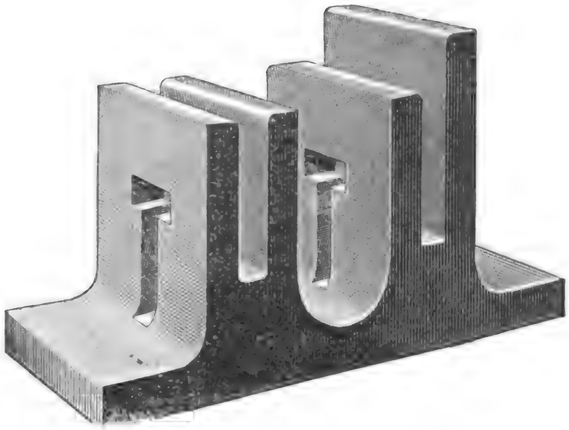
PROPOSED HYDRO-ELECTRIC POWER STATION AT LYONS.

In Lyons the number of domestic manufactures is very great, so that it offers a promising field for the distribution of power by electricity. A project to make use of the water power of the Rhone is now being inquired into by the Government. The promoters of the scheme have constituted themselves into a syndicate (Syndicat Lyonnais des forces motrices du Rhone), and they propose to spend nearly three quarters of a million sterling in digging a navigable canal 18.6 kilometers long, and establishing a hydro-electric generating station, having an output of 12,800 h. p. It is estimated that a charge of about 125fr. per h. p. year will yield a fair return on the capital outlay. Hitherto considerations connected with the navigation of the river have prevented any utilization on a large scale of the Rhone waters; but the present scheme overcomes that objection by the construction of the navigable canal.

THE GIBBON DUPLEX RAILWAY TRACK.

THE appreciation of electricity as the leading power for street railway propulsion, has led to belief in more than one quarter that a radical change will soon be demanded for the improvement in track construction. The essentials deemed necessary for this improvement, not only for electrical propulsion but for any other power, are :—

1. All material used in track construction should be of an



PERSPECTIVE VIEW OF SINGLE CHAIR.

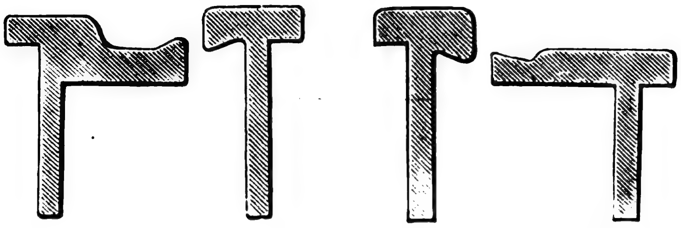
imperishable character. 2. Its design should be simple, and its parts few, and easy of access, so that only the part worn may be renewed with rapidity and with little disturbance to the street pavement. 3. It should possess lateral as well as vertical strength, and be able, under any circumstance, to keep true alignment, grade and gauge. 4. It should have absolute permanent contact of metal throughout the whole length of line, and under every and all circumstances be free from any depressions at the connection of rails, in order that the load which it has to carry may be transmitted uniformly, steadily and rapidly, with the least possible oscillation. 5. It should be of the stringer form, to act as a wall for the support of the paving.

A railway track composed solely of steel and iron, evidently insures the durability of character, and longer life and better service, than a structure composed of steel and timber. Such a structure would possess the strength laterally, as well as vertically, so that neither the lateral thrusts from the heaviest trucks could disturb its alignment, or the heaviest cars, running on it, cause permanent depression at the joint.

A track designed to meet all these requirements was exhibited by Mr. Gibbon, chief engineer of the Gibbon Duplex Railway Track Co., of this city, and received very marked attention at the late Buffalo Street Railway Convention.

The accompanying illustrations show the system to consist essentially of four parts, namely, the rail proper, the chairs, the tie-rods and automatic lock wedge. The rail is made in two separate sections, called the "head" section, and the "flange" section. The head section has a girder directly beneath the centre of the bearing surface. The flange section presents a bearing surface similar to the flange of a side bearing rail, and has a girder directly beneath the centre of the bearing surface. The two sections combined form a double girder side bearing rail, the girders acting as a wall for the support of the paving.

The chairs are of two kinds. The joint chair and the inter-



GROOVED RAIL. SIDE BEARING RAIL.

mediate chair; the joint chair being larger and having two T-shaped slots and the intermediate chair only one. Both, however, have a large area of bed plate surface.

The T-shaped slots are to receive the tie-rods and wedge keys, and it will be noticed that the wedges not only lock the rails and chairs, but lock themselves in place, so that there is no danger of their being jolted out of place by the action of the cars.

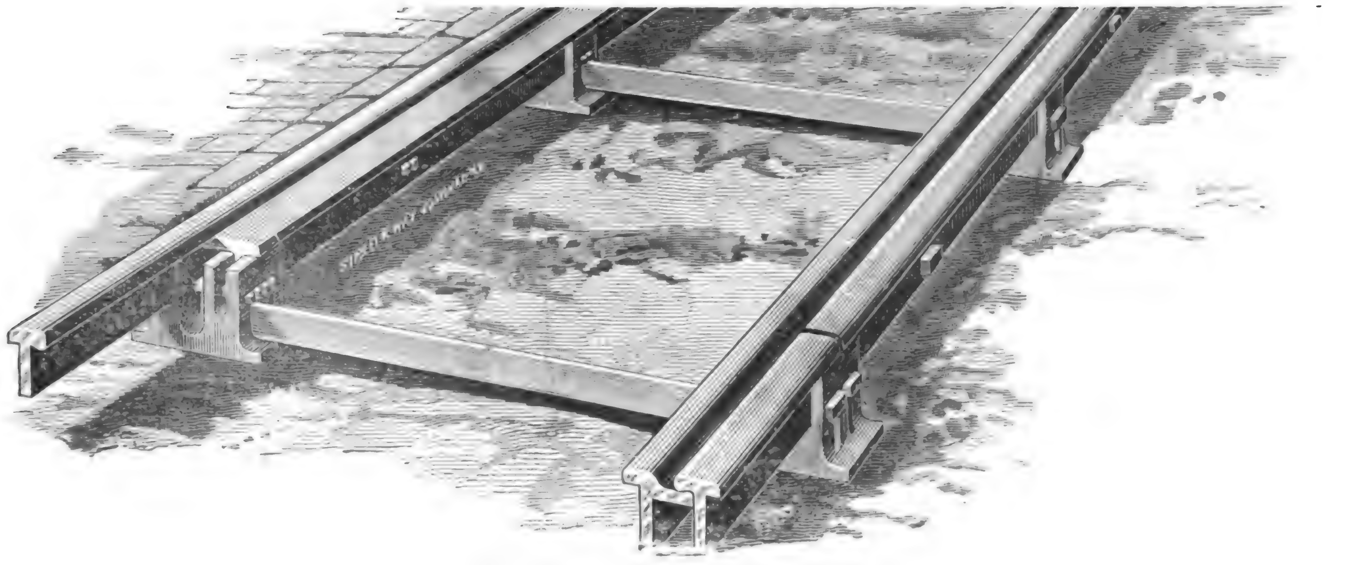
The tie-rods are ordinary strips of iron or steel about 2 inches in width and from ⅜ inch to ½ inch in thickness, which are slotted to the guage required; these slots receive the lower edges of the girders of the "head" and "flange" rails.

In laying track, the chairs are placed in position on their prepared foundation of concrete or stone, and the tie-rods are slipped through the slots in the chairs so that the slots in the tie-rods correspond to the slots in the chairs. A pair of joint chairs, with the tie rods, are placed every 15 feet, and the intermediate chairs and tie-rods every 5 feet, thus tieing and chairing every five feet of track.

After placing the chairs and tie-rods in position, a wooden template of the girder of each section of the rail is placed longitudinally in the grooves in the chairs, which operation spaces the chairs and gives alignment. The trenches are then filled with sand and firmly tamped; this being done, the inner template is removed, and the girder of the flange rail dropped in place. The outer template is then removed, and the girder of the "head" rail dropped in place, but in such a manner as to break joints, the

AUTOMATIC LOCKING WEDGE KEY.

TIE BAR.



THE GIBBON DUPLEX RAILWAY TRACK.

ends of the "flange" rails being covered by the solid head rail, and the ends of the head rails supported by the solid flange rail, thus making a compound rail.

The completed rail forms a box filled with sand, presenting a 5" x 6" beam for vertical and lateral stiffness.

After the two sections of rails are placed in proper position, the automatic lock wedge keys are driven in place.

The keys are so made that the narrow edge binds on the chairs only, the slots of the rail being longer than the width of the wedge. The broad edges bind on the rail; by this means, the rail is allowed to expand and contract by sliding on the broad surface of the wedges, thus giving continuous contact of metal at the joint with power to expand or contract in the space allowed by the engineer.

The rail being rolled in two parts, it is obvious that either can be renewed without discarding the other, thus insuring maximum wear with minimum waste of rail and with little disturbance to the pavement.

FLOOD'S CAR STARTER FOR GRADES.

The heavy currents usually required to start a car from a dead standstill to its normal speed are sufficiently marked even on a level track, but become a source of much annoyance and not infrequently of harmful strain upon the machinery, as in this case the car is obliged frequently to start with the brakes on, this latter condition being necessitated in order to prevent the car from running backwards down hill.

To avoid these necessarily excessive strains, and, indeed, to assist the motor in its work of starting the car, Mr. P. Flood, of Albany, has designed a simple car starter.

FIG. 1.—THE FLOOD CAR STARTER.

This starter consists of a dog or engaging bar, the end of which is pointed to facilitate its engagement in the pavement or ground between the tracks, and is pivoted to a sliding bar running under the rollers which reduces the friction to a minimum. On the sliding bar is a spring which compresses with the load, and so that the compression will be proportionate to the load. Thus, as soon as the car starts forward the resilient force of the springs aids in propelling the car in its forward movement.

The accompanying engraving, Fig. 1, shows a view of the car with the starter attached, and Fig. 2 shows a view of the details of the apparatus, which are exceedingly simple. The dog serves as a check or stop to prevent the car from running backward, and could, and is meant to, be used should the brake fail. It is operated by the driver by raising and lowering a foot lever attached to the dog by cables running on pulleys. When he wishes to stop on a hill, he drops the dog, applies the brake, and when the car stops, releases it, allowing the weight of the car to rest on the dog. The great advantage over the old way in starting with the brake on, and what a saving of power there is achieved, will be readily apparent.

These starters are in use on all the thirty-two cars of the Albany Railway Company, Albany, N. Y., and have proved so satisfactory that no car is allowed on the road unless equipped with one.

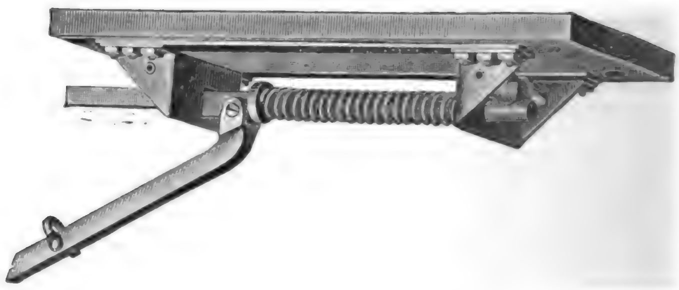


FIG. 2.—FLOOD'S CAR STARTER.

The grades on this road are amongst the steepest in the country, but with this starter the cars are able to stop when and where they please. They are simple and easily kept in order, and do not interfere with the wiring or motor mechanism of electric cars, and can be placed on any style of car or truck. If needed they can be attached to both ends of the truck.

PRIVATE TELEPHONE LINES IN GERMANY.

The German postoffice until recently held the sole right of erecting or licensing private telephone installations, thus practically prohibiting the development of telephony in Germany. On July 10 the Royal High Court of Justice decided, however, that the government had no right to restrain or prohibit the plaintiff erecting and maintaining private telephone installations. The decision was an important one, as it released private enterprise.

NEW ELECTRIC ROAD AT RICHMOND, VA.

Newspapers from Richmond report the successful starting up of the new road of the South Side Land and Improvement Company, equipped by the Equitable Electric Construction Company, of Philadelphia, whose noiseless gearing gives great satisfaction. The road starts with five cars of the vestibule pattern.

LITERATURE.

Incandescent Electric Lighting. By L. H. Latimer, C. J. Field and John W. Howell. Illus. Paper. 140 pages. Van Nostrand Science Series. D. Van Nostrand Co. New York, 1890. 50 cents.

THIS admirable addition to an admirable series comprises three papers. The first is "A Practical Description of the Edison System," by W. Latimer. It enters into a variety of details, and touches upon all points of interest with intelligence and success. The generator, lamp, meter, and other parts of the system are discussed in such a manner as to be useful even to those who do not follow electrical engineering as a profession. The next paper, that by Mr. Field, deals with "The Design and Operation of Incandescent Stations." It is based on Mr. Field's experience, especially that gained in the fine station built and equipped by him in Brooklyn. The third paper by Mr. Howell treats of "The Maximum Efficiency of Incandescent Lamps." It was read some time ago before the American Institute of Electrical Engineers, and now appears as a welcome permanent addition to the meagre literature of the glow lamp. It shows just what are the true conditions to aim at in running a plant, and formulates the law that the total cost is always a minimum when the cost of lamps is about 14.5 or 15 per cent. of the total cost of operation. Altogether the book is one we can heartily recommend.

Generation, Distribution and Measurement of Electric Current for Light and Power. By A. J. Lawson. M. Can. Soc. C. E. A paper read before the Canadian Society of Civil Engineers. Montreal, 1890. Printed for the Society by John Lovell & Son.

THIS is an extremely interesting review of the subject suggested by the title, and embraces, moreover, a valuable historical sketch of the development of electric light and power in the Dominion. Mr. Lawson has collated his facts with great industry and handled them with no less intelligence, and his paper is, so far as we know, the only treatise of its kind thus far published in Canada.

It is not necessary for us to go over the technical matter that forms a large part of the pamphlet, since it is an old story to our readers, but we may note the fullness of data as to many of the details, and approve the practical advice that Mr. Lawson gives in a kind of running comment. He is also to be praised for supplementing the text with so many excellent illustrations. Speaking of the work done in Canada, Mr. Lawson says that ten years ago there was not a single electric lighting plant in Canada. The first installations were of the Brush system, a pioneer evidently in the Dominion in arc work, as well as everywhere else. In 1882, two Maxim incandescent plants were installed in Montreal. In one instance, earth return was used, and in the other mere single cotton-wound magnet wire was used. The same year a contract was closed for a large Edison installation at Cornwall. At the present time—says Mr. Lawson in his paper, which is now a few months old—there are 13,530 arc lights in the Dominion and about 70,765 incandescents. Mr. Lawson states that 4,520 h. p. of water powers is used in lighting and motor work. He hazards the opinion that within the next ten years, three-fourths of the incandescent lighting in Canada will be done by the alternating system, while a large proportion of the mills and factories within five and ten miles of water power will be operated by electric motors by means of that natural agency.

ELECTRIC RAILWAY WORK AT OTTAWA, CAN.

A great sensation has been caused in Ottawa by the award to Ahearn & Soper of the electric railway contract by the city aldermen instead of to Howland & Gemmill. The *Free Press* of October 21 says: "The offer of Messrs. Ahearn & Soper to construct the proposed electric street railway has created a sensation, and the matter was the topic of general conversation to-day. Messrs. Ahearn & Soper began the electrical business in Ottawa in 1883. Reference to Dun, Wiman & Co., shows that the firm is to-day rated at from $150,000 to $200,000, and while the business they have done has largely been in contracts outside of Ottawa, they have built up an electric light business here that has been characterized as the most successful in Canada. Their principal contracts have been with the C. P. R., Bell Telephone Company, Mackay-Bennett Cable Company, of New York, North American Telegraph Company, and many other corporations of a more or less influential character. The Chaudiere Electric Light Company was organized by Messrs. Ahearn & Soper, with a capital of $400,000, which has since been increased to $500,000, and the stock of the company is now at a premium of 125. For the last four years the firm have employed from forty to fifty men, who are residents of Ottawa, on construction work from spring to fall."

LETTERS TO THE EDITOR.

Notice to Correspondents.

We do not hold ourselves responsible for the opinions of our correspondents.

Anonymous communications cannot be noticed.

The Editor respectfully requests that all communications may be drawn up as briefly and as much to the point as possible.

In order to facilitate reference, correspondents, when referring to any letter previously inserted will oblige by mentioning the serial number of such letter, and of the page on which it appears.

Sketches and drawings for illustrations should be on separate pieces of paper.

All communications should be addressed EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

THE HEDGEHOG TRANSFORMER.

[142.] We notice that you say in a note that a hedgehog transformer is admittedly less efficient at full load than a closed iron circuit. There is a general impression to this effect, but we think it is unfounded. Mr. Swinburne, in his British Association paper last year, showed that a "hedgehog" could be made more efficient than any possible form of closed iron circuit, unless some new brand of iron is discovered.

In England, where low frequencies and high pressure are used, quite small hedgehogs give 95 per cent. efficiency. In America low pressures admit of larger wires, and high frequencies are used, and some transformers we are sending over give 96 per cent. We do not consider full load efficiency of much importance, but this point is worth mentioning.

SWINBURNE & CO.

LONDON, Sept. 25, 1890.

EFFICIENCY OF TRANSFORMERS.

[143.] Mr. Steinmetz's letter, in your issue of Sept. 3, criticises my statement that the maximum value of the primary current corresponds with the zero value of the E. M. F. if there are no Foucault currents, and he points out that if there is also no hysteresis, and if the primary E. M. F. varies harmonically, the primary current does too, and does not lag a quarter of a period, but a little less, so as to allow for the waste of power in the primary coils. This is quite true, and admitted, assuming μ to be invariable, but the primary loss due to the magnetizing current is, I imagine, about $\frac{1}{10}$ of a watt, or something of that sort, and would not show on the curve referred to. I did not, however, refer to the primary E. M. F. in particular, and if Mr. Steinmetz will look up the curve referred to he will find the maximum value of the primary current is also before the zero of the secondary pressure.

Mr. Steinmetz also accuses me of stating that the Foucault current curve must be similar to the primary current curve; I said similar to the electromotive force curve. Neglecting the magnetizing current, it is similar to both primary and secondary E. M. F. curves; so we are agreed as to this point. I cannot see how either Foucault or secondary currents can give back power to the primary circuit unless these circuits have capacity or self-induction. To give the effects in Ryan Plate XIII., p. 19, enormous electrostatic capacity would have to exist in the circuits of the Foucault currents, which is impossible.

Mr. Steinmetz has, I am afraid, misunderstood what I said about the resistance of the incandescent lamps used to measure the primary current. I did not refer to any difference of resistance under a direct and an equal effective alternating current or pressure, but to chance of error through accidental confusion of the instantaneous and the effective pressure on the lamp or lamps. Prof. Ryan has kindly cleared up this point, showing that no such error was made.

JAS. SWINBURNE.

WIMBLEDON, LONDON, Sept. 23, 1890.

THE CANADA-AUSTRALIAN CABLE.

With regard to the projected cable between Canada and Australia, a cable dispatch from Ottawa of October 21 says: "Sir John Pender has informed Mr. Sanford Fleming that he hopes to visit Hong Kong next year by way of Canada, 'traveling by the Canadian Pacific line, when I hope to inspect that wonderful undertaking in which you have played such a prominent part, and at the same time discuss with you the best means of establishing closer telegraphic communication between Canada and the Australian colonies, when the time is ripe for carrying out the work.'"

The friends of the Eastern Telegraph Company have at last to recognize the absolute necessity for an alternative cable to Australia by way of Canada and the Pacific. In the same letter the chairman of the Eastern Company says:

"If the various governments interested are determined to have a line across the Pacific, and are prepared to incur the requisite expenditures for the purpose, I am quite ready, as I have always told you, to co-operate in carrying out the work on fair and reasonable terms. In this way the object might be obtained more easily and economically than if the third parties were employed."

Mr. Fleming says in his reply that the means taken to establish the new telegraphic communication are entirely secondary, provided that the new line be secured.

EUROPEAN CORRESPONDENCE.

LONDON.

Electric Lighting in English Towns.—Electric Lighting in Tramcars.—Telegraphs in Australia.—Telephones in Madrid.—The Johnson Storage Battery.

ALTHOUGH the Electric Lighting Acts clearly define the responsibilities of municipal bodies in respect to lighting, scarcely a week passes by without a stormy meeting, occasioned by the proposed introduction of electricity. The disagreement among the town authorities is followed by a meeting of ratepayers which often-times ends in a row. Similar public meeting have recently been held in Woking and Lewes, but though the friends of electric lighting in the last named place had the best of the argument, the matter was adjourned to enable the worthy townsmen to think over the matter. When the question primarily comes before a Town Council, the plan is usually adopted of sending a few members on a central station tour, which naturally includes London. After having an agreeable time of it and spending a good deal of money (ratepayers'), they return home greatly impressed with the wonders of electricity, and hand the whole business over to a private company.

The towns of Gravesend, Burton, Nelson, Pemberton, Reading, Heckmondwike and Stockport are considering the question of lighting by electricity. It is expected that most of these places will be worked by private enterprise.

An experiment of electrically lighting tramcars has been carried out by means of accumulators.

The report of the Superintendent of Electric Telegraphs of Queensland, Australia, states that there are now 9,662 miles of line and 17,193 miles of wire open for public business. During the twelve months reviewed by the report, great damage has been done to the lines. The total number of interruptions from various causes was 1,007.

The restrictive conditions in regard to telephones which have hitherto held in Madrid, are, I hear, about to be removed. Should this be the case, there will be a considerable development for apparatus somewhere.

A set of secondary batteries, manufactured by the Johnson Electric Supply Company, of Boston, U. S. A., has been exhibited to a few technical men in London. The importers of the battery stated they had the storage battery of the future, as its capacity, efficiency, and durability, as well as cheapness of construction, were absolutely unprecedented. The set shown had been discharged at the works at Boston, and gave a capacity of 260 ampere-hours working at 13.5 amperes; the E. M. F. at the commencement was 22 volts, and at the end of the discharge 18.91 volts. 33 lbs. was said to be the weight of the electrodes in each cell; the total weight of each complete element, however, was not given. The performance certainly was not any better than that of the well known English types of storage batteries. Nothing can be said as to durability, as the oldest have only been in use two years. As to cost, it is not easy to see why the plates on exhibition should be cheaper than those already in the market.

LONDON, Oct. 15th, 1890.

CORRESPONDENCE.

PHILADELPHIA.

Electric Cranes for Locomotive Works.—"Protectors" on Telephone Circuits.—Electric Railway Work.—Lapsed Privileges.

A DECIDED novelty in the mechanical world are the two immense cranes in course of construction by William Sellers & Co., of this city, for Baldwin's Locomotive Works. The cranes are being built in the shape of two large bridges, running upon tracks, with two trolleys, or carriages, each capable of lifting fifty tons. Two 40 h. p. electric motors are to be used in operating each crane. The motors are carried on the bridges, and the electricity conveyed to the cranes through two copper rods. The cranes will move rapidly in every way, and are capable of running along the shops at the rate of 200 feet per minute, the hoists from 5 to 40 feet per minute, and the carriages will run across the bridges at 100 feet per minute. The company will also build three smaller cranes for the Baldwins, all to be operated by electricity.

Suit was brought recently against the Bell Telephone Co. by the Brown Electric Protector Co., and damages to the extent of $100,-000 are asked because the Bell Co. recently issued a circular to its subscribers warning them against using the Brown protector on the ground that it is a "fruitful cause of annoyance and interruption." The reason the circular was issued, it is said, is that the Bell Company is interested in the sale of a protector invented by Dr. Plush, general manager of the Bell Telephone Co. in Philadelphia.

The People's Passenger Railway Co., of this city, contemplates introducing an ordinance in Councils asking permission to erect poles and electric wires on the Lombard and South streets branch. This includes both streets east of the Schuylkill River to Front street, and north on Front street to Market. In West Philadelphia, the line is known as the West End Branch, which is leased by the Lombard and South.

The ordinance will include Lombard and South streets as far west as Woodland avenue, Woodland avenue to Thirty-ninth street, and Baltimore avenue to Angora. It is said that the Spruce and Pine Streets Road will also ask permission to erect poles and electric wires.

The residents of the extreme western portions of West Philadelphia are urging the Traction Company to provide for the more frequent running of cars from the depot at Forty-first street, and to extend their tracks further west. Electric cars run by the overhead wire system are also wanted. A committee has been appointed to wait upon the officials of the company and request them to make these changes.

Another improvement will be the extension of the present line, running from Eighth and Dauphin streets to Chestnut Hill by way of Main street. The company is disposed to do away with its horses, if Councils grants it permission to erect overhead electric wires for the use of its cars. If successful in this attempt six four-inch iron poles, neat in construction, will be placed in every square of road over which the line is operated. Three such poles, in place of the ugly and unsightly telegraph poles, will be placed on each side of the street, and each pole will carry five incandescent lights. This illumination of the streets will be furnished to the city free. At present the cars are run on eight-minutes time. Under the proposed plan the cars will be run every three minutes.

The Traction Company also has in contemplation some important extensions, which will do a great deal toward developing hitherto neglected portions of the city. Electricity will be the motive power and surveys of the route have already been made, and it is expected that the work of construction will begin next year.

In response to a resolution passed at the last meeting of Select Council the Mayor sent that body this list of electrical companies which have not availed themselves of privileges granted by Councils: Atlantic and Pacific Telegraph, Municipal Telegraph, Underground Electric Conduit, Metropolitan Underground Telephone, Telegraph, Electric Light and Power, Continental Underground Cable, Morse Underground Conduit, People's Underground Electric Light, Cosmopolitan Telephone, Telegraph, and Electric Light, Bankers' and Merchants' Telegraph, Electro-Pneumatic Transit, Philadelphia Time Telegraph, Western Union Telegraph, and Postal Telegraph. The privileges of most of these companies under the license granted by Councils have expired. Mr. Moffett moved that a special committee of seven members from each Chamber be appointed to consider the report, which was agreed to.

PHILADELPHIA, Oct. 25, 1890.

PITTSBURGH.

Westinghouse Manufacturing Extensions.—Electric Railway Work.—Electricity in the Mines.

THE Westinghouse Electric & Manufacturing Company has just completed some very extensive improvements in the factory on Garrison alley, in this city, for the purpose of increasing the capacity of the street railway motor department. The company has added a number of new tools to the machine shop, and by that means the production of the motors will be much larger than it has been heretofore. The motor department has been increased by six gear cutting machines manufactured by Gould & Eberhardt; one Knowles key-seating machine; twenty new lathes have been added, as well as two new drill presses, six milling machines, two planers, several shapers and a special boring mill.

By the first of December, so it is promised, the Duquesne Traction Company will have its system of electric roads in operation. The company's lines cover the largest part of Pittsburgh, extending altogether for about twelve miles. Forty cars will be operated on the road, and the Pullman company is about to ship the first lot of them very shortly. The big power house is about completed and motor generators have been placed in position.

The Braddock borough council a few days ago granted the right of way through the town to the Braddock Electric Street Railway Company, which contemplates building a road through Braddock borough and township to connect with the Duquesne Traction Company's lines at Wilkinsburg. Work will be commenced almost immediately, and the cars are to be in operation in less than a year.

The Squirrel Hill Electric Railroad has been sold at auction for $25,000. The name of the purchaser could not be learned, but it is understood that the road was bought by the Pittsburgh Traction Company, and that that corporation intends to go immediately ahead and finish the construction of the line. When completed,

it will open up one of the most desirable locations of Pittsburgh for private residences.

The authorities of Kingwood, Va., are now making an investigation into the different systems of electric lighting with a view of establishing a plant to light up the streets and public buildings.

The introduction of electricity in the coal mines of Pennsylvania is finding great opposition among the coal miners, who aver that the electric mining machines displace a number of men. The coal operators, however, do not pay much attention to this agitation, and mining machines are becoming more general every week. The operators state that the introduction of mining machines operated by electricity is the only means they have by which they can make their business pay. When the production of coal depended chiefly upon the miners, the cost of operating a mine was so large, and miners' wages were cut down so low that no Americans could be induced to work at coal mining. The coal business was in fact going down from bad to worse. In this emergency the advent of the mining machine was hailed with delight by the operators, and wherever mines are using electric power the company not only can afford to pay its men good wages but the business also makes a good profit to the operators.

PITTSBURGH, Oct. 24, 1890.

BOSTON.

Wire Matters.—Electric Elevated Railroads.

THE main office of the Western Union Telegraph Company's building, at 109 State street, was somewhat damaged by fire this week by one of their wires coming into contact with an electric light wire, caused by the high wind storms. The damage was, however, slight, and business was only hindered for a day or so.

At a meeting of the Common Council the ordinance for the regulation of the supervision of electric wires was assigned to the next meeting.

At a meeting of the Board of Aldermen the Edison Electric Illuminating Company was authorized to lay and maintain underground conductors for electric wires in a number of streets. The same privilege was extended to the Western Union Telegraph Company. Through the efforts of Aldermen Wilson and Carruth the privilege of opening those streets is limited to December 31.

The Street Commission gave a public hearing this week on the proposed widening of certain streets, and the making of new streets, required for the elevated road of Boston, should it be granted the privilege of building. Mr. H. M. Whitney, in the interests of the West End Street Railway Company, made an eloquent address, giving many statistics of the amount of daily travel in Boston, and maintained that whether an elevated road were built or not, the changes proposed would be of immense value to the city, predicting that if they were not made now they would have to be made some time, at a much greater cost, to relieve the daily increasing traffic on Washington street. In the course of his remarks he made the following statement, which I give verbatim, as it may serve as an encouragement to some street railway magnates who are hesitating about adopting electricity as a means of propulsion: "If our experience stands for anything in connection with the introduction of the electric system, it shows this—that where people traveled once over the horse car system before the electrics were put in, somehow or other there is a very large increase, in some cases amounting to almost 50 per cent." The hearing was adjourned, and will be continued next Monday, the 27th inst.

BOSTON, MASS., Oct. 25, 1890.

CHICAGO.

Opposition to Overhead Lines.—New Alternating Current Motor.—Meeting of the Electric Club.

THE electric companies in Hyde Park and Englewood are having some trouble with their overhead wires. The Hyde Park District Telegraph Company and the Englewood Electric Light and Power Company started to erect poles along Sixty-first street last week. Each company endeavored to forestall the other, when the citizens stepped in and put an end to the quarrel by petitioning Commissioner Purdy yesterday against the poles. He revoked the permits of the companies and sent to each of them a letter ordering them to make a plan of the streets upon which they have rights and to specify in detail what they propose to do.

Your representative recently witnessed the performance of an alternating current motor which appears to possess some remarkable points of merit. This machine is the invention of Mr. Wm. M. Dresskel, of Brainerd, Minn., and is the perfected outcome of an immense amount of work done by Mr. Dresskel in this line. The machine is of the multipolar type, fitted with a peculiar form of commutator, and operates equally well either on the direct or on the alternating current without any changes being made in the machine. It requires but two wires, and can be attached anywhere between the secondary mains of an ordinary installation, when it will start in the direction desired, is instantaneously reversible by a turn of the switch, and starts up with quite a powerful torque. In fact, it seems to meet a long felt want, and if the large sizes give equally satisfactory results it will receive widespread adoption.

On Monday evening, Oct. 19th, the first regular meeting of the Club was held, being preceded by a meeting of the board of managers, when the following gentlemen were elected as resident members: John P. Barrett, Chas. A. Brown, George S. Searing, Robt. C. Clowry, Elisha Gray, W. J. Chalmers, Thos. M. Brooks. E. R. Gilman was elected a non-resident member.

After the meeting of the board of managers, at which various committees were appointed and vacant posts filled, the regular club meeting took place, in the parlors of the club; in the absence of President Beach, Prof. Badt, first vice-president, occupied the chair. Mr. B. E. Sunny then read a most interesting and able paper on "The Central Lighting Station as an Investment." Prof. Badt gave notice of certain amendments to the by-laws, the same to be posted in the club rooms, the principal among which was that resident members shall pay an entrance fee of $50 and annual dues of $40. On recommendation of the board of managers an assessment of $10 was ordered to be levied on all the members.

CHICAGO, Oct. 22, 1890.

SOCIETY AND CLUB NOTES.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

At the regular monthly meeting of the Council held on Oct. 21, the following gentlemen, 19 in number, were, on examination and approval of credentials, duly admitted to associate membership:—

Abbott, Arthur V., Mechanical Engineer, United Electric Traction Co., Closter, N. J.

Bulkley, J. Norman, Superintendent, U. S. Aluminum Metal Co., Boonton, N. J.

Colley, Benjamin W., First Ass't Superintendent, The Commercial Cable Co., Hazel Hill, N. S.

Fessenden, Reginald A., Assistant Electrician, U. S. Electric Light Co., Newark, N. J.

Fitch, Graham D., First Lieut., Corps of Engineers, U. S. A., Duluth, Minn.

Gaines, J. D., Second Ass't Superintendent, The Commercial Cable Co., Hazel Hill, N. S.

Lloyd, Robert McA., Electrician of the Marion, N. J., Factory, United Electric Traction Co., 2 W. 36th St., New York City.

Martin, F., Inspector of Isolated Plants, Edison Electric Illuminating Co., of N. Y., 16 Oak St., Newark, N. J.

Martin, J., Electrician, Hanson, Van Winkle & Co., 16 Oak St., Newark, N. J.

Miller, Wm. C., Gen. Man., Watervliet Turnpike & R. R. Co., 3 South Hawk Street, Albany, N. Y.

Perkins, Frank C., Student in Electrical Engineering, Cornell University, Ithaca, N. Y.

Reid, Thorburn, Consulting Electrical Engineer and Expert, 15 Wall and 26 E. 33d Sts., New York City.

Rosenberg, E. M., Supt. Manhattan E. L. Co., 80th St., and Ave. B., residence, 784 Lexington Ave., N. Y. City.

Schmid, Albert, Superintendent, Westinghouse Electric & Mfg. Co., Pittsburgh, Pa.

Sheble, Franklin, Electrical Engineer, Thomson-Houston Electric Co., Lynn, Mass.

Watson, Robert, The Elektron Mfg. Co., 79 Washington St., Brooklyn, N. Y.

Webb, Herbert Laws, Assistant Electrician, The Metropolitan Telephone and Telegraph Co., 18 Cortlandt, N. Y. City.

Weller, Harry W., Railroad Inspector, The Edison General Electric Co., Edison Building, Broad Street, and Jamaica, N. Y.

Wright, John D., Electrician's Assistant, United Electric Traction Co., 107 Garrison Ave., Jersey City, N. J.

The same evening, the monthly meeting of the Institute was held, President Anthony in the chair, when a paper was presented, entitled, an "Investigation of the Stanley Alternate Current Arc Dynamo," by W. B. Tobey and G. H. Walbridge. A brief description of the machine was given, and curves shown, giving diagrammatically the values of E. M. F. current, and watts for any part of a complete period; also the position of these curves relatively to the poles for different loads, thus showing the method of regulation; also curves of efficiency and regulation. The methods of obtaning these results was outlined.

Mr. Thorburn Reid also presented "A New Method of Analyzing Armature Reactions, Applied to the Stanley Arc Light Alternating Current Machine," printed for distribution at the meeting.

A motion was introduced by Mr. T. C. Martin and carried, giving the support of the Institute to the petition of the National Electric Light Association, asking Congress for a special census and report on the electrical industries of the country and for the sum of $50,000 to be placed for that purpose in the hands of the Census Office.

FINANCIAL MARKET.

QUOTATIONS ON ELECTRICAL STOCKS.

Mr. F. Z. Maguire, Electrical Securities, of 18 Wall street, this city, reports the following quotations of October 25th, from New York, Boston and Washington:

BROOKLYN INSTITUTE—ELECTRICAL DEPARTMENT.

At the regular meeting October 24th, of the Electrical Department of the Brooklyn Institute, twenty new members joined the department.

On account of Dr. S. S. Wheeler's illness, his promised lecture on "Some Applications of Electricity" had to be postponed, but the time was ably filled in by Prof. Samuel Sheldon, with a few remarks on "The Magnetic Circuit," and Mr Hewitt's discussion of "Some Electric Railway Questions."

On Friday, October 31st, an exhibit of electric batteries of various forms, will be given by members and other electricans in the lecture hall of the Union for Christian Work, 67 Schermerhorn street, near Court street, Brooklyn.

ELECTRIC MINING IN EL DORADO COUNTY, CAL.

The first practical demonstration of electric transmission of power for mining purposes in California has been inaugurated by the American River Syndicate in El Dorado County—an English organization under the management of Mr. George Cullen Pearson. The power station is located on Rock Creek, some 1,500 feet below the mine and mill and two miles distant in a straight line.

The plant consists of an 8-foot Pelton wheel, which, running under a head of 110 feet at 100 revolutions with a 5½ inch nozzle, has a maximum capacity of 130 horse-power. To this wheel is connected a 100-horse-power Brush generator, speeded at 900 revolutions, the current from which is carried to the mill through a single insulated copper wire, No. 3, B. & S. gauge, the return being made by a wire of the same size, making a four-mile circuit. The power from the generator is communicated to the countershaft of the mill by a 70 h. p. Brush motor running at 950 revolutions.

The machinery-operated consists of three centrifugal roller mills, a ten-stamp battery and a rock breaker. The Pelton wheel under these conditions shows an efficiency of 86 per cent., while 85 per cent. of the power thus generated is available for duty at the mill, though only 70 per cent. was called for in the contract with the Brush company. Sufficient power is taken from the main circuit to run sixty incandescent lamps for lighting the works, the current being cut in by means of the Brush multiple series cut-out box, which admits the incandescent lights being operated by a high-tension current.

The company owning their own water right, the operating expenses of this plant are almost nominal; only one attendant is required at the power station, and this not an electrical expert, but one of the company's employés. This equipment has now been in constant operation for five months and is a most pronounced success, no interruption to the service of any moment having occurred during this time. The mills named are handling an average of 4,000 tons of ore per month, effecting a saving of some 60 per cent. over the former method of working by steam power, estimating wood at $3.50 per cord, while the cost of maintenance is about as 5 to 1 in favor of electricity.

INVENTORS' RECORD.

Patents issued October 21.

Alarms and Signals:—*Electrical Water-Alarm*, F. M. Ashton, 438,598. *Electric Guest-Call*, A. Striemer, 438,658. *Electric Station Indicator*, G. H. Kirwan, 439,015.

Clocks:—*Electro-Pneumatic Clock*, V. Popp, 438,767.

Conductors, Conduits and Insulators:—*Insulating Composition*, A. E. Menuez, 438,698. *Device for Automatically Insulating Broken Wire*, M. Kerstein, 438,814. *Insulator*, F. Miro, 438,934.

Dynamos and Motors:—*Alternating-Current Generator and Motor*, C. S. Bradley, 438,602. *Electric Motor*, C. S. Bradley, 438,603. *Electric Motor*, E. Thomson, 438,656. *Brush-Holder for Dynamo-Electric Machines*, C. F. Winkler, 438,668. *Apparatus for the Rythmic Generation of Electric Currents*, C. Langdon-Davies, 439,017. *Electrical Transmission of Power*, W. Stanley, Jr., 439,042.

REPORTS OF COMPANIES.

AMERICAN BELL TELEPHONE OUTPUT.

The Bell Telephone Company reports the net output of instruments for the month ended October 20, as 3,173, a decrease of 198 compared with last year. This makes 476,333 instruments in use October 20, a gain of 2,976 over a year ago that date. The statement is as below:

Month Oct. 20.	1890.	1889.	Increase.
Shipments	5,378	5,152	226
Returned	2,205	1,781	424
Net output	3,173	3,371	*198
Since Dec. 20.	1889–90.	1888–89.	
Shipments	53,787	48,394	5,393
Returned	22,315	19,898	2,417
Net output	31,472	28,496	2,976
Instruments in use Oct. 20	476,333	440,037	36,296

*Decrease.

ELECTRIC RAILROADING AT SPRINGFIELD, MASS.

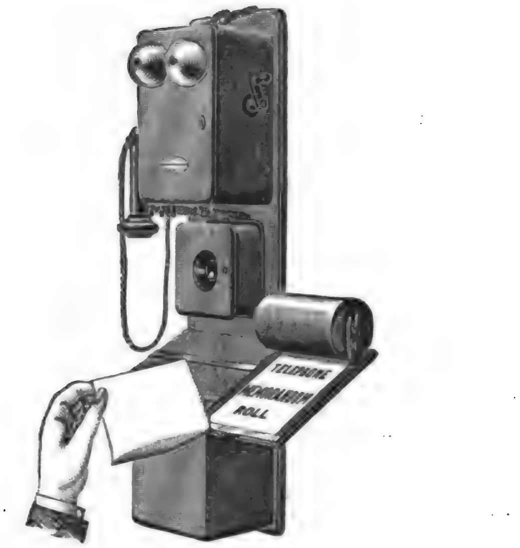
In our last issue, mention was made of the fact that the Springfield Street Railway Co. were going in for electric traction. The company has a capital stock of $400,000, and Mr. S. W. Munsell writes us that it will petition the State Board of Railroad Commissioners for leave to increase the capital stock $300,000. At the meeting held Oct. 18, it was voted to authorize the directors to adopt the overhead system, and to petition the city government for overhead privileges. John Olmstead is president of the company, and A. E. Smith, manager. It is understood that a Westinghouse car or two will be put on the road as soon as possible, and that the Holyoke Street Railway Co. will follow the Springfield example as to the adoption of electricity.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT

TATUM'S TELEPHONE ATTACHMENT.

The frequency with which orders are transmitted by telephone, and the numerous other occasions when it is desirable to make a record of the conversation, renders a convenient tablet alongside the telephone a thing of necessity. To afford a convenient adjunct to the telephone the Tatum telephone attachment, which is illustrated



TATUM'S TELEPHONE ATTACHMENT.

in the accompanying engraving, has been designed. As will be seen, it consists of a small tablet provided with a roll of paper. The arrangement is attached to the side of the box without the use of a screw, which telephone companies forbid, and hence can give rise to no objection from that quarter. The paper being in the form of a roll it is always in place, and there are no waste or loose leaves. The board is made of walnut, with nickel-plated trimmings. Messrs. Tommins & Adams, of 116 Chambers street this city, are the sole agents for the attachment.

WESTERN WORK OF THE THOMSON-HOUSTON CO.

The Chicago City Railway Co. have for some years been using a Thomson-Houston incandescent dynamo for lighting their power house and offices near the corner of 20th and State streets, with such good economy and satisfaction, that they have decided to adopt the same system for lighting the new power house at the corner of 61st and State streets. It is much to the credit of President Holmes that he has been quick to avail himself of the many advantages afforded by the use of electricity, as indicated by his adoption of it on many of the street railway lines, outside of Chicago, in which he is interested, notably, Moline, Rock Island, Davenport and Indianapolis, and also for the purpose of lighting his power houses. The fact that he has adopted the Thomson-Houston system to the exclusion of others, may be looked upon as an indication that the system is all that its promoters claim for it.

Last month, the Illinois Steel Co. ordered of the Western Isolated Lighting Department of the Thomson-Houston Electric Co. a 30 arc light plant for their works at South Chicago. They have, during the past week, placed another order for a 35 arc light plant to be installed at the same place. This plant was delivered and set up ready for operation the day following that upon which the order was given. From this, it would appear that, even though the Thomson-Houston Co. do an enormous business, they manage to take care of it in a manner that tends to disprove the old adage that "large bodies move slowly." The day is not far distant when a man can drop into an electric light company's office in the forenoon, place his order, and find upon his arrival at home in the evening, that the wiring is finished and lights are ready to turn on, to furnish illumination for his dinner table.

Dernberg, Glick & Horner, N. E. corner State and Adams streets, Chicago, who were reported last week as having closed with the Thomson-Houston Co. for a 45 arc light plant, have also been equipped with an incandescent lighting outfit. This concern has recently started a large department store to be known as the "Leader" and they evidently appreciate the value of electric light, as besides purchasing isolated arc and incandescent plants, they have also contracted with the Chicago Arc Light & Power Co. for some arc lights to be suspended over the side-walks, on both Adams and State streets.

A DISTRICT BEER-CALL SYSTEM.

Quite a novel application of electricity is reported from an enterprising town in Texas, it being practically a system of district calls in answer to which a supply of beer is sent to any of the call stations. It so happens that a wide-a-wake merchant controls all the saloons in the place, as well as some ice-houses, and in order to save the expense of keeping a stock at each saloon he has hit upon the call system as the simplest and best medium. He accordingly carries but a small supply at each of the refreshment places, and keeps the bulk of beer and ice at one central point, from which a fresh lot can be promptly sent to any of the saloons on receipt of call from that point. The cost of installing the system is so low that it is expected to pay for itself very quickly by the saving effected in ice, to say nothing of the valuable additional convenience of such a service. The Great Western Electric Supply Company, of Chicago, have furnished the apparatus and supplies, and are confident that similar systems will be installed for use with other lines of merchandise, especially in the Southern and Western towns.

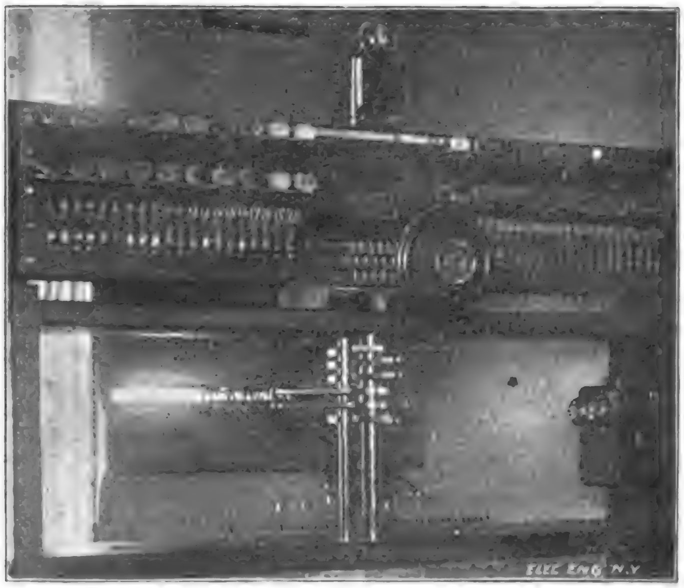
PROGRESS OF THE RAE ELECTRIC RAILWAY SYSTEM.

The Galveston, Tex., City Railway Co. has contracted with the Detroit Electrical Works, for a full electrical equipment of Rae motors and generators. The first installment of twenty motor cars and four generators with full station equipment, will be in operation on or before Jan. 1st, 1891. Col. Sinclair, president of the Galveston Railway system, made very exhaustive investigations of the various systems and his ultimate decision is a very high compliment to the Rae system.

The Detroit Electrical Works have forwarded to Portland, Ore., the first shipment of their standard 30 h. p. motors and trucks (Rae system), as the forerunner of a large order.

THE SHAVER TELEPHONE EXCHANGE AT LITTLETON, N. H.

The introduction of the Shaver mechanical telephone is being pushed with considerable vigor and one of the more recent installations is that of the exchange at Littleton, N. H. This exchange, which is illustrated in the accompanying engraving, has a capacity of 40 subscribers.



SHAVER MECHANICAL TELEPHONE EXCHANGE, LITTLETON, N. H.

The routes comprise numerous angles, the longest line being about three-fourths of a mile, and the longest connection through central is about one and three-eighths miles. According to local reports, the articulation is very satisfactory. The price charged for the service is $15 per annum; and the exchange is located in a drug store, where it is operated by the regular clerks.

The Shaver Corporation intend to install similar exchanges in neighboring towns in the same district.

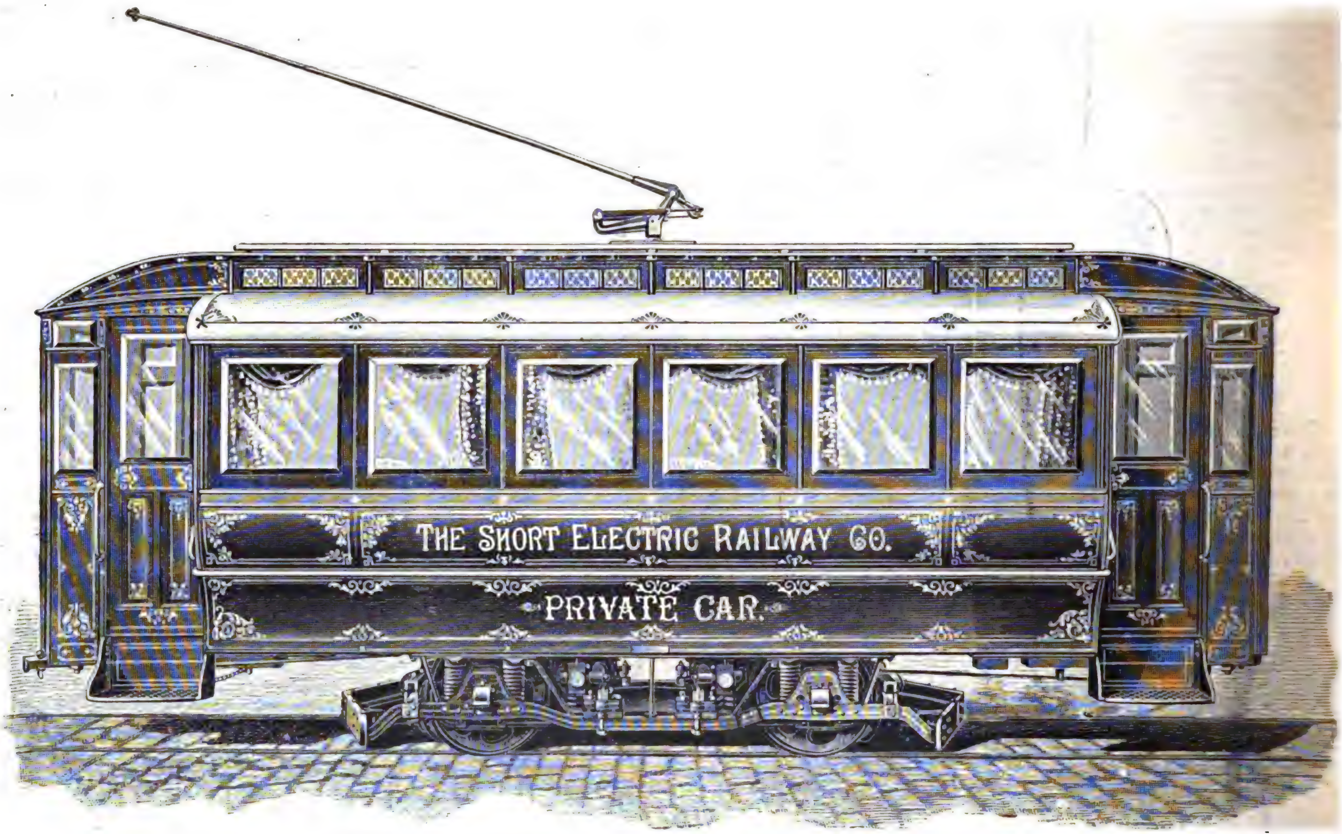
PRIVATE CAR OF THE SHORT ELECTRIC RAILWAY CO.

We present herewith a view of one of the most elegant and elaborately furnished electric street cars ever turned out from an American car shop. We are indebted to the *Street Railway Journal* for the engraving. The car, the body of which was built by the Gilbert Car Manufacturing Co., of Troy, N. Y., is intended for the use of the president of the Short Electric Railway Co. It is of the vestibule type, eighteen feet inside length and twenty-six feet over all.

The car and truck are painted black. The body is of carriage finish, ornamented with gold leaf and hand painted designs.

The truck which carries this car is from the J. G. Brill Co., Philadelphia, and is known as their No. 7 independent rigid motor truck. The car rides very easily on the running gear, which we understand is well liked by the Short company. The Stanwood perforated steps are used and the handles of the switch and brake levers are of bronze.

The interior finish is very handsome indeed. The headings are of embossed leather nailed on with medallion headed tacks; there are small panels of ornamented light-colored wood which relieve the sombre color of the leather, and from the two end panels the group of incandescent lamps are hung, each group having glass shades of different designs.



Short Electric Railway Co.'s Private Car, Cleveland, O.

The large heavy beveled glass windows are shaded by heavy silk damask curtains. The wood work is all mahogany and is wainscoted from floor to windows, and between every other window is a carved pilaster.

The furniture consists of twelve handsome rattan chairs in pairs, of different designs, some with high rolling backs and others with low backs and curved arms; they are upholstered in old-blue plush, almost a slate color, and the window ledges are covered with the same material. Corner chairs of rattan fit two diagonal corners and the other two have low stools upholstered with lockers underneath. Rich carpeting covers the floor.

The car is to be operated upon the company's tracks about the works in Cleveland, and will always be held in readiness to take the company's guests over any of the electric lines in the city. The company's tracks and trolley wire are connected with those of the East Cleveland line from which the current is derived for operating the works line, and which has switches connecting with the other city lines. This private car was on exhibition at the recent street railway convention at Buffalo, and was one of the most attractive features among the exhibits, hundreds of people passing through it every hour.

THE "A. B. C." INCANDESCENT LAMP.

Among the many evidences of enterprise on the part of the vigorous young firm of Alexander, Barney & Chapin, 20 Cortlandt street, is their production of a new incandescent lamp, which they call the "A. B. C." It is a lamp made under new and improved processes and for either high or low volt circuits. It is of excellent and symmetrical shape, and gives a clear pure, white light of the highest photometric value. It is made for any candle power.

The firm also announce that they handle Edison lamps at Edison prices, and carry all kinds of Edison supplies for central stations and isolated plants. Keeping an eye also on the rapid development of the new field of electric railroading, they are handling Thomson-Houston and Edison electric railway supplies. The indications are that they will be kept very busy in electric railway work. They are also giving their attention to wood screws and machine screws, especially adapted for electrical purposes. They are now carrying also a full line of line wires, office wires, magnet wires, etc., as well as underground cables of high insulation; electrical books, and a magnificent assortment of measuring and testing instruments. In fact, it would be hard to say where they draw the line, as they regard the whole boundless continent of electricity as their field.

W. R. FLEMING & CO.

W. R. Fleming & Co., of 174 Fulton street, New York City, the selling agents for the "Ide" and "Ideal" engines, simple and compound, and other manufactures of the foundry and machine department, Harrisburg, Pa., including steel return tubular boilers, report that they have just closed a very large contract for a complete steam plant to go to Mexico. This is the second order on account of the same electric company. Fleming & Co. state that they are having a great run on their engines, particularly the "Ideal," which is a centre crank automatic self-oiling engine. It is built very heavy for severe duty, and is held in great favor by the electric light and street railroad companies because of its simplicity, wonderfully close regulation, and little care it requires when running. All parts of the engine run in oil, and are accessible while the engine is in operation, without the removal of a single bolt or screw. Their side crank "Ide" engine is, they say, leading the market in the sale of its class.

NEW ENGINES OF THE FITCHBURG STEAM ENGINE COMPANY.

BY W. E. SHELDON.

THE economical use of fuel is a question pressing more and more upon manufacturers in this country, as competition reduces profits to a very small margin. This condition of things for the past few years has made the demand for a thoroughly economical engine, and this demand has been met by the production of the best compound and triple expansion types of engine. Where water can be easily obtained and the cost is slight, the subject of condensing and compounding will well pay a close investigation by any one thinking of purchasing an engine. In a compound engine, not only is the power increased at a less cost for fuel, but there is required but about two-thirds the usual boiler capacity to develop a given power and it is often true that sufficient additional power can be supplied for a large increase in the machinery of a mill without any increase of boiler plant and with a large saving in fuel. In the use of power for electric lighting and railway purposes the question of producing this power with the smallest quantity of fuel, has become a very important item, and the amount of money saved by using a good compound engine means so much toward a dividend to the stockholders at the end of the year. To meet the present demand for a first-class compound engine, we are prepared to furnish our "cross," our "twin" compound, "tandem" compound or high speed compound engines. Fig. 1 in this article represents our "cross" compound low speed engine, such as we are putting in for a great many electric light companies and street railway companies. In this engine we use our regular balanced double ported, piston valve, made positively expansible so that it can be kept perfectly tight at all times without any expense. The inlet valves are actuated by a wrist plate motion, giving a very sharp cut-off of steam and are worked

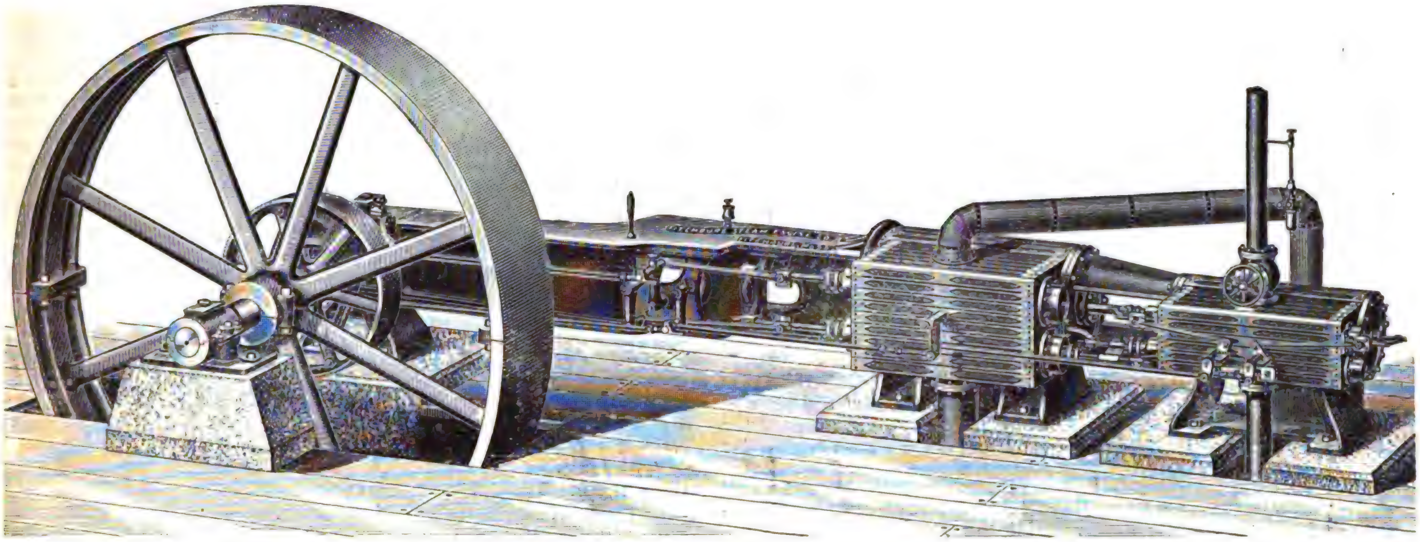


FIG. 2.—TANDEM COMPOUND ENGINE, FITCHBURG STEAM ENGINE CO.

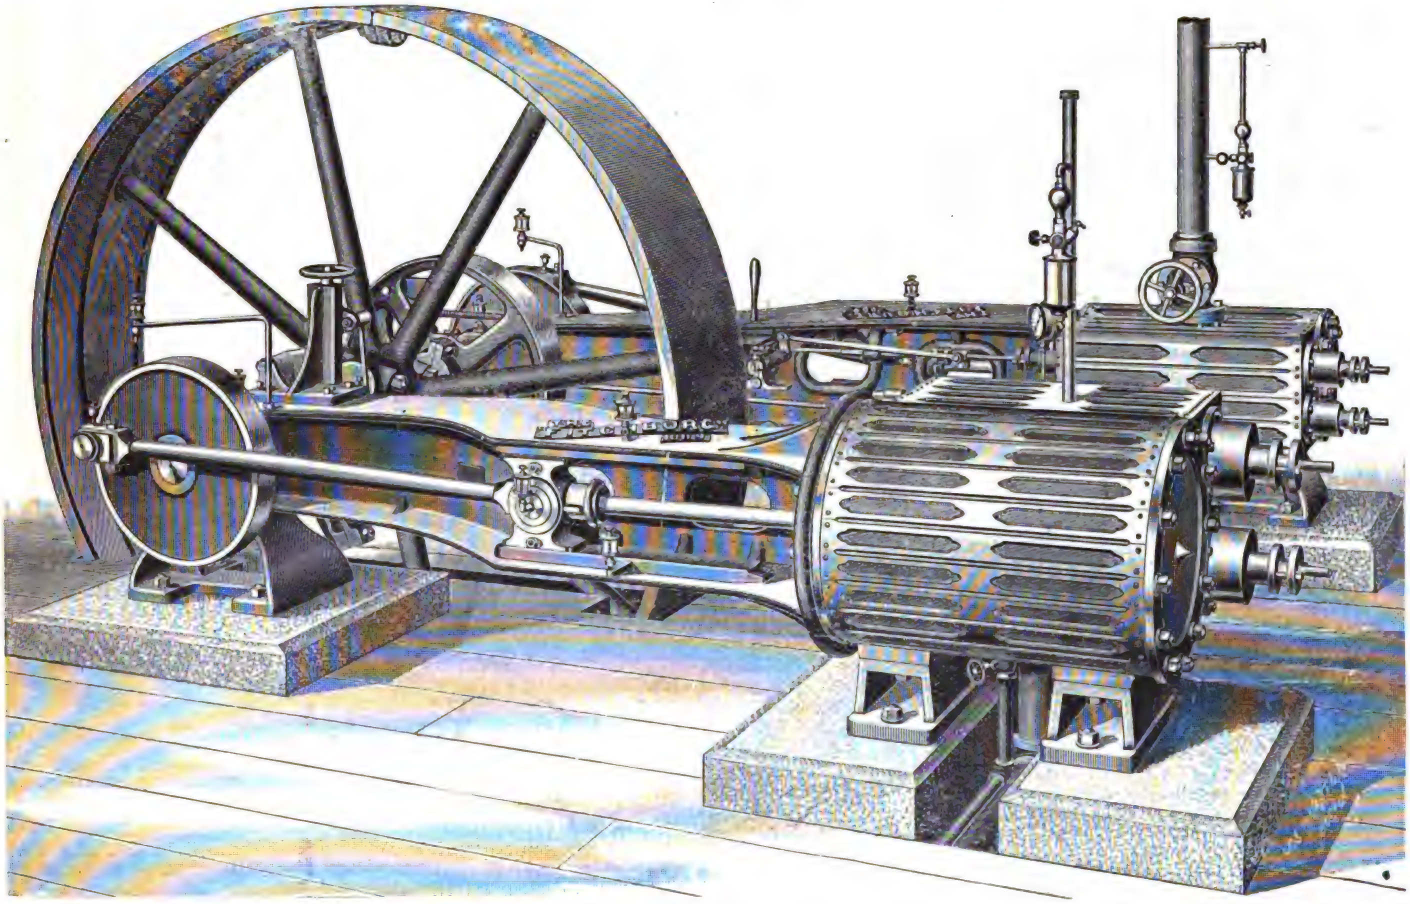

FIG. 1.—CROSS COMPOUND LOW SPEED ENGINE, FITCHBURG STEAM ENGINE CO.

directly from our shaft governor, the exhaust valves being run independently from an eccentric on the shaft.

Between the high pressure and low pressure cylinders we use a reheating receiver, the steam passing from the high pressure cylinder into the receiver, being superheated by means of live steam passed through the coils of the receiver. By this means we obtain the very best results when the steam reaches the low pressure cylinder. In the construction of these engines we have retained the first-class features of our regular horizontal engine, which is so well known in electric light circles. We use only the very best of material and workmanship in our construction, and we build all parts strictly in duplicate. This latter is a very important item, as accidents will happen in all engines. Our connecting rod boxes are of solid hard bronze: the crank and crosshead pins are of hardened steel, ground perfectly true after hardening; piston rods and valve rods are of steel, the valve rods being hardened and running in bushings inside the stuffing boxes; the connecting rods and shafts are solid forged iron and everything is of the very best throughout. The governor is of the "shaft governor" type, but unlike the majority of shaft governors, the large frictional surfaces are entirely done away with, thus preventing the sticking, and consequent jumping, of governor. We are at present putting in of this type two 250 h. p. engines for the Powelton Electric Light Co., Philadelphia, also two of 400 h. p. for the Suburban Electric Light Co., Tacony, Pa., and we have many others in use in electric light plants, as well as other places. As we use a short stroke we have an engine which takes up less room in length than that of many of our competitors.

In the second cut, Fig. 2 we represent our "tandem" compound engine, having both cylinders in one line, one cylinder in front of the other using one piston rod and one connecting rod for the two. This engine is sometimes better adapted for particular conditions than our "cross" compound, as it takes up considerably less room in width, although a little more in length. In this engine we use the same reheating receiver between the two cylinders and practically the same valve motion.

In addition to the two cuts shown we have also a strictly high speed engine, with centre crank, having two fly wheels, one on either side, and this we also furnish compound and compound condensing. We have had a large experience in fitting out complete power plants in electric light stations and are prepared to give estimates for complete plants, including engines, boilers, foundations, pumps, heaters, smoke stacks, etc., turning over to the purchaser the plant in complete running order.

THE WESTINGHOUSE ELECTRIC RAILWAY SYSTEM IN GREENSBURG, PA.

Last week, the Greensburg and Hempfield Electric Railway Company, of Greensburg, Pa., started the operation of their street car line. The road runs from the Pennsylvania railroad station through the principal streets of the town to Hempfield, a small suburb of Greensburg, a distance of 2¼ miles.

Greensburg had heretofore no street car line of any kind and the commencement of rapid transit by the electric system was quite an event in the history of the town. All the local papers had made an announcement of the occasion and of the hour at which the first car would come along the streets, and the public came out en masse to witness the turn out.

The road is operated with the Westinghouse system of electric motors and were not the success of that system already established, Greensburg afforded an excellent opportunity to make the final tests.

As was already stated above, the road is 2¼ miles long. In covering this distance, the cars have to climb no less than eight hills, and the majority of these hills incline at a grade of 10 per cent. In addition to the hills, however, the line is also peculiar on account of the large number of curves, all of them short ones. But in spite of all these obstacles to an easy and smooth operation of the motors, it is satisfactory to note that they have given more than excellent service from the moment the first car rolled out of the shed.

Owing to the novelty of rapid transit in Greensburg generally and of electrically propelled cars in particular, the Greensburg residents have taxed the capacity of the cars to their utmost limit. Every car has hitherto been crowded from the starting point to the terminus and return, the cars having carried on the average 75 passengers right along.

The track is composed of the Johnstown rail and the T-rail. With the exception of a short distance in the business portion of the town, where the tracks are laid on asphalt covered streets, the road bed has been stone ballasted.

The power house is situated near the terminus of the road at the foot of one of the steepest hills along the entire route. It is very comfortably arranged. The car shed and a repair shop are immediately attached to it, everything being situated level with the ground.

The motors are placed upon Brill trucks and the bodies of the cars are made by the Chester Car Company. The latter are very commodious and handsomely painted.

Mr. F. Y. Clopper, a well-known Greensburg business man, has charge of the road, and he expressed himself as being in every way satisfied with the equipment of the road, which he intimated could not have been better.

The North American Construction Company did the construction work on the Greensburg road.

WESTERN TRADE NOTES.

THE KNAPP ELECTRICAL WORKS are very busy and shipping orders both large and small of Grimshaw, White Core, and other grades of wire right along. They are also doing a brisk trade in their well known annunciators.

MR. MASON, general manager of The Electric Merchandise Co., has returned from his trip to the Buffalo street railway convention perfectly loaded down with orders for electric street railway supplies. Their exhibit in parlor F at the Iroquois Hotel was one of the most popular and interesting, and they added more prestige to their already wide reputation. All classes of their goods are in large demand, and they always take care to carry a stock of the older specialties and devices for roads equipped with the early class of supplies, as well as the latest designs and novelties. This is a feature specially appreciated by roads built some while back, who want some of the parts then used.

FOREE BAIN is in Minneapolis supervising the construction of the electric street railway there, for which he is the consulting electrical engineer. His shop on Market street is pushed to its utmost capacity on repair work, and turning out his now widely known motors and dynamos recently illustrated in our pages. His hot wire and other pattern lightning arresters are also having a ready and active sale.

THE ILLINOIS ELECTRIC MATERIAL CO. report business as elegant with them. Their Murray overhead switch for electric street railways is in especially large demand. Bishop and Canvas Jacket wire are also meeting with usual large success, and giving the best of satisfaction.

MR. THOS. G. GRIER, of the National Engineering Bureau, is actively engaged in making specifications and plans for new electric lighting and power installations, and as consulting electrical and mechanical engineering work.

MR. CRAIGHEAD, recently connected with the firm of Fraser & Chalmers, as electrical engineer, has joined the forces of the Westinghouse Company, with whom he was formerly connected.

THE GREAT WESTERN ELECTRIC SUPPLY COMPANY report continued activity in all departments. Their orders for railbonds, pole-ratchets and curve insulators are in keeping with the spread of electric railways, and their new designs of fixtures are beautifying hundreds of homes. They are also supplying the coming generation with learner's telegraph instruments and with experimental apparatus.

NEW ENGLAND TRADE NOTES.

PETTINGELL-ANDREWS COMPANY have secured the agency for New England and Canada for the Universal Arc Lamp, manufactured by the Universal Arc Lamp Company, of 49 West Twenty-second street, New York. These lamps are intended for use on incandescent direct current circuits, and they can be adjusted for circuits having a pressure of from 100 to 125 volts, using from 8 to 9 amperes. The lamp is also specially adapted for theatrical purposes, taking the place of calcium lights; it can be easily handled and will give all the effects of the calcium.

EDDY ELECTRIC MANUFACTURING COMPANY.—The Spencer Arms Company, at Windsor, Conn., have completed their work and will remove their machinery from the building immediately to make more room for the Eddy Electric Company.

THE WRIGHT ELECTRICAL ENGINEERING COMPANY have installed a 100 light incandescent plant in the factory of the American Circular Loom Company, at Hanover, Mass. The dynamo is of the Mather type, furnished by Frank Ridlon & Co., and will be run by water power. They have also installed a 30 light plant (Tremont dynamo) in the factory of the Smith Improvement Company, Atlantic, Mass., and a 75 light plant (Thomson-Houston dynamo) for Darling Brothers, Worcester, Mass. They are at present wiring the publishing house of Ginn & Co., in Boston, for 75 lights, the current for which will be supplied by the Boston Electric Company. The Wright Company are preparing a slate switchboard for arc, incandescent and motor circuits for the electric light station at Clinton, Mass. This board will take care of two 50 light Schuyler arc dynamos, three 650 light Thomson-Houston alternating dynamos, and one 50 horse power Thomson-Houston 500 volt motor generator. Most of the machine work on the board is being supplied by W. S. Hill, of Boston.

IT is reported, as we go to press, that the Manhattan Elevated Railroad Co. has decided to light its cars by electricity, and will proceed at once to make the necessary arrangements for the work.

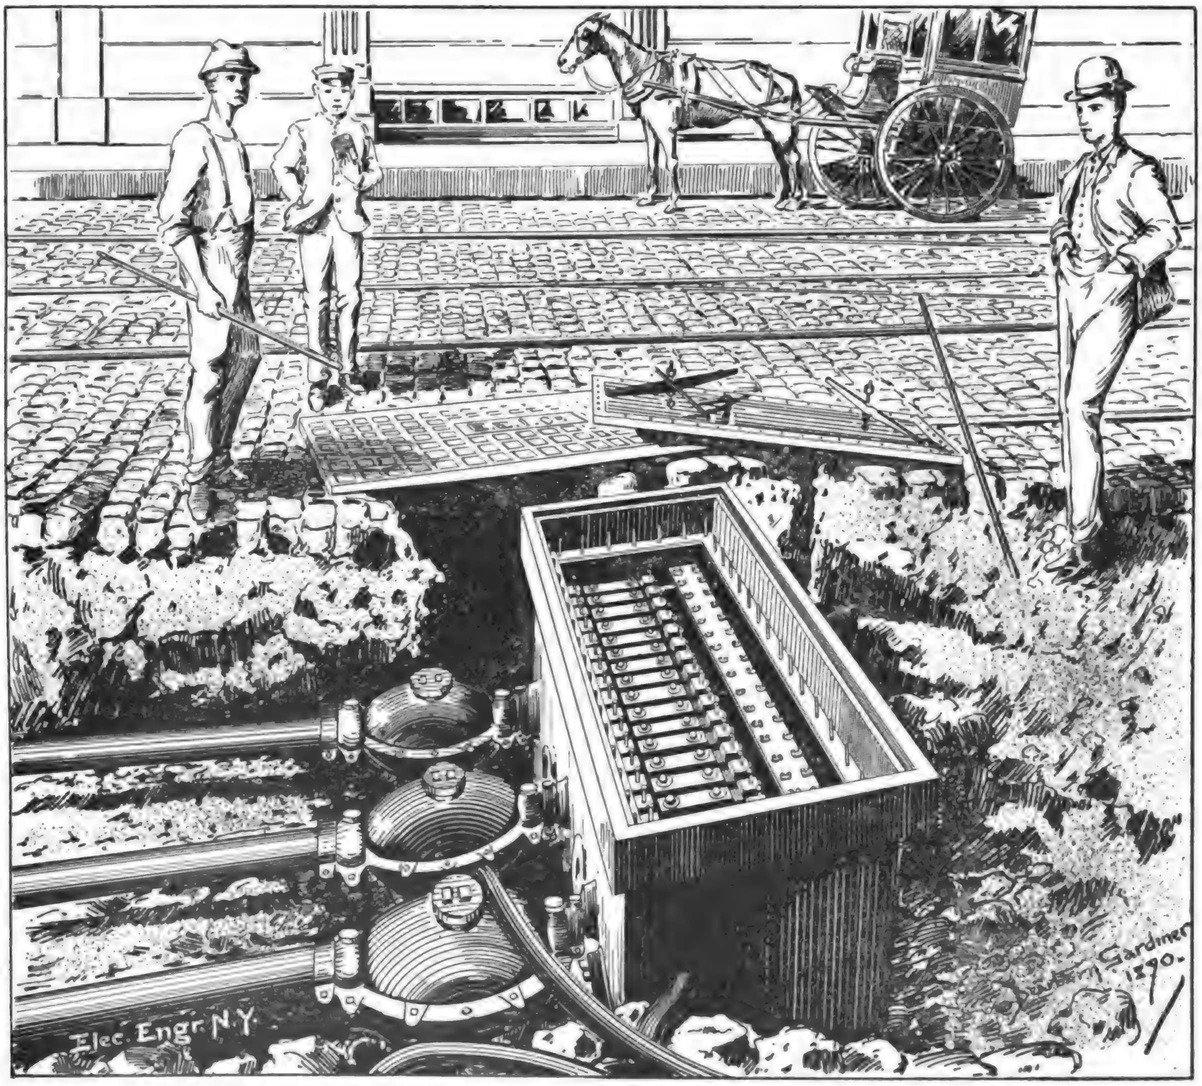
THE
Electrical Engineer.

Vol. X. NOVEMBER 5, 1890. No. 131.

EDISON UNDERGROUND WORK IN BOSTON.

BY A. C. SHAW.

To the outside observer electric lighting in stores, theatres, private residences, etc., is simply a beautiful feature in the progress of illumination, and hardly any thought is ever given to the question of how the current is conveyed from the central station to the scene of lighting. To the electrical engineer, however, this question is a most important one, especially in large cities, where these currents have got to be conveyed underground. The Edison system of underground feeders and mains is well enough known, but there are constantly improvements being made ; and I show in the accompanying engraving a special feeder junction box, which has been designed and put into operation by the Edison Electric Illuminating Co., of Boston. The object of the junction box is to subdivide long feeders into sections of not over 1000 feet in length, so that, should any trouble ever develop on such a feeder, it is not necessary to dig up the streets, and cut the feeder in two, three, four or six parts to locate the trouble. As lighting extends, the feeders become longer and in Boston there are some feeders as long as 6000 feet, and it becomes a serious matter to locate possible trouble. The junction box, as shown, is designed for six feeders, and is made of cast iron, the inside dimensions being 3 feet wide, 5 feet long and 3½ feet deep. There is a projecting ledge in the ordinary manner with screw studs for fastening down the inside cover, which is made water-tight by means of a rubber gasket, and melted wax, in the usual way. As will be seen, there is provision for pressure wires, the small terminals on the right hand side being for that purpose, while copper strips shown on the left hand



Laying Edison Mains in Boston.

side serve to make connections for the feeder. By use of this box, when two or more feeders run through it, when a feeder is faulty it is not necessary to cut out the whole feeder while repairing; the faulty section only is cut out, and flexible insulated cable connections can be used from the upper nuts for short-circuiting the faulty part. The pressure wires are then connected from the junction box instead of the catch boxes at the end of the feeders, and the remainder of the two feeders are used like large mains, the potential being kept constant at the junction box instead of at the catch box. The Edison Co., of Boston, have now six in use, and provision is being made for putting them on all long feeders, different sizes of boxes being used according to the number of feeders in the locality. A few figures regarding the Edison work in Boston, may be found interesting. From the two stations, one in Head Place and the other on Hawkins street, there are now running some 32,000 incandescent lights, about 1400 h. p. in motor service, and about 50 Ward arc lights. The extreme distance covered by the underground system is about two miles and extends from Richmond street in the North End, to West Chester Park in the Back Bay district. The following streets may be taken as bounding the territory covered by Edison tubes, and the streets within that section are thoroughly supplied:—Richmond street, Atlantic avenue, Causeway street, Mount Vernon street, Beacon street, West Chester Park, Boylston street, Berkeley street, Tremont street, Waltham street, Washington street, Kneeland street, Federal street, Atlantic avenue; so that it will be seen that the most important parts of the city and residential quarter are now well provided. In all, there are some 40 miles of underground feeders and mains, the longest feeder being 6000 feet, several of 3750 feet, and the shortest being about 250 feet. The largest feeder used is 750,000 circular mils, solid copper. In crossing the bridges over the railway on Shawmut avenue, specially prepared Clark cable, pulled into three-inch gas pipe, has been used, and a similar method will be adopted for crossing the Concord street bridge to South Boston, an armored Clark submarine cable being used under the drawbridge. In addition to the underground work, the Edison Co., of Boston, have a pole line of 100,000 circular mils with several tie lines, extending from station to station, by way of Atlantic avenue, taking in all the wharves, and supplying power to large numbers of motors used in these busy thoroughfares. When the increase to the station in Head Place is complete, it will be one of the finest and safest of the numerous Edison stations scattered throughout the country.

TWO RECENT "ACCIDENTS."

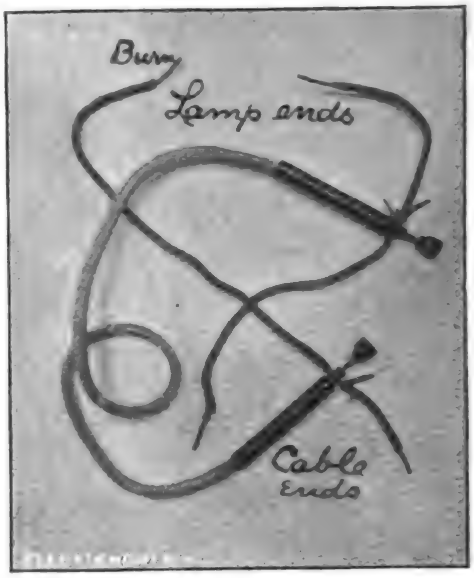
BY DR. S. S. WHEELER.

It may be interesting to the readers of The Electrical Engineer to learn the particulars of two accidents of recent occurrence in New York which have gone the rounds of the press, the circumstances of both of which are rather remarkable.

On the 13th of September the daily papers contained long accounts of a "terrible shock" received by a boy in Pearl street. The subject was thoroughly worked up, the boy and his relatives, his doctor, various policemen, etc., were interviewed by the reporters, and a thrilling account was given of the boy's experience. He was said to have received a "frightful shock," to have had his clothes and body "badly burned," etc. Even the doctor who examined him wrote, in answer to an inquiry, that the boy's coat was burned and in his opinion he "came very near his end."

The city officials ordered a careful investigation. A number of witnesses were found who said they saw a wire fall and knock the boy down, while others said they saw it catch the boy and raise him in the air. Investigation showed that there were no electric light wires in the neighborhood. Further investigation showed that there were no signs of burns on the boy's body or coat, but that the coat had been cut and torn, and bore decided traces of iron rust. The tip of one ear was bruised and there were signs of abrasion under the opposite arm. The wire was found to be an ordinary house top iron wire, and the majority of the evidence showed that it had hung down into the street some time before the boy arrived there.

The great mystery was, How was the boy stunned, what lifted him into the air, and why did it take him several days to recover? Finally a citizen was found whose statement of what he saw was as follows: The end of the wire dropped in the street under the elevated railroad and was carried along about one hundred feet by a passing cab; just as the boy approached the wire a train on the elevated road came up, caught the wire and gave it a sudden heavy jerk, causing its lower loose end to wrap around the boy and lift him about a yard into the air before uncoiling and dropping him in the gutter. The wire tore his coat and the fall stunned him.



Position of Circuits and "Jumper."

Two days after this, and just in time to attract attention and give plausibility to the first case, a patrolman of the Brush Illuminating Co. found one of his lamps out of order while on watch at about 10:45 P. M., in rainy weather. He ascended the pole, which was an ordinary iron one carrying a city lamp supplied by underground wires. The lamp, an uninsulated one, in which the frame forms one pole, was found to be grounded under its hood. The man's subsequent actions show that he decided to disconnect it from the circuit in order to free the circuit of the ground. For this purpose he cut through the insulation of both of the short, well insulated wires, which connected the cable terminals to the binding posts of the lamp, making a bare spot on each about one inch long. He then joined these wires by a well insulated "jumper" or flexible connection wire. Having thus provided a path for the current around the lamp he pulled the ends of the wires out of the lamp binding posts, thereby removing the lamp and the ground from the circuit. Then he touched the exposed end of one of the wires and was killed. He had left his rubber gloves behind, contrary to the rules of the company and the Board of Electrical Control.

Some comment has been made upon the fact that he finished his work before receiving the shock although he had to bare the wires. In removing the insulation from the wires, probably with his penknife, he must have come in contact with the circuit, but did not receive a shock because

the circuit was already grounded at precisely this point through the grounded lamp frame and the iron post. The leakage, therefore, did not pass through his body until he had severed all connections between the line and the lamp. The next time he touched the wires he received the shock.

The photographic view given herewith shows the pieces of connecting wire which had been in use between the cable ends and the lamp, and the insulated flexible jumper which he put on, all in about the position in which they were found on the lamp post. The bits of wire were run cross wise in order to make the polarity of the lamp right without disturbing the cables.

The ragged bits of insulation may be seen sticking out from the wire just as he cut them, and they show that they were cut with a knife. There were slight marks of burning on the upper left hand end of the wire. The circuit consisted of 4½ miles of underground cable, 1½ miles of overhead wire and 48 lamps, of which 37 were on the aerial portion.

Its insulation had been tested one week before with a reflecting galvanometer, and measured 1.6 megohm. It was also tested five days after and measured .9 megohm, both in clear weather. Between these tests there had been a period of very stormy weather, during which no galvanometer tests were made; but it was the duty of the roundsman to try the circuit twice a day with a magneto.

ELECTRIC GYROSCOPES FOR DEMONSTRATING THE EARTH'S ROTATION AND FOR THE CORRECTION OF SHIPS' COMPASSES.

BY G. TROUVÉ.

The instrument for demonstrating the rotation of the earth about its axis consists of an electric motor A, Fig. 1,

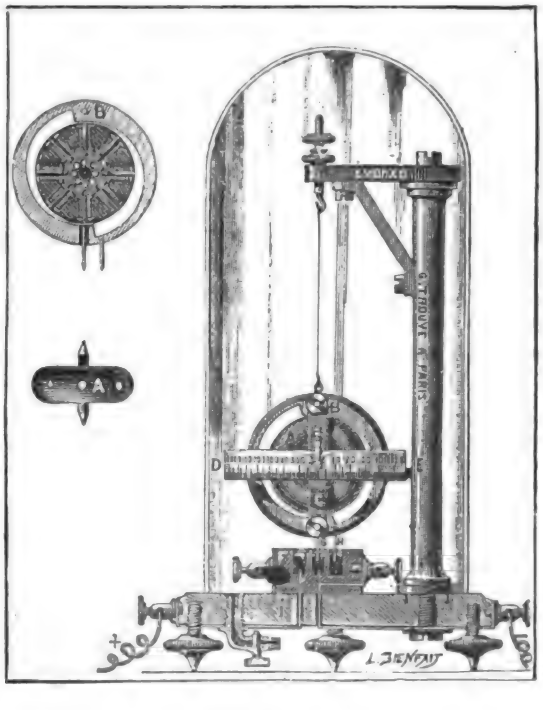


Fig. 1.—Electric Gyroscope for Demonstrating the Earth's Rotation.

which revolves in a vertical plane, on a steel spindle between ruby points. Within the rounded circumference of the motor are fixed eight small electro-magnets. The armature B of iron is of the form shown. To give the rounded surface to the ends of magnets they are first covered, together with the spindle and commutator, with a special cement. This is perfectly balanced and then it is placed in a copper bath where it is left several days until the metal is deposited to a thickness of about 3 millimetres. This is then turned down and the whole balanced again with great care. The motor operated by electricity occupies the centre of a cage formed by the iron armature B and the brass ring C, on which it is pivoted. As it apparently resembles a homogeneous copper disc it gives

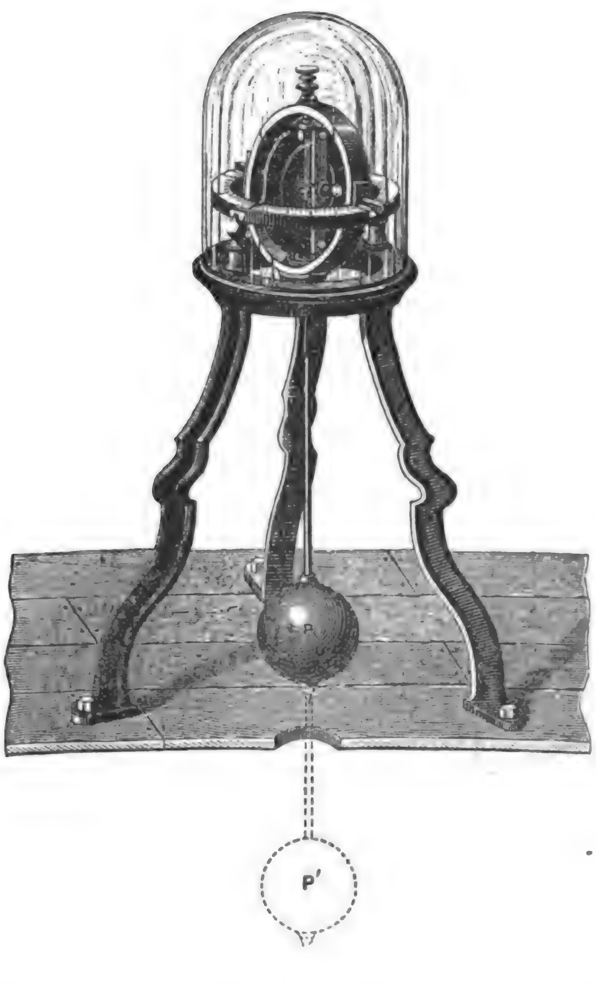

Fig. 2.—Electric Gyroscope for Correcting Ship's Compasses.

rise to surprise when it is seen turning without apparent cause at a speed of 300 to 400 revolutions per second.

The cage and the armature are suspended from a frame by an extensible wire in the centre of a horizontal graduated ring before which a pointer is moved, fixed to the armature B. The latter remains immovable in space, whereas the rotating disc is moved at a high speed. The rotation of the disc may also be ascertained by leveling a microscope on the micrometer scale fixed to the standard E, the divisions of which pass before the pointer.

The current is conducted to the motor by two small platinum points which plunge into mercury cups G and H, one cup being concentric within the other. The whole apparatus it placed within a glass globe which can be exhausted of air in order to remove all external disturbances.

As constructed, the gyroscope acts in a regular manner during the entire time that the current is on; and is thus able to furnish a perfect proof of the movement of the earth and to control it by observation, the displacement being calculable in advance.

To adapt the gyroscope to the correction of ships' compasses, M. Trouvé has constructed an instrument which, while of a heavier construction, still preserves all the advantages of the one just described. He has considered, in effect, that if it is impossible to eliminate entirely the

thousand external causes met with on board ship, they can at least be made negligible with reference to the directing force of inertia by augmenting the latter considerably. For that purpose he has increased the mass, the diameter and the speed of the revolving disc to such proportions that it requires a force of several kilograms to alter the plane of rotation, and so that a strong man cannot suddenly reverse the poles. Under these conditions the disturbing forces exercised are absolutely negligible.

The new instrument consists of the same parts as the one described above, only its form and dimensions have been slightly modified; the turning part of the motor, weighing several kilograms, has in its interior a Gramme ring armature. This ring is placed at the rounded extremity of the disc, the central part of which remains hollow, and has the metallic appearance of the former, which is obtained in the same way as described above. The field magnet is a ring of iron with consequent poles, in which the armature turns concentrically. The field and armature are connected in series. The entire system, instead of being suspended by an inextensible wire, is supported in the centre of a Cardon suspension system by a vertical axis ending in points, which are pivoted in a gate bearings, like the spindle of the motor itself. This Cardon suspension has a long pendulum with a stiff rod fixed to the prolongation of the axis of the system, giving to the whole a perfect vertical position notwithstanding the continuous oscillations of the ship. The slight inclinations to which the apparatus would be subjected are, in fact, reduced in the ratio of the length of the pendulum to the radius of the revolving armature. The pendulum might be prolonged, if desired, even below the level of the base of the instrument.

Constructed in the manner described, neither rolling nor pitching need be feared. It is adapted to correct the compass with certainty, since its axis of rotation remains fixed in space as long as it is necessary to prolong the observation.

STANLEY'S NEW ALTERNATING MOTOR.

The modifications to which the alternating current adapts itself are nowhere better demonstrated than in the variety of alternating motors, which are constantly being brought out. Among the recent work in this direction is a motor designed by Mr. Wm. Stanley, Jr., in which the

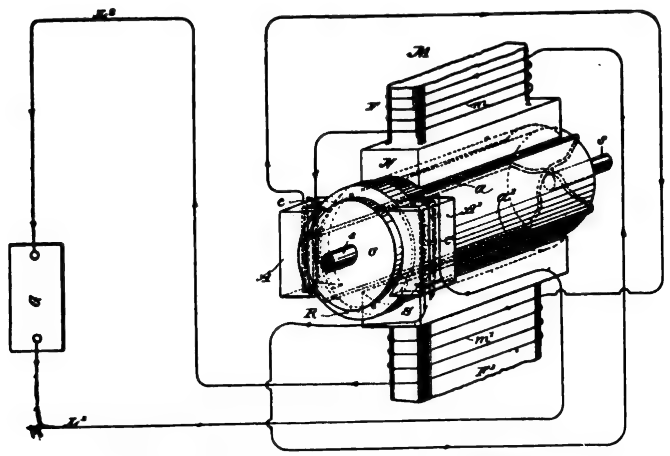

Fig. 1.—Stanley's Alternating Motor.

distinguishing feature consists in the fact that the poles inductively developed in the armature of the motor by means of alternating currents always appear upon a line which occupies a fixed position in space so that a given pole disappears and is succeeded by a pole of the opposite sign, which in turn is followed by a pole of the same sign as before, and so on; the alternations of polarity being synchronous with alternations of polarity in the field magnets of the motor, and the two lines of polarization being so related in position as to produce rotation of the armature.

The accompanying engraving, Fig. 1, shows the general construction of the motor, and Fig. 2 illustrates the circuit connections. As will be seen, the field magnets F F′

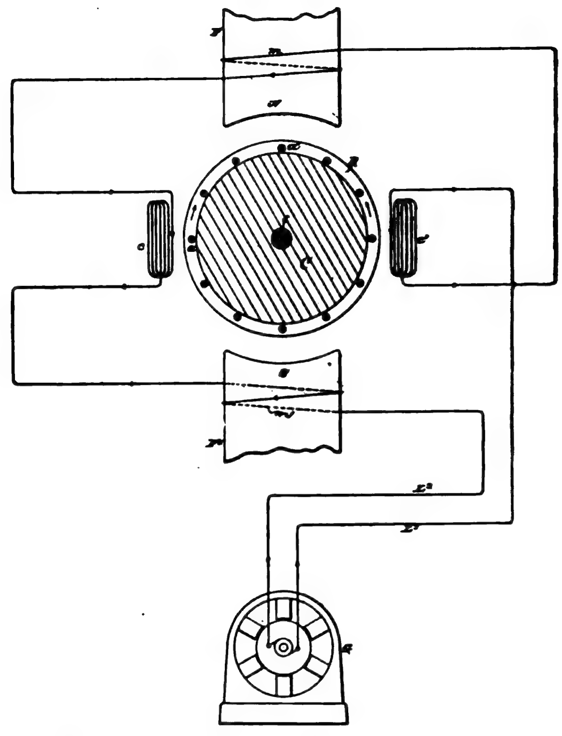

Fig. 2.—Stanley's Alternating Motor—Diagram of Circuits.

of the motor are connected across the mains L′ L². The armature conductors, $a\,a'\,a''$ consist of copper bars extending longitudinally along the armature-core, thence diametrically across the end of the core, and back along the core in a direction parallel to the first course. The terminals of each of the armature-conductors are connected to a conductor R, consisting of a ring or band of copper mounted upon the core and insulated therefrom, as are also the armature-conductors. At diametrically opposite points of the ring R and upon a line approximately at right angles with the magnetic axis of the field-magnets are located iron cores A A′ which partially embrace the ring R. They are wound, respectively, with coils $c\ c'$, which are connected with the mains leading from the generator, either in series with the field-magnet coils $m\ m'$, as shown, or in parallel. The coils $c\ c'$ are wound in such directions that when alternating currents are passed through them the resulting fields of alternating polarity acting upon the ring R will develop opposing electromotive forces, as indicated by the arrows, which, owing to the position of the coils $c\ c'$, will operate to drive current through the ring R towards these armature-conductors; the latter, when the armature is at rest, are not inductively acted upon by the field of force developed by the current in the field-magnet coils.

The method of operation of the apparatus is as follows: Considering the armature in a state of rest, alternating electric currents from the generator traverse the field-magnet coils $m\ m'$ and also the coils $c\ c'$. A line of polarization of alternating polarity is established by the currents flowing in the field-magnet coils, and at the same time alternating currents are inductively developed in those armature-conductors, as a, which occupy positions of inductive effect. The currents thus inductively developed enter the ring R and are carried along the ring to and

through those armature-conductors, as a', which at the moment are not in positions of inductive effect. Thus a second line of polarization is developed in the armature-core, which lies at an angle to the line of polarization due to the current flowing in the field-magnet coils. If current were flowing only in those armature-coils, as a, which occupy positions of inductive effect, the line of polarization established thereby would coincide in position with that due to the current in the field-magnet coils and the armature would remain at rest. The flow of current, however, in those armature-coils, as a', which are not in positions of inductive effect will cause the line of polarization due to the induced currents to lie at an angle with that due to the currents in the field-magnet coils.

The poles in the armature-core will alternate synchronously with those of the field-magnets, and since the armature is subjected to the influence of two lines of polarization lying at an angle with one another rotation will result.

THE NEW THOMSON RECORDING WATTMETER.

The subject of electric meters has always been one that has attracted attention on account of the interest which it has for both those who supply and those who consume electrical energy. Numerous forms of meters have from time to time been devised, each possessing certain advantages and disadvantages.

There was recently published a description of an electric meter invented by Prof. Elihu Thomson, in which an oscillating body moved by the current, and suitably damped, was made to give the required registry of the energy consumed, being, virtually, a wattmeter.

The new meter of Prof. Thomson, which is illustrated in the accompanying engravings, is based upon work done in this field quite a number of years ago by him. In brief, it consists of a peculiarly constructed electric motor which drives a register counting the number of its revolutions, and which also drives a magnetic damper consisting, in

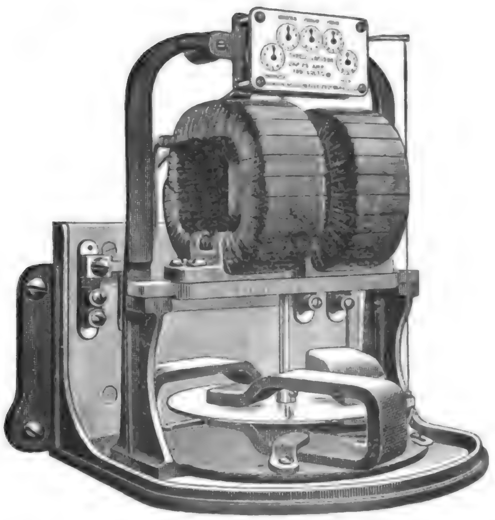

Fig. 1.—The Thomson Recording Wattmeter.

substance, of a closed circuit moved between the poles of three magnets. The magnets generally used are permanent magnets, although it is evident that where continuous currents of constant potential, or constant strength, are obtainable, these magnets may be replaced by electro-magnets.

An interesting fact in connection with this meter, is that it is an energy meter, or wattmeter, and operates equally well with continuous or alternating currents. Its motions are quite positive and almost unaffected by friction. Depending on electric actions throughout, it is said to be not so much affected by temperature and barometric pressures as are meters whose motions are checked by air fans or wings driven in the air.

The new Thomson meter, as made by the Thomson-Houston Electric Company, has a remarkable range in the load it can measure, meters being made having a range of registry from 1 to 200 amperes, the usual range being 1 to 100 amperes. Meters are also constructed to measure currents of as high potential as 500 volts continuous current, and much higher than this, in alternating currents, and

Fig. 2.—The Thomson Recording Wattmeter.

these meters take account of the variations of potential and multiply the potential by the current in measuring the energy. This feature is not essential, of course, as, by supplying a definite strength of current, to take the place of that which is generally taken in derivation to the mains, the instrument becomes one which takes account only of the variations of current. It is exceedingly prompt in its adjustment to variations of load, as is demonstrated by throwing on or off large loads, the effects of momentum being scarcely appreciable.

The meter consists of a vertical shaft resting in a jewelled bearing below, and, guided by an upper bearing, carries on its upper part a hollow frame wound with a set of coils, forming a sort of Siemens' armature of polygonal outline without any iron core. The coils of the armature are attached to a commutator carried on the shaft near its upper bearing, the commutator being made of a little larger diameter than the shaft on which it is placed, and is of special construction both as to material and mounting of its parts. Two light springs bear upon the commutator and constitute the commutator brushes. The armature coils are wound with quite fine wire of many convolutions, and in circuit with the armature is placed a non-inductive resistance, carried in the frame at the back of the meter. The connections of the armature circuit and the resistance in series with it are generally made in shunt, on mains where the potential permits of this being done; or, where the potential is too high for direct action of this kind, a transformer is used to bring it to a desirable potential for use in the armature circuit.

It will be seen that the construction of the armature and the commutator gives a minimum of friction, and the special construction and materials used are found in actual practice to give very good satisfaction. The amount of current which has to be commuted at the commutator is, in any case, quite small. The armature coils or revolving coils have placed adjacent to, and surrounding, them, a set of fixed coils, generally made without iron, through which

coils the main current to be measured passes. They furnish an air field of greater or less strength according to the current flowing in the coils. The field coils and winding, of course, are varied according to the desired capacity of the meter, and sometimes a few turns of a winding in shunt to the mains are placed alongside the main circuit coils to assist the effect on the armature under the lightest loads. An endless screw on the shaft engages with a wheel in the registry train whereby the rotations of the armature are recorded. A variation of the dead resistance in circuit with the armature can, of course, be made the means for the standardization of the readings on the register by increasing or decreasing the armature current flowing under any definite load or current passing in the field-producing coils.

On the lower part of the shaft which bears the armature is mounted a copper disc the plane of which is at right angles to the length of the shaft, and which rotates with the shaft. This copper disc moves between the poles of a number of permanent magnets which are placed so as to embrace it. These magnets are made movable so that their position of action on the disc may be changed with respect to its centre and periphery, whereby the retardation they exert may be modified in such a way as to control the speed of turning of the shaft and its attached parts, under any definite load which the meter is called upon to register. Of course, it is necessary that great care be taken in making

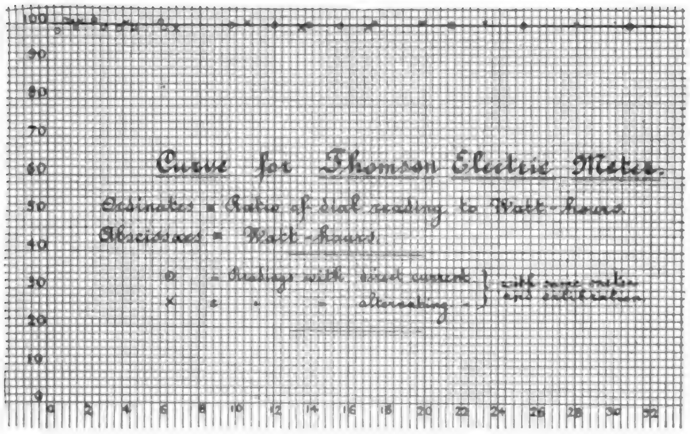

FIG 3.—CURVE SHOWING ACTION OF THOMSON WATTMETER.

the permanent magnets so as to secure permanency of magnetization; the adjustments, however, provided, make it easy to restandardize the instruments at any time.

It will be seen that the commutator of the armature never receives the full potential difference existing between the mains, and that, therefore, there can be no damaging short circuits around it. This is due to the large dead resistance which is in circuit with the armature.

The principle of action, of course, is quite simple. The amount of load or retardation obtained by the copper disc moving in the magnetic field is directly dependent on the speed, and the retarding effect may be said to vanish when the motor stops, and to increase regularly as the speed increases. In like manner the torque or turning force exerted by the armature may be said to vanish when the field current becomes nil, or when there is no load, and to increase regularly under constant potential between the mains as the load of lamps, or other working devices, is increased; that is, as the current passing through the stationary field coils increases. The result of this is that the speed of the meter shaft increases in strict proportion to the load so that the registry is uniform throughout the range, except with the very smallest loads. This will be seen by examining the curve, Fig. 3, obtained from a meter having 25 amperes capacity. This property of the meter is found to be present whether the currents used are alternating or continuous currents. The curve given shows the rate of registration for each load, the verticals indicating the value of the registry for a given current under variations of the total current or total load.

The commutator brushes of the armature are, of course, placed at right angles to the magnetic axis produced by the field coils, and it will be readily understood that an increase or decrease of the current in the armature due to increase or decrease of potential, and of increase or decrease of the field current due to variations of the load put on, or thrown off, together act to vary the speed of the register, and that the meter multiplies the two together and registers the *energy*. The effects of variation of potential may readily be eliminated by causing the magnetization of the magnets which retard the copper disc to depend upon the potential, as when they are made electro-magnets and put in series with the armature; in this case the meter becomes merely responsive to change of current in the field coils, provided, of course, that the retarding magnets are far below the saturation point.

It will also be readily seen that from the relative disposition of the armature and the field, the current returning from the work, as in case of a storage battery, discharges reversely through the meter and results in the reduction of the registration by the meter moving backward; and in a similar manner energy restored by alternating currents due to displacement of phase by self-induction is also deducted and credited by the meter as returned energy. Hence if the meter were used to register on a circuit of alternating currents feeding lamps, the current and potential might be the same as when alternating currents were feeding an inductive resistance, such as self-induction coils, and the current traversing the field coil of the meter, and also that traversing the armature circuit might be the same under these conditions. But the registration of the energy consumed would be much larger in a given time in the case of the lamps, than in the case of the self-inductive coils used as a load.

A ROUGH TEST OF TRANSFORMER EFFICIENCY.[1]

MANY engineers in charge of central stations want a rough method of arriving at the efficiency of a transformer in the case of closed iron circuits. This may easily be carried out with the help of a resistance box, and an alternating current ammeter and voltmeter, which are always available in stations. The primary current when the secondary is open is measured. This is multiplied by the primary pressure, and the product is divided by 2 to give the loss in the iron. The loss in the copper at any load is then calculated by C^2R in the primary and secondary. For instance, suppose a 500 watt transformer for 2,000 and 100 volts takes, with the secondary open, 0.073 ampere. The iron loss is $0.073 \times 2{,}000 \times \frac{1}{2} = 73$ watts. If the primary and secondary resistances are [illegible]8 and 0.16 ohm, respectively, the full load losses by copper are [illegible].5 watts. The total loss is then 82.5 watts at full load, giving an efficiency of 85.9 per cent. The measured efficiency of this transformer, according to Prof. Ryan, was 86.3 per cent. This rough method probably gives the loss in iron well within 10 per cent.; that is to say, gives the efficiency within 1 per cent. It is probably more accurate than calorimeter experiments or calculations from clock-face diagrams. To get the "all-day efficiency" the iron loss is taken as constant. For instance, if the transformer has an average load equal to four hours' full load per day, the iron loss is taken as $73 \times 6 = 438$ watts, and the copper at an outside value of 5 watts. This gives an all-day efficiency of 53 per cent. This is low, but then the transformer is very small, and of an old form.

1. *Industries.*

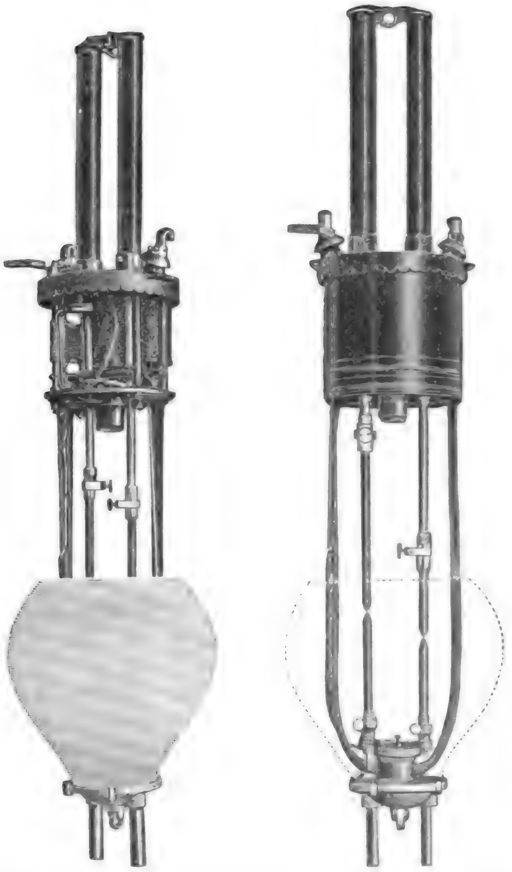
THE NEW BRUSH-ADAMS ARC LAMP.

The experience which has been gained during past years with arc lamps under the disturbing influences to which they are subjected out-doors has led to the construction of a new lamp, in which advantage has been taken of the many lessons taught by the "troubles" of the past.

This lamp, known by the name of the Brush-Adams lamp, has just been put out for general use by the Brush Electric Co., of Cleveland, and as it embodies numerous excellent features will prove interesting to many of our readers.

To begin with, all springs that can in any way influence the arc have been abolished, and thus the chief cause of uneven and changing adjustments is at once eliminated, while at the same time the use of glycerine, oil or mercury is entirely avoided. The frame of the lamp is thoroughly insulated from the working parts, and unless a hanger-board is desired no hood need be used, as the lamp is weather-proof. The hanger-boards, globes, jackets, rod protectors, etc., are all alike for single and double lamps, and a large saving is thus made to lighting companies in the stock of spare parts required to be kept on hand.

The accompanying engravings show the method of securing the globe upon the lamp. This method effectually prevents the blowing off of globes or breakage from heating or drops of melted copper from the carbons. As will be seen, no thumbscrews, which frequently crack the globes, or drop out and loosen them, are used, and it is claimed that the flaming arcs which sometimes occur when the lamps are about to cut out, cannot possibly cause breakage



Figs. 1 and 2.—The New Brush-Adams Arc Lamp.

of globes. Another important feature, which will be readily appreciated, especially in "hot trimming," is the ease and rapidity with which the globe can be removed and placed out of the way, as shown in Fig. 3. The careless trimmer who might wish to delay the cleaning of the globe cannot be troubled by sleet or dust sticking to the globe-holder.

The Brush-Adams lamp is adjusted to a standard current and voltage and no means of changing this adjustment is provided. The current required is stamped upon the lamp, and with this current the manufacturers claim that it will burn with perfect steadiness and reliability on any circuit. Lighting companies and the public suffer much

Fig. 3.—The New Brush-Adams Arc Lamp.

from re-adjustments made by careless and incompetent employés. The adjustments of the new lamp need never be changed, or, if required to be altered for a different current, must be changed with special but inexpensive tools provided by the manufacturers.

Cleanliness of arc lamps is necessary for perfect working, but is often neglected in dusty or smoky locations on account of the difficulty of cleaning, involving in the old forms the taking down, and apart, of the lamp. The Brush-Adams lamp is so constructed that while the lamp is in its ordinary burning position in the street or elsewhere, the rods, clutches and other parts requiring cleaning can be slipped out quickly and put back without any soldering or other work.

Another feature is the arrangement of carbon rods and clutches, which are shown separate in Fig. 3. The clutches are claimed to be as durable as any other part of the lamp, and the rods do not require to have the true round surface usually necessary, as the bearing surface of the self-cleaning clutches will feed a rod pitted or scarred or worn. The cut-out is positive and sure, with no liability to burn out, and a very effectual device is provided for preventing the "lapping" of carbons and for insuring the lighting of the

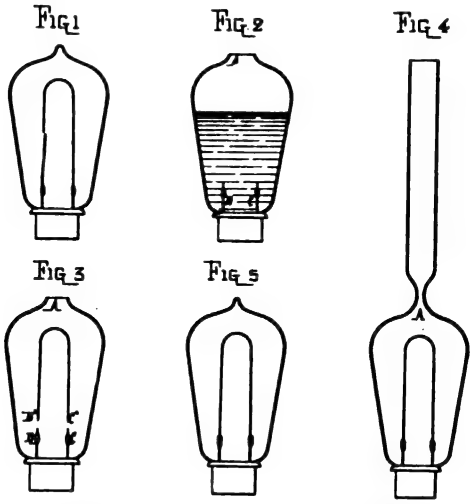
lamps whether trimmed with the carbons apart or in contact.

The exterior finish of the standard lamp is black japan with bronze trimmings, the idea being that the user can bronze or ornament this surface for special purposes if necessary. The bright brass lacquered finish of many lamps, while showy when new, is difficult and expensive to renew.

The hangerboards, alike for single or double, indoor or outdoor lamps, are provided with a switch very strongly made, arranged to close one circuit before the other is opened, so as to prevent arcing, and to cut the lamp entirely out of circuit when switched off.

PAUTHONIER'S METHOD OF RENEWING INCANDESCENT LAMPS.

Ever since the present type of incandescent lamp became an article of regular manufacture, attempts have been made to overcome the necessity now existing, of discarding practically the entire lamp when but a single element, the filament, is ruptured or destroyed. Some method by which a new filament can be introduced leaving the remaining solid parts of the lamp intact will therefore be conceded to be of considerable value. To accomplish this object, M. Casimir Pauthonier, of Paris, a few years ago devised a simple process which has been in operation



Pauthonier's Method of Renewing Incandescent Filaments.

abroad, and which has been recently patented in this country. For this purpose the broken filament is withdrawn from the lamp, the tip A, Fig. 2, having been previously opened. There are thus only left two short stubs of the old carbon which act as primers to the soldering at B and C. The lamp is then filled with a hydrocarburet, and a new filament introduced into the bulb, the ends of which are brought opposite the stubs, as in Fig. 3. The carbon is held in this position by a thread of copper attached to a frame, the arm of which may be raised or lowered, as required. The ends are brought to the stubs B and C by means of a small plier, the head of which is connected by a flexible conductor to a source of current. By passing a current first through one leg of the filament to the juxtaposed stub, and then through the other, carbon is deposited at the joint and the ends firmly supported, thus furnishing the lamp with a new filament. Fig. 4 shows the latter ready for exhaustion, and Fig. 5 the completed lamp. We may add that it is proposed to introduce the process in this country.

A MUSEUM ON A TRAIN.

At the shops of the St. Charles Car Co. there have recently been built four gorgeous museum cars. The gilding alone cost over $3,000 and the cost of the entire coaches is about $24,000. The idea is to run the train into a town and have the exhibition on the cars. One car contains the electric light plant which is to light the museum train.

BRADLEY'S ALTERNATING MOTOR.

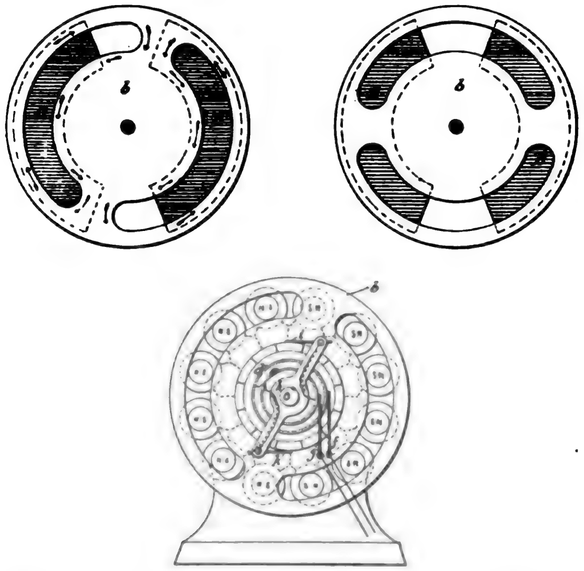
For some time past Mr. Charles S. Bradley, whose multipolar continuous current dynamo will be known to many of our readers, has devoted considerable attention to alternating current motors and as a result has worked out a number of types possessing considerable originality. Among these is one in which a single current field magnet is employed, influencing an armature carrying closed induced circuits and having a commutating device for shifting the neutral point in the field magnet and producing a progressive torque.

To explain the action of the motor we may take, for example, a disc *b* having two circumferential slots, as in Figs. 1 and 2, and set it so that each slot surrounds or threads the lines of force from alternate fields A and B; the disc becomes thus the seat of induced or secondary currents when the field-magnets are energized by an alternating current, the paths of such currents being approximately indicated by small arrows on the disc, which constitutes two closed circuits. If the disc be placed in the relation shown in Fig. 1, as soon as the alternating current is admitted to the field A B the rise and fall of potential therein sets up induced currents, and motion of the disc results from the following principles: All the lines of force momentarily produced during one phase of alternation of magnetism in the field-poles cause momentary induced currents, as indicated by the arrows. These currents pass from the centre to rim and rim to centre of the disc at the two unslotted portions shown, being from centre to rim at one and from rim to centre at the other at the same instant; and therefore the currents generated by A and by B have common directions through the unslotted portions, and are therefore attracted one by the nearest part of field A; and the other by the nearest part of field B; and as these attractions take place at opposite sides of the shaft or centre, motion of the disc necessarily results. This motion continues in one direction till the disc is about in the position shown at Fig. 2. Motion then ceases, because the closed circuits of the disc are equally attracted by the oppositely-induced field-magnets, which neutralize each other. Thus continuous rotation can be effected by subdividing and angularly displacing or commutating the field-magnets.

One way in which the principle has been carried out in practice by Mr. Bradley is shown in the accompanying engraving, Fig. 3. Here a disc *b* is fixed on a shaft having the two insulated rings *d e*, on which bear the brushes *f g*. The shaft has fixed to it the brush-arm *h*, which in turn carries at diametrically-opposite points the insulated brushes *i k*. These brushes bear on a stationary segmental commutator C, having its blocks looped in successively to the subdivided field-circuit, so as to shift the polar line of the latter accordingly. The field-magnet is composed of a group of cores arranged in a circular series, each provided with its own coil, and the pole-pieces facing the path of the semicircular slot in the disc *b*. Fig. 3 shows a series of field-magnets facing one side of the disc only; but it is preferable to have two series of such field-magnets facing each other and so wound that at any instant at which a given pole has north polarity the pole-piece opposite it on the other side of the disc has south polarity, and so on, so that the lines of force pass directly from the pole-piece of one series to the pole-piece of the opposite series of field-magnets. The entire annular series of field-magnets have their coils connected in series similarly to the connections of a Gramme ring, so as to form a closed circuit, and between each coil and the next adjoining one a loop is taken and connected to the corresponding plate of the commutator C, which is supported in a stationary position so as to always preserve the same angular relations with the field-magnets.

Obviously the line-current passing in at the brush *f* to ring *d* would go through brush *k* into the commutator, and then dividing, one half would pass around the magnet-coils

on the right of the vertical line and the other half around the magnet-coils on the left of the vertical line, and at the top both currents join together at the commutator and pass out at the brush *i* through ring *e* into brush *g* and thence to line. Consequently at any given moment all the field-poles on one side of the vertical line will have one polarity and all those on the other side of the vertical line the opposite polarity. Thus, in the position shown in Fig. 3, the neutral line will be a vertical line drawn through the figure, and this line will be the line of commutation and correspond with the operating position of the brushes *i k*. The disc *b* being already advanced a little toward the right, so as to correspond with Fig. 1, immediately takes up motion due to the preponderating attraction, as already explained, and this motion continues with a powerful torque until the brushes have reached the next segment of the commutator, whereupon the neutral line is immediately shifted to the right and the position of maximum torque is again obtained, causing a further attraction of the disc *b* in the same direction, and the corresponding movement of the brushes *i k* repeats this indefinitely as the disc rotates, owing to the commutation of the field-magnets, so as to



Figs. 1, 2 and 3.—The Bradley Alternating Motor.

keep the position of maximum torque continuously ahead of the actual position of the disc.

In Fig. 4 is illustrated a form of motor wherein the disc *b* rotates between the adjacent ends of two circular series of field-magnet poles, as already alluded to. In this form of machine the field-magnets are commutated, as before, and the opposite pole-pieces will at any one instant be always of opposite polarity, so that the lines of force between the two will pass through the rotating disc *b*. Laminated cores are employed for the field-magnets and their back ends joined by means of laminated yokes.

Instead, however, of connecting the members of the field-magnet and commutating them, as shown in Fig. 3, the arrangement shown in the diagram, Fig. 5, has been adopted. On the shaft, and rotating with it, are placed the insulated rings *d* and *e*, as before, and on these brushes bear and convey the line-currents to the commutator. There are also fixed on the shaft the two semicircular commutator-plates 1 and 2, plate 1 being connected to ring *d* and plate 2 being connected to ring *e*. Surrounding the commutator is a ring 3 carrying at points corresponding to the angular displacement of the several field-magnets the brushes 4, 5, 6, 7, 8, 9, 10 and 11. The plates 1 and 2 at their adjoining ends are separated from each other by a gap at least equal in width to that of one of the brushes, as shown in Fig. 5. These respective brushes are connected to the corresponding ends of the field-magnet coils, 12, 13, 14, 15, 16, 17, 18 and 19. The other or outer terminals of all the field-magnet coils have a common connection in the circle *m*, which is obviously the same as if all the outer terminals of the coils were connected together at one point.

Suppose, now, an impulse of current arrives from the

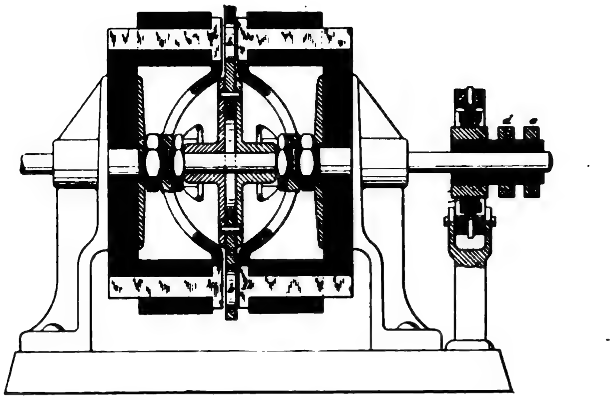


Fig. 4.—The Bradley Alternating Motor.

line to the ring *d*. It passes thence to the plate 1, from it through the three brushes 8, 9 10, and divides in parallel circuit through the three field-magnets 16, 17, 18, joining together at the common connection and passing into the field-magnets 12, 13, 14, thence through the brushes 4, 5, 6, thence to the plate 2, ring *e*, and back to line.

It will thus be observed that field-magnet coils 19 and 15 are open-circuited. As the commutator 1 and 2 rotates, field-magnets 12 and 16 become open-circuited, and in the further rotation of the armature and commutator each diametrically-opposite set of coils becomes open-circuited, while the set of coils on each side of that line respectively contribute opposite polarities to the circular range of field-magnet poles and the commutation proceeds with the same effect as in Fig. 3, but with the additional advantage that the short-circuiting effect which would take place in the form shown at Fig. 3 with the brushes connected to ad-

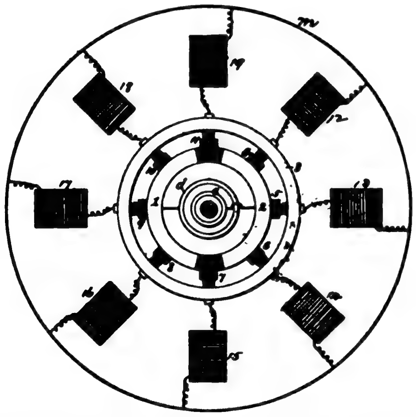

Fig. 5.—The Bradley Alternating Motor.

joining plates of the commutator is totally absent, and consequently the damaging sparking is entirely eliminated.

MOTORMEN AT THIRTY CENTS PER DAY.

A drunken motorman, whose salary was less than thirty cents per day, caused an accident at Fiesole, Italy, which resulted in fatal injuries to several passengers, and so prejudiced the public there against the road that it will be years before it can be worked without loss. A company that hires an ignorant man at thirty cents a day to fill so important a position not only should be forced out of existence, but should be held strictly accountable for the damage that resulted from its misdirected economy.—*Boston Transcript.*

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, *150 Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

VOL. X. NEW YORK, NOVEMBER 5, 1890. No. 131

It is not derogatory to the dignity of Mathematics to approach the subject by means of a pair of compasses or a foot-rule or a metre-scale, instead of the stately process of proposition-lemmas and corollaries ending by Q. E. D.—John Trowbridge.

LIGHTING THE NEW YORK ELEVATED TRAINS.

BRIEF mention was made in our last issue of the intention of the Manhattan Elevated Railway Company to light its trains by electricity. The report to which we gave publicity is well founded. The company has been seriously considering the matter and, in fact, is said to have gone so far as to have secured preliminary estimates upon no fewer than 216 individual outfits. This, of course, would imply an intention to equip each train with a plant of its own, the dynamo and engine being placed either upon, or in close juxtaposition to, the steam locomotive. If we take the train to consist of five cars, each with a dozen lamps, and allow as many more for the locomotive cab, tender, headlights and taillights, we have a total of 72 lamps of 16 c. p., or a requirement of, say, 7 to 8 h. p. of engine and dynamo on each train. Smaller lamps could be used with satisfactory results, but the figures above will serve. Such an equipment of 216 plants would therefore represent in the neighborhood of 1,500 h. p. of dynamos and engine capacity in the small units named.

It is gratifying to know that a change of this kind is imminent. The lighting of the elevated trains has long been unsatisfactory, and what with breakage, cleaning, oil, attendance, &c., must be expensive. It is the common experience to travel in poorly lit cars. Not infrequently one sees passengers endeavoring to improve matters by either raising or lowering the flame; and very often the lamp chimneys burst, scattering hot, greasy glass over everybody. The lamps are badly placed, and it is difficult to assume any position near them or under them so as to secure the full benefit of their obscure rays.

It seems to us, however, that the matter for consideration is more than merely one of lighting the trains. There are all the stations to be taken into account, and they need better light fully as much as the cars do. With this element brought in, the problem takes a different shape, and the desideratum, apparently, is a system that shall at one and the same time light both the stations and the trains. The resort to 216 distinct plants would imply train lighting alone, by direct service, maintained only as long as the dynamo and its special engine are running. But, with an agency so flexible in its application as electricity, there are several ways of gaining the end sought. At the present moment, for example, a movement is on foot for the establishment of special cars for smokers. If this were granted, it would evidently be easy to concentrate in such cars, at one end, all the auxiliary apparatus for heating and lighting without any drain on the locomotive for steam except in the extra haulage. Here storage batteries could come into play, a very small plant charging throughout the day, and the lamps drawing a large part of their current from the batteries in the evening. This plan, however, still leaves the stations and track signals unprovided for, and suggests another, by which current supply plants, being placed advantageously along each line, each track could be wired up so that the circuits to the stations would run on the elevated structure and the trains would pick up their current by the simplest kind of contact devices.

If the whole road were operated by electricity, as it should be, the lighting problem would be swallowed up in the settlement of much larger ones, and would be no more heard of. On large numbers of street electric railways, the cars to-day derive the current for all their lights direct from the motor circuits. No better place than the New York elevated roads could be asked for the application of such methods. Yet it begins to look as if Boston and Chicago would have their elevated electric roads before New York, although the time is so ripe here for the new departure. Steam transit in cities is an anachronism and a nuisance, despite its enormous benefits, and we believe steam locomotives will disappear from the elevated tracks almost as soon as the horses do from the surface roads. This may not be in the immediate future of next week, but it is coming as surely as to-morrow's sun. The 250 American cities enjoying electric rapid transit set an example that even the stolid conservatism of New York cannot resist.

ELECTRICAL ACCIDENTS.

OUR readers need hardly be told that the alleged dangers of electricity which the daily press delights in bringing to the attention of the awe-stricken public are largely drawn from the imagination, and that little, if any, trouble is taken to go to the bottom and determine the true causes of such accidents. We think Dr. Wheeler has, therefore, done a public service in presenting what is undoubtedly a correct explanation of the causes which led to the death of a lineman in this city. Leaving out of consideration the non-observance on the part of the lineman of the strict rule regarding the wearing of rubber gloves, and which, if followed, would certainly have prevented the accident, the

condition of the circuits, as evidenced by the photographic reproduction in another column, are evidence that the unfortunate man did not exercise sufficient care in the handling of the connecting wires. It seems strange indeed that men who ought to be, and no doubt are, well aware of the character of their work and the precautions necessary to prevent accident, should invite disaster by what cannot be characterized as anything else but sheer carelessness. It may be true, as has been assumed, that rubber gloves may not be the most convenient things to work with, but where the question involved is one in which the whole electric light industry is interested, as well as the safety of the employé, the rule ought to be strictly enforced. The explanation of the injury done in another case of an alleged electrical accident would be ludicrous, but for the fact that it shows the unnecessarily alarmed state of the public mind, and the proneness to ascribe to the current an innate viciousness which it does not possess.

THE DETERMINATION OF SELF-INDUCTION.

THE construction of alternating current apparatus in its various forms now occupies so largely the attention of electrical engineers that those who are engaged in this class of work, together with those who are about to undertake similar pursuits, will be interested in the admirable article by Mr. C. Steinmetz which is concluded in this week's issue. The apparent difficulties with which exact determinations of this nature are accompanied are largely due to the necessity of employing apparatus requiring some skill and training for their management; but in the majority of cases a fair approximation is quite sufficient for practical purposes. It is with this in view that Mr. Steinmetz describes some methods for determining the self-induction of electric circuits requiring the use of instruments with which all practical electrical engineers are familiar. An intelligent application of these methods may save much time and expense, and as an exercise for the student a simple series of tests with apparatus usually at hand, will go far towards inculcating sound ideas as to the nature and effects of self-induction.

THE STANLEY ALTERNATING ARC MACHINE.

THE description of the Stanley alternating arc dynamo, which first appeared in our columns about six months ago, at once attracted attention to the machine as one possessing remarkable characteristics and the study of which would, no doubt, as we at that time suggested, be taken up in the near future. The results which have been detailed by Messrs. Tobey and Walbridge in their paper read before the American Institute of Electrical Engineers certainly confirm the claims made for the remarkable regulating power of this machine and bring out a number of peculiarities which are worthy of attention. Probably the most characteristic action of the machine is that exhibited by the form which the curve of E. M. F. assumes, approaching with increasing load almost to the form of a reversed pulsating current instead of the sinusoid of the incandescent machine. Evidently such a curve is due to the enormous self-inductive properties of the machine, in virtue of which naturally all the actions observed are due. It is not uninteresting also to note the reactive effect of the main current in this machine upon the exciting current. Although the latter is generated from independent coils, it nevertheless is subjected to the influence of the armature poles and partakes of the wavy motion, its strength varying over considerable range with each pulsation of the main current. In Mr. Thorburn Reid's paper the result of analysis bears out the results found in practice and affords a means which may guide others in the predetermination of similar machines. While the test of Messrs. Tobey and Walbridge extended over the full range of the capacity of the dynamo, even at a short circuit, it would have been interesting, we believe, to have obtained the data resulting from the machine when run on open circuit. Naturally a varying difference of potential would have been generated at the terminals, the magnitude of which would have been interesting to determine.

The New Thomson Alternating Meter.

RECOGNIZING the value of a simple and reliable device for measuring current, Professor Elihu Thomson has in the past devoted not a little attention to the design of various meters, among which probably those of the oscillating type, in which a volatile liquid is employed as the moving force, as it were, are best known. Recently, however, Prof. Thomson has devoted particular attention to the construction of a meter which shall be adapted to both continuous and alternating currents and at the same time indicate not only the consumption of current, but give it in the value of the pressure on the mains; in other words, a power or wattmeter. The manner in which Prof. Thomson has worked out this problem is highly ingenious and is evidently based on simple principles. The problem to be solved evidently was to construct a motor in which both the pressure and the current should be the factors determining the speed and a device embodying a retarding force which should vary in the direct ratio with the speed of the machine. The relative disposition of field and armature of the motor and their connection with the working circuits fulfills the former conditions, while the disposition of the copper disc retarded by the encircling magnets fulfills the second. With constancy of magnetism assured in the permanent magnets and friction reduced to a minimum, as it appears to be in this instrument, its accuracy ought to be very high. Not the least interesting point in connection with it is the quality it possesses, as exhibited by the curve, of affording practically uniform readings for both continuous and alternating currents.

Electrical Work at the World's Fair.

SEVERAL weeks ago, the use of electric power on a large scale to run the World's Fair was discussed by us at some length. Mr. Gardiner C. Sims, Commissioner from Rhode Island and Chairman of the Electrical Committee, has now formulated his ideas on this subject in an admirable communication to the Executive Committee of the National Commission. He proposes not only the use of motors to drive exhibits, but the operation of elevated electric railways between the sections of the Fair, and special novelties, such as the electrical repairing of ship's hulls afloat, and the like. As we have said already, the scheme recommends itself at once to the approval of every electrical engineer in the country, and we hope to see it carried out.

SOME PRACTICAL METHODS FOR THE DETERMINATION OF INDUCTIVE RESISTANCES AND SELF-INDUCTION OF ALTERNATE-CURRENT INSTRUMENTS.—II.

BY CHAS. STEINMETZ.

B.—DETERMINATION OF THE SELF-INDUCTION OF MEASURING INSTRUMENTS.

The static electrometer is considered the best instrument for measuring alternate current potentials. But, unfortunately, this delicate instrument is hardly adapted for practical use in the factory. The calorimetric instruments, as, for instance, the Cardew voltmeter, can also be highly recommended.

But for direct measurement of the strength of alternating currents, hardly any other instrument can be relied upon but the electro-dynamometer, although its self-induction has to be considered sometimes, as shown in Part I. If we make the necessary corrections for self-induction, the electro-dynamometer can also very well be used as a voltmeter.

The main condition for all electro-dynamic alternate-current instruments is, that their magnetic field always corresponds to the instantaneous strength of the current, so that for the same current the magnetism is the same, no matter whether the current is increasing or decreasing. This condition excludes all instruments containing iron, and also such instruments in which eddy-currents can be set up.

Seeing the difficulty of securing practical alternate current instruments without self-induction, we have to find methods to determine the amount of this self-induction and the corrections necessitated by it. In measuring the strength of currents only, by the electro-dynamometer-ammeter, self-induction has no influence; but its determination becomes necessary where these readings are to be used for calculations of resistance, self-induction, power and so on.

To determine the self-induction of an alternate-current instrument, a very reliable way is, after having tested the instrument by continuous currents, so that it can be used as an ammeter, giving the effective current flowing through it, to proceed as follows:—

1. Connect it, together with an additional non-inductive resistance, if necessary, in parallel with a current-indicator. For this any instrument can be used, which for the same effective current always gives the same reading, no matter whether this reading is right or wrong; therefore, most of the non-polarized continuous-current instruments can be used.

Let the electric resistance of the instrument proper $= r$.
Let the additional bifilar resistance $= r_0$.
Let the alternating current flowing through the instrument, and read by it as an ammeter $= c_1$.
Let the reading of the current-indicator in the shunt-circuit $= v$.

2. Connect the instrument r with its additional resistance r_0 in series with a bifilar resistance R and in parallel with the same current indicator, and vary the alternating current so that the current-indicator gives again the same reading v, thereby showing that the shunt-current, and therefore the potential-difference at the terminals of the branch-circuit containing the instrument, is again the same as in connection (1).

Then let the alternate current flowing through the instrument $= c_2$.

Now, in the first connection (1), the electromotive force consumed by overcoming the electric resistance, is

$$e_1 = (r + r_0)\, c_1.$$

The E. M. F. due to self-induction:

$$e_1' = \frac{2\pi X}{T}\, c_1;$$

where X is the coefficient of self-induction of the instrument, and T the period.

Therefore, the resulting or impressed E. M. F., according to the parallelogram law, is:—

$$\sqrt{e_1^2 + e_1'^2} = c_1 \sqrt{(r + r_0)^2 + \frac{4\pi^2 X^2}{T^2}}$$

In the same way, the resulting or impressed E. M. F. with the second connection (2) is found:—

$$\sqrt{e_2^2 + e_2'^2} = c_2 \sqrt{(r + r_0 + R)^2 + \frac{4\pi^2 X^2}{T^2}};$$

and, both being equal, because of the shunt current being the same:—

$$c_1 \sqrt{(r + r_0)^2 + \frac{4\pi^2 X^2}{T^2}} = c_2 \sqrt{(r + r_0 + R)^2 + \frac{4\pi^2 X^2}{T^2}} \qquad (9)$$

and therefrom we get:—

$$X = \frac{T}{2\pi}\sqrt{\frac{c_2^2 (r + r_0 + R)^2 - c_1^2 (r + r_0)^2}{c_1^2 - c_2^2}}\,; \qquad (10)$$

and the shifting of phase, that is, the difference of phase between current and terminal pressure of the instrument:

$$\tan\omega = \sqrt{\frac{c_2^2\left(1 + \frac{r_0 + R}{r}\right)^2 - c_1^2\left(1 + \frac{r_0}{r}\right)^2}{c_1^2 - c_2^2}} \qquad (11)$$

Now in making several readings with continuous currents, we can eliminate the resistances r_0 and R, also. In connecting the instrument in a continuous-current circuit in series with r_0, with R, and with both $r_0 + R$ and varying the current so that the current indicator in the shunt gives the same reading v_0; or, interpolating for this reading v_0, we may get the three currents:

c_3 through r_0 and the instrument r.
c_4 through $r_0 + R$ and the instrument r.
c_5 through R and the instrument r.

Then we have:—

$$c_3 (r + r_0) = c_4 (r + r_0 + R) = c_5 (r + R); \qquad (12)$$

and therefrom:

$$\left.\begin{aligned} r_0 &= \frac{r\, c_3 (c_5 - c_4)}{c_4 c_5 + c_3 c_4 - c_3 c_5} \\ R &= \frac{r\, c_5 (c_3 - c_4)}{c_4 c_5 + c_3 c_4 - c_3 c_5} \end{aligned}\right\} \qquad (13)$$

Substituting this in formula (10) and (11):—

$$X = \frac{r\,T}{2\pi} \cdot \frac{c_5}{c_4 c_5 + c_3 c_4 - c_3 c_5}\sqrt{\frac{c_3^2 c_2^2 - c_1^2 c_4^2}{c_1^2 - c_2^2}} \qquad (14)$$

$$\tan\omega = \frac{c_5}{c_4 c_5 + c_3 c_4 - c_3 c_5}\sqrt{\frac{c_3^2 c_2^2 - c_1^2 c_4^2}{c_1^2 - c_2^2}} \qquad (15)$$

Now, when we can attribute to the additional resistance r_0 a particular value, for instance make it $= 0$, or $= R$, we shall save one of the continuous current readings and formulas (14) and (15) become simpler.

(A.) Without additional resistance, for instance: $r_0 = 0$. Therefore: $c_5 = c_4$.

$$X = \frac{r\,T}{2\pi\, c_4}\sqrt{\frac{c_2^2 c_3^2 - c_1^2 c_4^2}{c_1^2 - c_2^2}} \qquad (14a)$$

$$\tan\omega = \frac{1}{c_4}\sqrt{\frac{c_2^2 c_3^2 - c_1^2 c_4^2}{c_1^2 - c_2^2}} \qquad (15a)$$

(B.) With the additional resistance: $r_0 = R$.
Therefore : $c_5 = c_3$.

$$X = \frac{r\,T}{2\,\pi\,(2\,c_4 - c_3)} \sqrt{\frac{c_3^2 c_2^2 - c_1^2 c_4^2}{c_1^2 - c_2^2}} \qquad (14b)$$

$$\tan\,\omega = \frac{1}{2\,c_4 - c_3} \sqrt{\frac{c_3^2\,c_2^2 - c_1^2\,c_4^2}{c_1^2 - c_2^2}}. \qquad (15b)$$

A few examples will show the application of this method:

1. In the electro-dynamometer-ammeter which was mentioned above, the resistance was very low : $r = .01$ ohm. Therefore, an additional resistance r_0 was used. As a current indicator a small continuous current ammeter was used.

$T = .01$ second.

It was found that for alternating currents :

$c_1 = 18.527$ amperes ; $c_2 = 10.679$ amperes.

For continuous currents :

$c_3 = 9.526$ amperes ; $c_4 = 5.074$ amperes.

Therefore, by formula (14b) and (15b) :—

$X = .0000657$ henry,

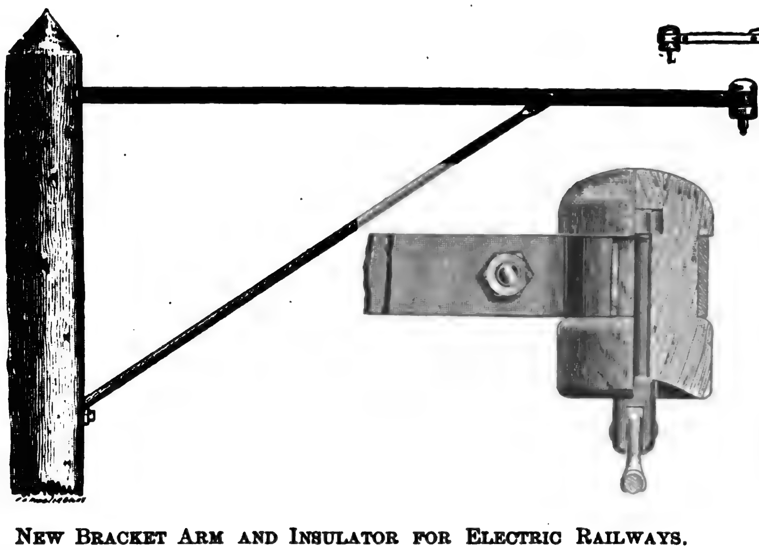
the coefficient of self-induction of this ammeter ; and the angle of shifting of phase :—

angle $\omega = 76.4$ degrees.

$$r_0 = R = \frac{r\,(c_3 - c_4)}{2\,c_4 - c_3} = .056 \text{ ohm.}$$

2. In a low-reading voltmeter of the electro-dynamometer type the resistance was :—

$r = 19.68$ ohm.
$r_0 = 0$;



New Bracket Arm and Insulator for Electric Railways.

no additional resistance used.

The same continuous current ammeter as in the former instance was used as a current indicator, but with about 13 ohms ordinary resistance in series.

It was found :

For alternating currents :

$c_1 = .3478$ ampere ; $c_2 = .1697$ ampere.

For continuous currents :

$c_3 = .3734$ ampere ; $c_4 = .1628$ ampere.

Therefore, by formulas (14a) and (15a) :—

$X = .03543$ henry,

the coefficient of self-induction of this voltmeter; and the angle of shifting of phase:

Angle $\omega = 29.5$ degrees.

$$R = \frac{r\,(c_3 - c_4)}{c_4} = 25.45 \text{ ohms;}$$

and $$\frac{1 - \cos\,\omega}{\cos\,\omega} = .149 = 14.9 \text{ per cent.}$$

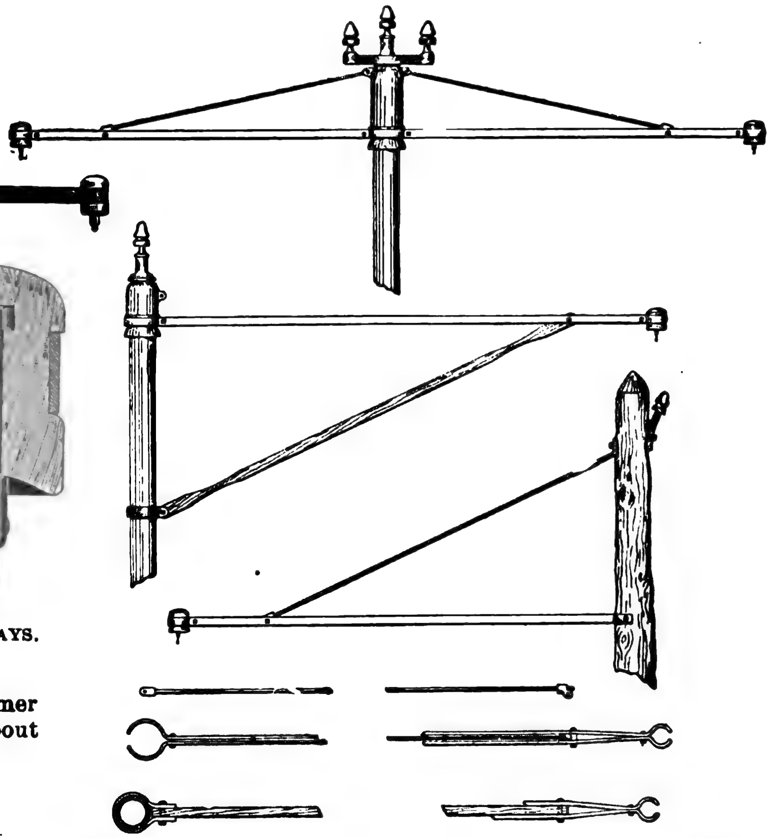
Therefore for such alternating currents of 100 full periods per second the readings of this instrument have to be increased by 14.9 per cent. to get the correct voltage. The correction for any other number of periods can easily be calculated.

This method is open to the objection of inaccuracy upon the assumption that the alternate currents are true sine-waves. But in looking further into the matter, we shall often find this to be of advantage for practical purposes.

Because, if we do not want to know the absolutely exact value of the coefficient of self-induction for scientific purposes, but want to use the instruments to measure alternating dynamo currents and the behavior of inductive resistances toward them, then the figures obtained in this way hold good for the same kind of dynamo currents, and allow us to assume them again as true sine-waves in the calculations of electric machinery. Besides, in most of the alternators built to-day, the deviation of current from the sine-wave is rather small.

NEW BRACKET ARM AND INSULATOR FOR ELECTRIC RAILWAYS.

The accompanying cuts shows a new form of bracket arm which attracted much attention at the recent Buffalo Street Railway Convention, and which has several distinct advantages over the existing forms. The cut shows



New Bracket Arm and Insulator for Electric Railways.

the simplest possible form, although the same principle readily admits of ornamentation. The arm consists of two flat bars bolted together. At their inner end they are bent apart so as to partially clasp the pole, and have holes near their extremities by which the arm is attached to the pole with lag screws. A brace clamped between the two bars supports the arm from above or below. The outer ends of the bars are so shaped that when clamped together they embrace and hold an insulator specially designed for the purpose. The insulator is firmly held in a vertical

position, and a brass foot is riveted into a malleable iron stem with a stout and deeply forked end. This admits of free oscillation of the foot in the line of the wire, but no lateral movement. The advantages of this arm are its great simplicity and strength. It is attached to the pole in such a manner that a break or slacking of the wire will not injure it or its attachment to the pole. It is suitable for curve and straight line work. The insulator is strong and efficient, and exactly suited to the work required of it. This form of bracket arm is made also for use with iron poles, in which case it clamps at the inner end to an insulated iron pole top of special design, and is so arranged that the entire bracket arm is insulated from the pole. These devices are manufactured by Emmet Bros., of this city. They are being used in large quantities by the North American Construction Co., of Pittsburgh.

A NOVEL WIRE CONNECTOR FOR HEAVY WIRES.

Good joints in wires for electric circuits, whether for indoor or aerial work, are recognized to be just as important for successful work as the necessity for good copper. We illustrate in the accompanying engraving a new form of connector, called the Brennan "No-Solder" Wire Connector, a device designed more especially for jointing large wires ranging from No. 0 to No. 00000 in size. This connector, which was patented on October 14, is made of cast bronze, the holes being drilled to fit the wire to be connected. The horizontal slot joining the two holes, as shown, is made so that the connector will grip the wire tight and make a good electrical contact when pounded with a hammer. When stranded wires are used, solder may be applied

Novel Connector for Heavy Wires.

at the slot running across the face of the connector. The Pettingell-Andrews Company, of Boston, are introducing these goods and have the exclusive sale for the whole of the United States.

WESTERN UNION TROUBLES IN THE WEST.

A special dispatch from Chicago of Oct. 27th says:—"The trouble between the Western Union Telegraph Company and its operators grows daily more serious and promises to become widespread. It already extends over a good deal of territory throughout the West. The entire night force of the St. Paul office, to the number of thirty-seven, struck to-night and left the office in a body. It is reported here that the day force, numbering about 50 men, will refuse to report for duty at 8 o'clock to-morrow morning. St. Paul is the repeating station for the Northwest, and the entire telegraphic business of the Northwest is paralyzed.

"The strike was precipated by the discharge of operators Cooper, Gibbons, Moore, Dempsey, Leadsworth, and Patterson, late on Saturday afternoon. The men were discharged while at work at their wires. They were all supposed to be prominent in the new Telegraphers' Brotherhood, and, when one of them pressed the official who executed the orders for a reason, he replied: 'You know very well.'" There is trouble of the same kind at St. Louis.

THE WOOD DOUBLE BREAK LIGHTNING ARRESTER.

The experience gained during past years in arc lighting, which has been amply confirmed by numerous experiments, has demonstrated that lightning arresters in order to be effective in their action must not present to the path of the discharge any inductive resistance. Such a resistance, if in circuit, evidently creates an enormous counter E. M. F. which opposes the discharge to earth and is apt to cause

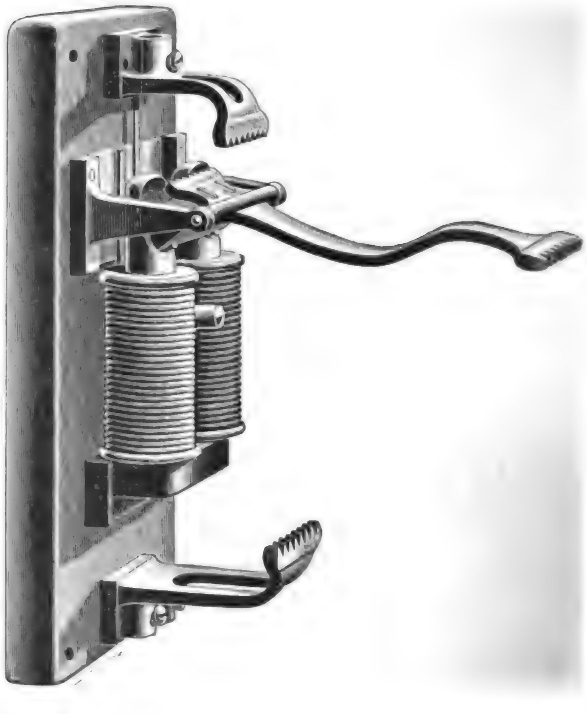


Fig. 2.—Wood's New Lightning Arrester.

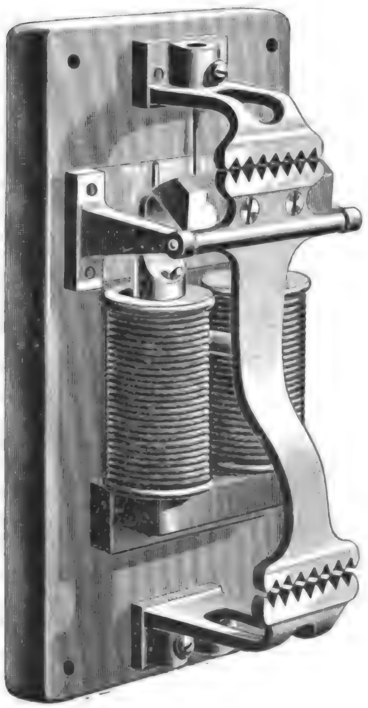
the destruction of the machines which the arrester is designed to protect. The modern form of lightning arrester designed for arc lighting purposes, while preserving the saw tooth form of arrester, has therefore been modified to prevent the maintenance of the arc which would be due to the current from the dynamo following the flash to ground. For this purpose several devices have been constructed, which, upon the passage of a discharge, separate the saw teeth and those break the arc and the current to ground at the same time. This breaking of the arc is usually effected by the action of electro-magnets in circuit with, and a part of, the arrester.

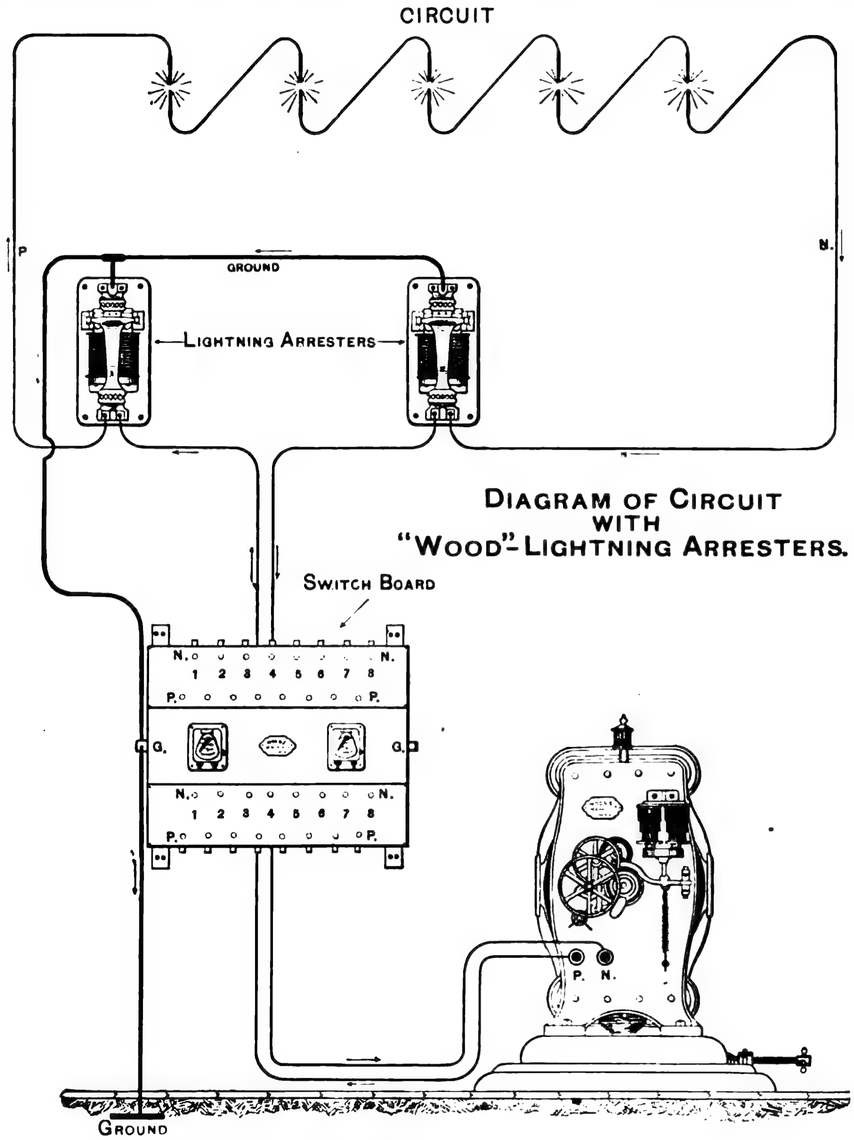
But it is evident that while this device is in itself a very useful one, the precaution to be observed with regard to the insertion of inductive resistances still holds true. It is a well known fact that the current will jump an air space of very high resistance in preference to passing through such an electro-magnet.

To avoid this action, therefore, but at the same time to retain the electro-magnet to break the arc, Mr. J. J. Wood, the electrician of the Fort Wayne Electric Co., has recently designed an ingenious lightning arrester, which is illustrated in the accompanying engravings. Here Fig. 1 shows the arrester in its normal condition ready to receive a discharge to earth and Fig. 2 shows its condition immediately after receiving such a discharge. As will be seen, the arrester consists of a cross-bar pivoted horizontally, carrying two tongues, an upper short one, and a lower one of greater length. These tongues are serrated and come opposite similar saw tooth plates. Attached to the horizontal pivoted shaft is a soft iron armature which is acted upon by the prolonged cores of the electro-magnets so that when a discharge passes through the arrester the armature is attracted and swings the tongues out of

their original position, breaking the arc at two points, above and below, as shown in Fig. 2. As soon as the discharge has taken place and the current is broken, the arrester at once falls back to its original position due to the overbalancing of the armature by the lower tongue.

The distinguishing feature of the arrester, however, consists in the fact, that instead of being placed in series with the arrester points, the electro-magnets which serve to break the arc are placed in a shunt around the upper pair. The result of this is that the discharge, instead of being required to pass through the electro-magnets and then through the discharge plates, has two paths open to it, one directly across the discharge plates without any hindrance,





FIGS. 1 AND 3.—WOOD'S NEW LIGHTNING ARRESTER.

and another through the electro-magnets. Assuming then that the discharge would prefer to pass directly across the plates, the current to earth established thereby would have a part of it immediately shunted through the electro-magnets, which, being energized, at once attract the armature and break the arc by separating the plates at the two points.

The diagram, Fig. 3, shows very clearly the arrangement of the circuits. The circuit after passing through the switch-board is connected to the lower plate of the lightning arrester, passes from there through the lamps, back to the incoming lightning arrester and back to the machine. The upper terminals of the lightning arresters are connected to ground. This ingenious arrester is now being manufactured at the works of the Fort Wayne Electric Co., in Brooklyn, N. Y.

ELECTRIC WELDING APPLIED TO THE MANUFACTURE OF PROJECTILES.[1]

BY LIEUT. W. M. WOOD, U. S. N.

AFTER describing the tedious and expensive methods heretofore in vogue, Lieut. Wood proceeded to the explanation of the new processes adopted, with the aid of the Thomson electric welding apparatus as follows:

First, instead of the solid, rough-forged ingot, we have these three component parts, which when welded together will form a 6 lb. armor-piercing shell. Each piece is now finished to exact size, except that there is a little extra length to allow for the take-up in welding. The head and base pieces are forged in dies to shape; the central portion is simply a piece cut from a length of solid drawn steel piping. It has all the additional strength due to the fibrous skin inside and out caused by the drawing process. To join these three pieces, they are clamped into a form of electric welding machine designed for the purpose, and in less than a minute are joined together and made a homogeneous mass like this.

It only now remains to grind off the two burrs which you see in this specimen, and cut in the groove for the rotating band. The front one of these burrs may be used to form an enlargement used in many forms of projectiles, called technically, a "bourillet." It supports the front portion of the shell in the bore of the gun, the remainder not touching except at the rotating band. The other burr may be removed at the same time the rotating band groove is cut. The fuse hole has already been cut and threaded in the base piece. The shell is now ready for the hardening process. I wish to call attention here to the fact that the burrs are allowed to remain on the inside and thus form

1. Abstract of paper read before the Boston Society of Arts, Boston, Oct. 23, 1890.

strengthening ribs which help materially to support the shell against the great crushing strain it receives on impact. You will see that we have thus formed a stronger and better shell with minimum of labor on the individual parts and a few seconds' work to join them together.

In order to illustrate the wonderful strength that may be gained by this welding process, I have here a shell which was constructed exactly as I have shown. It was fired through a 3-in. plate of iron at the Naval Proving grounds at Annapolis, recently. You will see that it has not changed its shape in the slightest degree, nor has it even lost the copper rotating band which was carried through the hole with it. Here is another which shows a still more remarkable result. This projectile was fired against heavy steel armor which has a resistance of about 75 per cent. more than iron and which was much heavier than a projectile of this size could be expected to perforate. It, however, penetrated 5 inches, and then, owing to the elasticity of the oak backing of the plate, was thrown back about 30 feet, as perfect in condition as before it was fired from the gun. The experience of the Welding Company has been that the metal seems to be strengthened at the point of welding and this certainly seems to justify the supposition.

A NEW METHOD OF ANALYZING THE MAGNETIC REACTIONS OF ARMATURES APPLIED TO THE STANLEY ARC LIGHT ALTERNATING CURRENT MACHINE.[1]

BY THORBURN REID.

THIS analysis is a result of looking at an old and well-known phenomenon from a new point of view, and is merely a development of the principle of the magnetic circuit a little further than has heretofore been usual. Hopkinson, I find, has used much the same method in his analysis of the transformer, and seems vaguely to have foreseen its application to dynamos; if I may judge from a part of a sentence which I ran across in one of his articles a few days ago, this same principle has been discussed at some length in the English electrical journals lately, but I am not aware that any analysis has been attempted by means of it.

By this conception dynamos are considered to consist of a magnetic circuit composed partly of iron (or steel) and partly of air, one part being at rest and the other in motion (generally rotary). Magnetism is induced in this circuit by means of two or more coils of wire carrying an electric current, wound around some part or parts of the circuit. One or more coils may be wound on the fixed part of the circuit and one or more on the moving part, and the magnetism induced will be that due to the sum of all the magneto-motive forces in all the coils, divided by the sum of all the magnetic resistances. The magneto-motive forces in the fixed

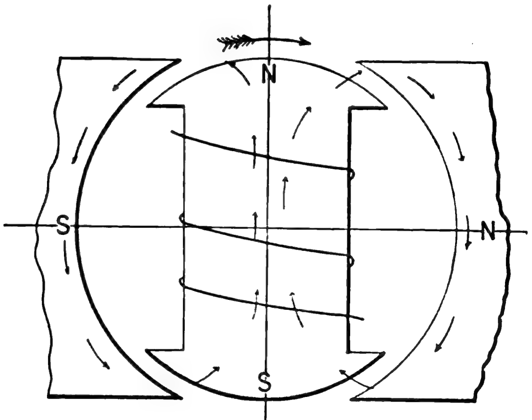


Fig. 1.

coils are generally approximately constant, except where they are varied for purposes of regulation. In the movable coils, however, the M. M. F. is generally variable. In direct current machines its effect on the total flux around the magnetic circuit is also almost inappreciable, chiefly for the reason that it acts almost at right angles to the magnetic circuit. In alternating current machines, however, it is quite considerable, and is generally taken into account, but attributed to the self-induction of the armature. The connection between the counter M. M. F., as it may be called, of the armature and its self-induction will be brought out more fully in a subsequent part of this paper.

1. A paper read before the American Institute of Electrical Engineers, New York, October 21st, 1890.

To simplify our conceptions we will assume a two pole dynamo with one coil on the armature, as shown in Fig. 1. Referring to the diagram, Fig. 2,

Let $\overline{ON} = N$, represent the magnetic induction through the armature due to the field in magnitude and direction.

Let $\overline{OO'}$ represent the position of the armature coil at that instant.

Let $\overline{OA} = A$, at right angles to $\overline{OO'}$, represent the magnetic induction due to the armature coil at that instant.

Let $\overline{PP'}$, at right angles to the field lines, be the neutral line.

Let $POC = \theta$ be the angle through which the coil has moved from its neutral position.

By completing the parallelogram, and thus compounding the two magnetizations N and A, we obtain $M = \overline{OR}$ as the resultant magnetic induction through the armature coil in amount and direction, at that instant, and $\overline{QQ'}$, at right angles to $\overline{OR}$, as the

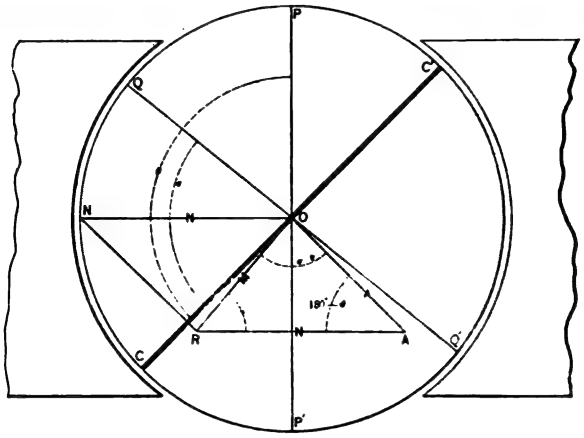

FIG. 2.

neutral line with reference to this resultant magnetization. Then QOC $(= \sigma)$ is the angle through which the coil has turned from this new neutral line.

Let the angle $\overline{NOR}$ $(= ORA) = \alpha$. We are to deduce the value of M from the known quantities N, A, and the angle θ. In the triangle ROA, $\overline{RO}$ is perpendicular to $\overline{OQ}$ and $\overline{OA}$ is perdendicular to $\overline{OC}$; therefore the anglo $ROA = \overline{QOC} = \sigma$.

Also $\overline{OA}$ is perpendicular to $\overline{OC}$ and $\overline{AR}$ is perpendicular to $\overline{OP}$; therefore $\overline{OAR} = \overline{OOP} = 180° - \theta$.

From trigonometry we have :—

$$\frac{M}{\sin (180° - \theta)} = \frac{N}{\sin \sigma} = \frac{A}{\sin \alpha};$$

or

$$\frac{M}{\sin \theta} = \frac{N}{\sin \sigma} = \frac{A}{\sin (\theta - \sigma)} \qquad (1)$$

therefore

$$N \sin (\theta - \sigma) = A \sin \sigma.$$

Expanding $\sin (\theta - \sigma)$, dividing by $\cos \sigma$ and solving for $\tan \sigma$, we have

$$\tan \sigma = \frac{N \sin \theta}{N \cos \theta + A} \qquad (2)$$

whence by trigonometry

$$\cos \sigma = \frac{N \cos \theta + A}{\sqrt{N^2 + 2\, A\, N \cos \theta + A^2}} \qquad (3)$$

$$\sin \sigma = \frac{N \sin \theta}{\sqrt{N^2 + 2\, A\, N \cos \theta + A^2}} \qquad (4)$$

Therefore, from equation (1)

$$M = N \frac{\sin \theta}{\sin \sigma} = \sqrt{N^2 + 2\, A\, N \cos \theta + A^2} \qquad (5)$$

This last expression gives us the actual value of the induction through the armature coil at that instant in terms of the field strength, the armature strength and the angle θ through which the coil has been turned from the position perpendicular to the field lines. The direction of this resultant magnetization is along $\overline{OR}$, and the neutral line has been shifted from $\overline{OP}$ to $\overline{OQ}$ and the number of lines actually passing through the coils is $M \cos \sigma$.

From equations (3) and (5) we obtain $M \cos \sigma = N \cos \theta + A$.

The E. M. F. at any instant is then

$$E = -\frac{d}{dt}\left\{ S N \cos\frac{2\pi t}{T} + S A \right\} \quad (6)$$

where S is the number of turns in the coil; t is the time which has elapsed since the coil passed the position $\overline{OP}$, and T is the time of one revolution.

Therefore,

$$E = \frac{2\pi S N}{T} \sin\frac{2\pi t}{T} - S\frac{dA}{dt} \quad (7)$$

The armature magnetization, A, depends on the number of turns in the coil, on the current flowing through it, and on the magnetic resistance offered to its lines of force; or

$$A = \frac{S i}{\rho} \quad (8)$$

where ρ is the magnetic resistance, and i the instantaneous value of the current.

Letting $\frac{S^2}{\rho} = L$, dividing through by R, the resistance in the main circuit, and collecting the terms, we have

$$\frac{di}{dt} + \frac{R}{L} i = \frac{2\pi S N}{L T} \sin 2\pi\frac{t}{T} \quad (9)$$

Let

$$\frac{2\pi S N}{L T} = a,\ \frac{2\pi}{T} = p, \text{ and } \frac{R}{L} = b,$$

and we have

$$\frac{di}{dt} + b\, i = a \sin pt \quad (10)$$

a differential equation which must be integrated.

This equation may be reduced to the following form

$$i = e^{-bt}\int a \sin pt\, e^{bt}\, dt \quad (11)$$

which may be integrated by parts thus

$$i = a e^{-bt}\int e^{bt} \sin pt\, dt$$

Let $u = \sin pt$ and $dv = e^{bt}\, dt$; then $du = p \cos pt\, dt$ and $v = \frac{1}{b} e^{bt}$; $\int u\, dv = \frac{1}{b} e^{bt} \sin pt - \int \frac{1}{b} e^{bt} p \cos pt\, dt$;

$$i = \frac{a}{b} \sin pt - \frac{ap}{b} e^{-bt} \int e^{bt} \cos pt\, dt.$$

Let $u = \cos pt$, and $dv = e^{bt}\, dt$; then $du = -p \sin pt\, dt$, and $v = \frac{1}{b} e^{bt}$ $\int u\, dv = \frac{1}{b} e^{bt} \cos pt + \int \frac{1}{b} e^{bt} p \sin pt\, dt$;

therefore $i = \frac{a}{b} \sin pt - \frac{ap}{b^2} \cos pt - \frac{p^2}{b^2} i$; or

$$i = \frac{a}{\sqrt{p^2 + b^2}}\left\{ \frac{b}{\sqrt{p^2 + b^2}} \sin pt - \frac{p}{\sqrt{p^2 + b^2}} \cos pt \right\}$$

Let $\tan^{-1} \varphi = \frac{p}{b}$. Then substituting for a, b and p, their values, we have

$$i = \frac{2\pi S N}{\sqrt{R^2 T^2 + 4\pi^2 L^2}} \sin(\theta - \varphi) \quad (12)$$

where φ is the angle of lag, or the angle by which the effective E. M. F. lags behind the impressed E. M. F.

This is the instantaneous value of the current at any instant. Since the average value of the square of the sine of any angle is ½, we have, calling C the square root of the average square of the current:

$$C = \frac{\sqrt{2}\, \pi S N}{\sqrt{R^2 T^2 + 4\pi^2 L^2}} \quad (13)$$

$$E = \frac{\sqrt{2}\, \pi S N R}{\sqrt{R^2 T^2 + 4\pi^2 L^2}} \quad (14)$$

You will no doubt have already recognized this equation as the ordinary equation of the alternating current dynamo, *when the self-induction of the armature coils is taken into account.* This analysis so far has taken no account of the self-induction in the armature coil. There has, however, been introduced into the discussion a factor not generally treated in this connection, namely, the counter M. M. F. of the coil. This factor occurs in the equation as the expression for which I have used the letter L. L is ordinarily used to denote the coefficient of self-induction, and I chose it for that very reason. The connecting link is shown by the value given to L in our equation; namely $\frac{S^2}{\rho}$.

We shall now show that L, the coefficient of self-induction of a coil, is equal to the square of the number of turns in the coil, divided by the magnetic resistance of the circuit, through which the lines of force of the current flowing in the coil must travel. There are several ways of getting at a definition of L and perhaps the simplest is the following:

The counter E. M. F. of self-induction of a coil, in which a varying current is flowing, is $L\frac{di}{dt}$ where $\frac{di}{dt}$ is the rate of change of the current at the instant considered; or, more simply, if the current is changing at a constant rate, it is the number of amperes through which the current is increasing or decreasing in a second. If the current is changing at the rate of one ampere in a second, $\frac{di}{dt}$ becomes unity and $L\frac{di}{dt}$ becomes equal to L. Therefore L represents the counter E. M. F. of self-induction of a coil, in which the current is changing at the rate of one ampere in a second.

Now selecting suitable units, the number of lines of force which will be sent around a magnetic circuit of magnetic resistance ρ by a current of one ampere flowing through a coil of S turns, will be $\frac{S}{\rho}$. Therefore if the current is increasing at the rate of one ampere per second, $\frac{S}{\rho}$ lines of force will be inserted or taken out of the coil in a second, and the E. M. F. set up will be $\frac{S}{\rho} \times S = \frac{S^2}{\rho}$; but, since the current is changing at the rate of one ampere per second, the E. M. F. set up $= L$. Therefore $L = \frac{S^2}{\rho}$.

These equations (13 and 14) might have been arrived at a little differently by resolving the counter magneto motive force of the coil parallel to the induction due to the field, and then considering the comparative values of the resistances through the inside of the coil and around the outside; but this method is more complicated than the one I have chosen, and a little consideration will show that it is precisely the same thing, merely looked at from a different point of view.

Now let us see how this equation must be modified to suit the conditions obtaining in the Stanley alternating arc machine. This machine is of the multipolar type, with the coils laid flat on the armature core. It differs from the ordinary Westinghouse alternating machine mainly in the facts that each coil consists of a large number of turns, and is laid in longitudinal grooves in the armature core in such a manner as to be almost entirely surrounded by iron, and that the number of alternations per second is large. As a result of this arrangement the machine maintains a nearly constant current throughout wide variations of resistance and speed.

To explain this phenomenon we will use equation (13), first substituting for L its value, $\frac{S^2}{\rho}$, and we have

$$C = \frac{\sqrt{2}\, \pi S N}{\sqrt{R^2 T^2 + 4\pi^2 \frac{S^4}{\rho^2}}} \quad (15)$$

Since there is a large number of turns in the armature coil, S is very large and S^4 correspondingly larger. Then, since the coil is almost completely surrounded by iron, ρ is very small, and accordingly $\frac{S^4}{\rho^2}$ is exceedingly large. Then, since the number of alternations is very large, T, the time of one alternation, is a very small fraction, and, therefore, $R^2 T^2$ may be neglected as compared with $4\pi^2\frac{S^4}{\rho^2}$. Neglecting this term then and reducing, our equation becomes

$$C = \frac{N \rho}{\sqrt{2}\, S} \qquad (16)$$

This equation shows that C is dependent on the magnetic induction through the coil due to the field, on ρ the magnetic resistance to the lines of force of the coil, and on S, the number of turns in the coil. *Resistance and speed are conspicuous by their absence.*

We must remember, however, that if R and T are increased

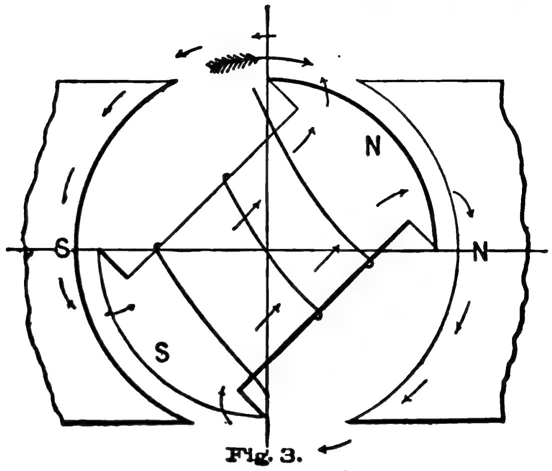

Fig. 3.

sufficiently in value, $R^2\ T^2$ will cease to be negligible as compared with $4\ \pi^2 \frac{S^4}{\rho^2}$, and therefore, every increase in R will increase the denominator of equation (15), and C will decrease.

If, therefore, we fix the limits between which the current may change, while the resistance in the main circuit is changing from its lowest to its highest value, we may determine the speed below which the machine must not run. Any increase of the speed above this point merely tends to lessen the fluctuation of the current between the highest and lowest resistances. Again, any increase in the speed above this point will widen the range throughout which the resistance may vary, without the fluctuation in the current passing the prescribed limit. R will have its lowest value when the armature is short-circuited, and will then equal the resistance of the armature coils, and the current will be at its maximum value. The minimum value of the current then

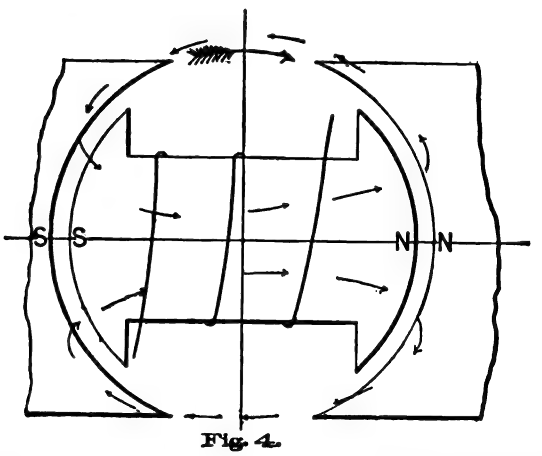

Fig. 4.

being fixed, the maximum value of R will depend on the value of $R^2\ T^2$, as compared with $4\ \pi^2 \frac{S^4}{\rho^2}$ or R (maximum) may vary inversely with T, or directly as the number of alternations per second.

Returning now to equation (16) we see that C varies directly as N (the field is separately excited) and N varies directly as the exciting current. Therefore any increase in the magnetizing current will correspondingly increase the main current. This is in fact the method by which the main current is brought to its proper value. The machine is short-circuited and the main current brought to its proper value by varying the magnetizing current. The main current will then remain practically constant throughout the prescribed range of resistance.

Secondly, the current varies directly as ρ. This, too, has been shown to be true, for in one of the first machines built the coils were wound in cylindrical longitudinal holes in the armature core so that they were entirely surrounded by iron, and as a result the current obtained was too small to be measured. Longitudinal slots were then cut in the armature core so as to increase ρ, and by widening these slots to the proper amount, the desired current was obtained.

Finally C varies inversely as S, the number of turns in the armature coil. That is, the more turns in the armature coil the less the current delivered. This, too, was found to be true in the experimental stage of the work. But it must be remembered that S must not be made so small that the term $4\ \pi^2 \frac{S^4}{\rho^2}$ becomes comparable with $R^2\ T^2$. We may perhaps obtain a simple conception of the reaction by slightly changing the form of our equation. We may write equation (15) thus,

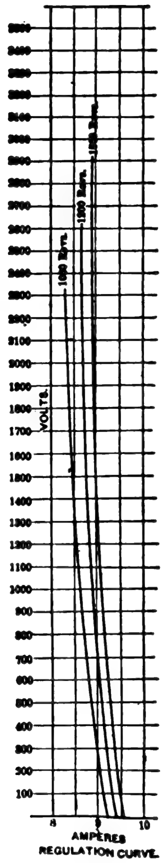

Fig. 5.

$$C = \frac{\sqrt{2}\, \pi\, S\, N}{R\ T \sqrt{1 + \frac{4\ \pi^2\ L^2}{R^2\ T^2}}} = \frac{\sqrt{2}\, \pi\, S\, N}{R\ T\ \sqrt{1 + \tan^2 \varphi}} \qquad (17)$$

where φ is the angle of lag.

Neglecting the term 1, under the radial sign, we have

$$C = \frac{\sqrt{2}\, \pi\, S\, N}{R\ T \tan \varphi} \qquad (18)$$

$\tan \varphi$ varies inversely as $R\ T$, and therefore the product of $\tan \varphi$ and $R\ T$ in the denominator remains constant. Referring to Fig. 1, and remembering that φ is the angle by which the effective E. M. F. lags behind the impressed E. M. F., we observe that if there is no lag the effective E. M. F., or, the current will reach its maximum value when the coil is in the position shown in Fig. 1; and therefore the largest possible number of lines will flow through the coil and will be taken out of it during the revolution. As φ increases, the current is delayed in reaching its maximum value, until the coil has passed the position shown in Fig. 1, and when φ is nearly 90° the coil will have nearly attained the position shown in Fig. 4 before the current reaches its maximum value; but in this position the M. M. F. of the coil almost exactly opposes that of

the field, thus largely reducing the number of field lines which will pass through the coil. As φ increases, the E. M. F. decreases. Then we have: a decrease in R tends to increase the current, but a decrease in R tends to increase φ, which, in turn, decreases the effective E. M. F. and reduces the current. φ must be nearly 90° so that the demagnetizing effect of the coil may vary inversely as R, which it will not do if φ is small. The result may be viewed in still another way; we may write our equation thus,

$$C = \frac{\sqrt{2}\,\pi\,S\,N\,n}{\sqrt{R^2 + 4\,\pi^2\,L^2\,n^2}} \quad (19)$$

where n is the number of complete waves per second. The numerator of this fraction will then represent the E. M. F., which would be set up in the coil, if there were no self-induction. The denominator consists of the ohmic resistance R, and of another term due to self-induction, which is equivalent to an added resistance and has been called the inductance. This quantity $2\,\pi\,L\,n$ multiplied by C will equal the counter E. M. F. of self-induction of the coil. As long, then, as the inductance or induction resistance of the coil is very large as compared with the ohmic resistance, any change in the ohmic resistance will only very slightly affect the total resistance, which is the sum of the two.

Let us now consider what light these equations will throw on the question of designing the machine. The problem is to obtain a current of the desired strength and constancy, with the least

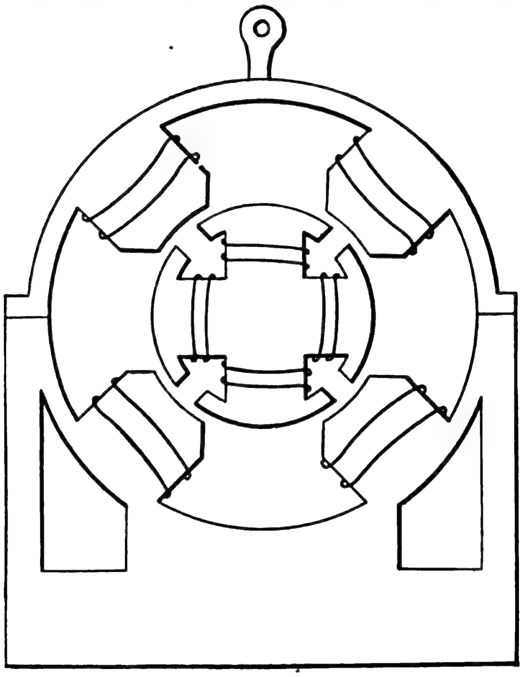

Fig. 6.

expenditure of energy and at the least expense, and the quantities with which we may work to obtain this result are $N\,S\,\rho$ (or L) and T. We see immediately that it is advantageous to make T as small as mechanical considerations will allow, since the smaller T is, the more constant will the current be throughout the range, or the wider the range the resistance may have without causing the current to vary below the prescribed limit. This points then to a multiplicity of poles, or high speed, or both.

N, on the other hand, should be as large as possible, for the output of the machine varies directly with that factor, and its increase does not at all affect the fluctuation of the current. S, again, should be as small as it can be made without affecting too much the regulation of the machine.

ρ is the one indeterminate quantity in this equation. It is almost impossible to calculate its value beforehand to any reasonable degree of accuracy, for several reasons. The magnetic circuit of which it is the resistance, varies in cross section throughout its whole length, and this variation is not uniform but has several points of discontinuity. Furthermore, ρ varies during the revolution of the armature, for when the armature pole is half way between two field poles, part of the path of the lines of force is through the field pole, and when the armature pole is opposite the field pole, that same part of the path of the lines of force will be made up of the air gap between the two field poles, and ρ will be much increased. An approximate value might be obtained by determining L with the armature in different positions and taking an average of the values thus obtained; but if in actual practice the iron is worked anywhere near the saturation point, this method would be of doubtful utility, unless the currents used in determining L were the same as those used in practice.

Probably the best method for practical work would be by means of a curve of current and E. M. F., where, all the terms being known except ρ and probably N, we can obtain $n\,\rho$ from one point on the curve, and both ρ and N from two points. This method, while it would probably not give us very accurate values of these two terms, would be of value for purposes of comparison, so that by means of a large number of determinations we might obtain data which would be very useful in designing future machines.

Another useful thing to know is what is the highest value which the E. M. F. will attain on open circuit. This may be obtained from equation (14) thus: Dividing both numerator and denominator by R and neglecting the second term under the radical sign (since R is infinite on open circuit) we have,

$$E = \frac{\sqrt{2}\,\pi\,S\,N}{\sqrt{T^2 + \frac{4\,\pi^2\,L^2}{R^2}}} - \sqrt{2}\,\pi\,S\,N\,n \quad (20)$$

where n is the number of complete periods per second.

This E. M. F. will of course be very high, since there are very many turns in the armature coil, and n, the number of periods per second, is very large. As a consequence of this, if the machine is allowed to run on open circuit, the armature insulation will soon break down, thus producing a ground which will speedily burn out the machine.

The following is the complete formula where all the terms are expressed in practical units.

$$C = \frac{\sqrt{2}\,\pi\,S\,N}{10\sqrt{10^{18}\,R^2\,T^2 + 12.768^2\,\pi^2\,S^4\,\mu^2\,\frac{A^2}{l^2}}} \quad (21)$$

INVESTIGATION OF THE STANLEY ALTERNATE CURRENT ARC DYNAMO.[1]

BY W. B. TOBEY AND G. H. WALBRIDGE.

BEFORE entering directly upon the subject to be presented this evening, *i. e.*, the investigation of the Stanley alternate current arc dynamo, it may be well to give a brief description of that new and extremely novel type of machine. Descriptions of it have been given in some of the electrical papers during the past spring, but some here may not recall its general mechanical construction. The dynamo is manufactured and sold by the Westinghouse Electric Company under patents granted to Mr. Wm. Stanley, Jr., the inventor. Mr. Albert Schmid, superintendent of the Westinghouse Electric Company's shops, deserves much credit for perfecting the machine in detail, and to him is largely due its success commercially. In general appearance it closely resembles the Westinghouse alternate current constant potential dynamo, which has become so familiar to all. In fact, the frame, pole pieces, field windings, etc., for any given size machine are identical, whether for constant current or constant potential. The distinguishing feature between them lies wholly in the form and winding of the armatures. Figs. 12 and 13, showing diagrammatically half sections of the machine, will aid us in a description of the armature, which is built up of thin iron plates stamped in the form shown. It will be observed that a number of cores corresponding to the number of poles off the dynamo project radially from the armature, and from the sides of each core project overlapping lugs. The armature coils are not of the original "pancake," or oblong flat coil type, placed on the periphery of the armature, but are quite thick and placed around the core projections. The overlapping lugs serve the double purpose of preventing the coils from slipping off the cores and also aid in the regulation of the machine. All the armature coils are connected in series and the terminals connected to the two collector rings, upon which bear the brushes furnishing current to the line. The field coils are also in series, so connected that the poles presented to the armature are of alternate polarity. The terminals of the field go directly to a small shunt wound exciter. Thus it is seen that the machine consists simply of an even number of field coils, corresponding to the number of poles on the machine, joined in series, and an equal number of armature coils also joined in series. That from such a simple combination of coils without any external regulating device, an almost constant current is obtained for all loads, from short circuit to the maximum output of the machine, seems incredible, but such is the case.

Through the kindness of Mr. Stanley, a complete 40-light plant was sent the writers at Cornell University, at which institution

1. A paper read before the American Institute of Electrical Engineers, New York, Oct. 21, 1890.

we were then students. Later, the Westinghouse Company made the University a gift of the entire plant. It has been our aim to show how the regulation takes place; also to determine the actual electrical output of the machine, and from the latter and the corresponding dynamometer readings to calculate the efficiency of the dynamo.

The alternator was mounted on a bracket cradle dynamometer calibrated to read in watts direct at 1000 revolutions, the speed at which we were running.

The general method has been to obtain instantaneous values of E. M. F., arc and exciter currents at a sufficient number of points to indicate by curves the performance of the dynamo at every part of a revolution. For this purpose runs were taken with the

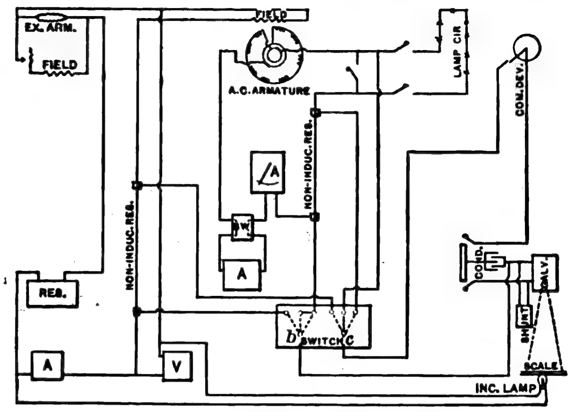

Fig. 1.—DIAGRAM OF CONNECTIONS.
A, A, A. Ammeters; V. Voltmeter.

dynamo at short circuit and with loads of 5, 10, etc., up to 40 lamps. The dynamo was run under normal conditions, viz., at a speed of 1000 revolutions and with such excitation as to cause an output of approximately 10 amperes. For obtaining values of E. M. F. at low loads, pressure wires were run from the terminals of the dynamo and for larger loads were taken from around 10 lamps. At all points where instantaneous values of E. M. F. were taken corresponding values of arc and field, or exciter currents were obtained by "fall of potential" method. Pressure wires were brought from the terminals of each of two non-inductive resistances of German silver wire placed in arc and field circuits. (See Fig. 1.) These resistances being constant, any pressure around the terminals corresponded to a certain current. The termi-

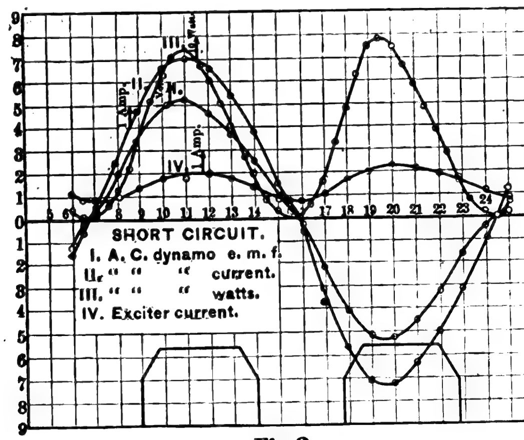

Fig. 2.

nals of the three pairs of pressure wires were connected to the contacts of the triple-throw switch, so that by placing the switch on any pair of contacts desired, those terminals could be put in circuit with a line in which was a condenser and the revolving contact or commutating device by means of which the condenser was charged. The revolving contact used was similar to the one described in detail by Prof. Ryan in his article on "Transformers," read before the Institute last December.[1] It consists essentially of a knife edge of steel fastened by a wooden clamp to the collector end of the armature, and revolving with it through a circle of about eight inches diameter. The centre of the knife edge was in line with the centre of one of the armature coils. Upon a frame at the same end of the armature was held a wooden semicircle, upon the periphery of which was a paper scale, divided to

1. See Transactions of the American Institute of Electrical Engineers, Vol. VII., p. 1.

millimeters. At the centre of the semicircle was pivoted an arm carrying a brushholder in which was a steel spring. The brushholder was so adjusted that the revolving knife edge made contact with the spring several times per second. The arm carrying this spring could be clamped wherever desired, and its position designated by means of a pointer over the scale.[2] Thus, the condenser, placed in series, could be brought to the same difference of potential that existed between the spring and the knife edge. The arc circuit was, as shown by the diagram of connections, Fig. 1, taken from one brush directly to a Westinghouse ammeter through a switch, by means of which a Thomson balance, or gravity ammeter could be put in circuit when desired. From the Westing-

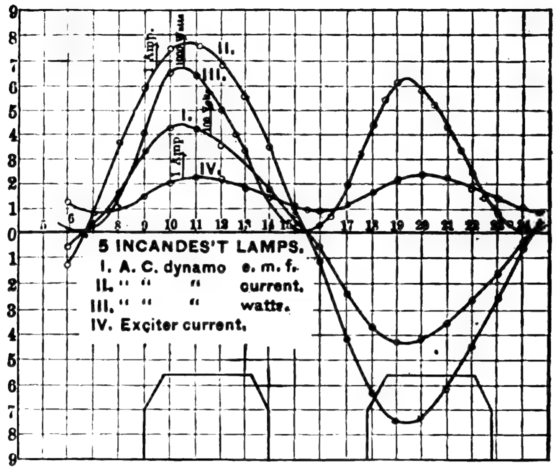

Fig. 3.

house ammeter the current was taken through the non-inductive resistance to the dynamo short circuiting switch, where the other terminal of the machine was directly connected. The exciter current was measured by a Ryan gravity ammeter, and a Hartmann and Braun type voltmeter indicated the potential around the terminals of the field. The arm of the commutating device being clamped at some desired position, the spring was adjusted so that the revolving knife edge made contact, then the switch was thrown on any one of the three pairs of terminals, for the circuits of which we wished to obtain instantaneous values. The half microfarad condenser was so connected that by closing a key it would be charged. Opening this key and closing one in

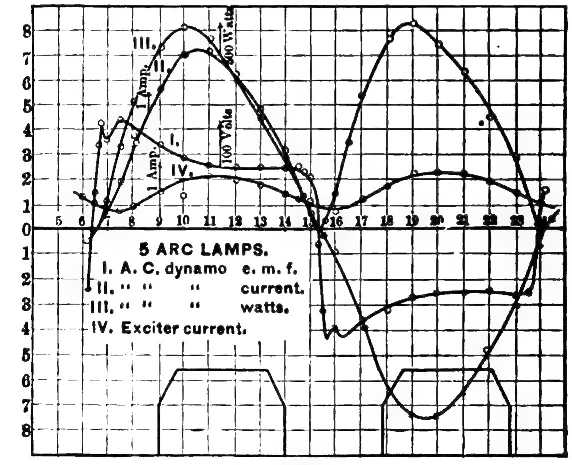

Fig. 4.

circuit with the galvanometer sent the charge through the galvanometer and the throw was noted.

The galvanometer used was of 5000 ohms resistance, and consisted of the coil of a Sir Wm. Thomson marine galvanometer, in which was suspended a small, concave mirror, having several very small magnets constituting the needle fastened on the back. The controller was a large horse shoe magnet. A simple wooden frame supported the coil. A narrow slit in a screen, behind which stood an incandescent lamp, allowed an image of part of the filament to fall on the galvanometer mirror and be reflected back to the screen, on which was a graduated scale. By placing a resistance box in shunt around the galvanometer, the throw of the needle was reduced when it was desired to read the arc E. M. F.

2. Much trouble experienced by other investigators in this line, due to breaking of the spring, was entirely obviated by us by putting a piece of thin rubber packing above the spring where it was clamped in the brushholder.

When current readings were taken the whole charge of the condenser was passed through the galvanometer. The galvanometer was calibrated for E. M. F. by putting the condenser and a standard potential instrument in multiple around the terminals of a storage battery giving about 120 volts. Readings were then taken of the voltage, and the corresponding throw of the needle was noted. The calibrations for currents were made by running the exciter alone and passing the current through both of the non-inductive resistances, determining its amount by an ammeter, and observing the corresponding throw of the galvanometer needle for each non-inductive resistance.

So much for a description of the dynamo, the instruments and the methods used. We now come to that which is of most interest, viz., the results obtained. In order that the curves may be more easily followed we will give a brief general explanation of them.

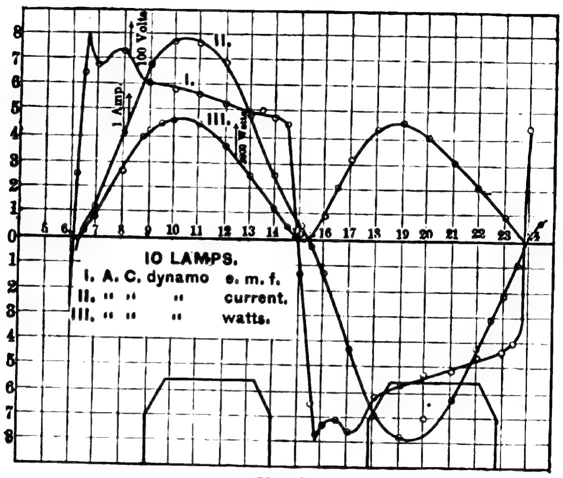

Fig. 5.

The figures on the zero line, always commencing with 5, correspond to the divisions on the scale of the wooden semi-circle, a part of the commutating device. Under each plate of curves will be seen two rectangular figures, representing pole pieces, which show the relative position of the curves with respect to the poles. From each curve projects a vertical arrow, always equal to one or two divisions, and its value marked near it. In all curves the direction of motion of the armature relatively to the poles is from left to right.

Fig. 2 represents the performance of the machine at short circuit.

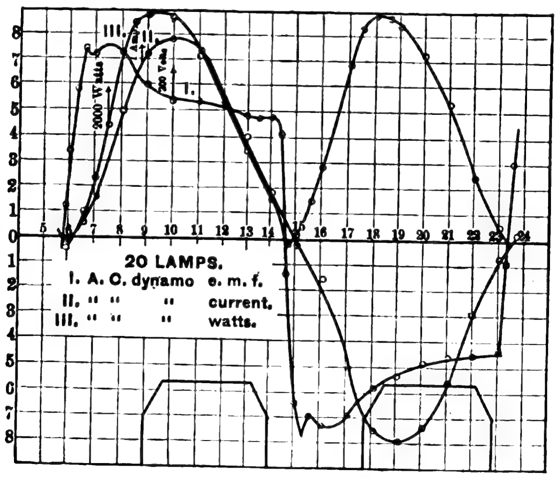

Fig. 6.

The curves of E. M. F. and current both approach sine curves; the current rising almost in unison with the E. M. F., there being no perceptible lag. The curve of exciter current in this, as in all cases, exhibits a wavy form. Fig. 12 shows the position of the amature relatively to the poles when the E. M. F. is zero and the machine running on short circuit.

Fig. 4, representing the curves for a load of five arc lamps, shows a radical change in the E. M. F., which now approaches more nearly to the form of a rectangle than a sine curve, and immediately after passing the zeros exhibits very sharp peaks. In this case the current continues to rise after the E. M. F. has begun to fall, and also lags slightly with respect to it. A shifting of the zeros has also taken place. Comparing this E. M. F. curve with that for short circuit it is seen that the first zero shown occurs at about 6.35 instead of 6.85. The curves for all loads of arc lamps are quite similar in form, as will be seen by referring to Figs. 5, 6, 7 and 8. As the load is increased, however, the zeros occur earlier with respect to the poles, and the current lag increases slightly. The efficiency curve, Fig. 9, tells the story of the dynamo from a commercial point of view, reaching as it does an efficiency of between 93 per cent. and 94 per cent. at full load while at half load it is 92 per cent.

A most interesting set of curves is shown in Fig. 10, giving a comparison of the forms and values of E. M. F. for 40, 30, 20, and 10 lamps, their position with respect to the poles, and also the position of the zeros of E. M. F. at short circuit.

Figs. 13 and 12 show respectively the positions of the armature relatively to the poles for full load and short circuit.

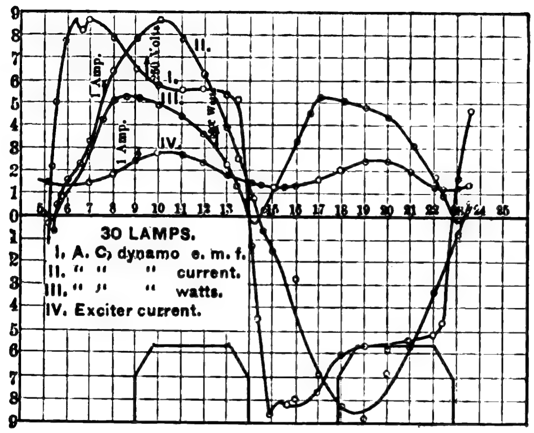

Fig. 7.

An apparently remarkable feature of the machine is that it may be short circuited when running at full load, without the slightest injury, and it may be run at short circuit indefinitely. That the machine regulates with great rapidity is proven by the fact that upon short circuiting it, the ammeter indicates but a slight increase of current. The peculiar form of the E. M. F. curve for arc lamps led us, so far as time would permit, to an investigation of the cause, to ascertain which the following runs were taken:

First, with a non-inductive resistance of five large incandescent lamps, but no arcs in circuit; each lamp consuming about the same amount of energy as an arc lamp. Second, with nothing but an inductive resistance, consisting of a solenoid having 440 turns of No. 10 wire. The curves in both cases were similar and approached sine curves, proving the rectangular form to be

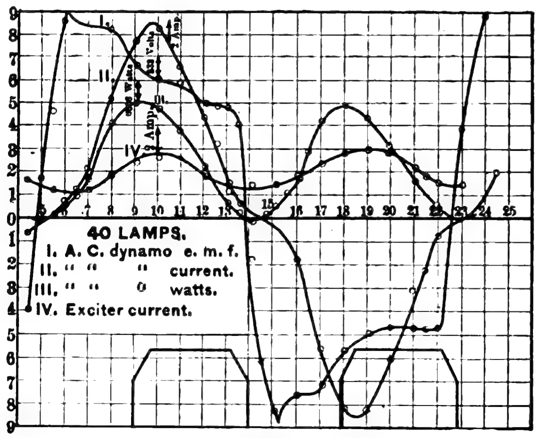

Fig. 8.

due entirely to the action of the arc. Fig. 3 shows the curves obtained from the load of incandescent lamps. To more fully determine this action with no other resistance in circuit, an arrangement was made whereby an arc could be regulated by hand with the aid of a hot wire voltmeter. We took no curve for a single lamp under normal conditions with which to compare the one taken in the above manner; but the latter (see Fig. 11) has very high and abrupt elevations of E. M. F. immediately before and after passing the zeros. The theory advanced to explain the high point of E. M. F. in all the arc curves is, that when the arc breaks, the rush of cold air adding resistance to the circuit, prevents the arc forming again until the potential has risen to a point considerably higher than that required to maintain an arc

once formed. To test this we attempted to heat an arc by means of an alcohol blast, and thus prevent, in a measure, the rush of cold air. This means of heating proved inadequate, so that the results were not all that could be desired. As before stated, we had no one-lamp curve with which to compare it, but as compared with the one lamp regulated by hand, the sharp

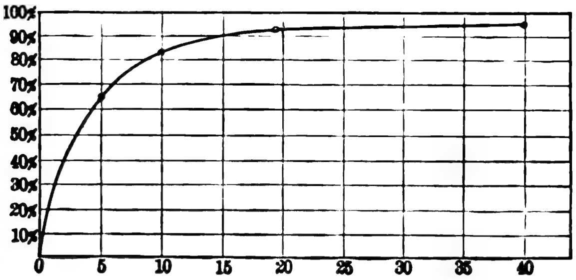

Fig. 9.—EFFICIENCY CURVE.

corners of E. M. F. were much modified. It is not certain, however, whether this was due to the action of the lamp regulating coils, or to the action of the flame. The current curve in all cases approaches a sine curve in form, but is always slightly steeper on the left or front side; direction of rotation being from left to right. Although the current lag is practically nothing at short circuit, or for any load except arc lamps, it increases slowly as arc lamps are added. For 40 lamps it is about 4½ per cent. of the time of an alternation. The wavy form of the exciter current is probably caused by the variable resistance of the magnetic circuit, due to the projecting cores and lugs of the armature as they approach and recede from the poles. The values of E. M. F. and

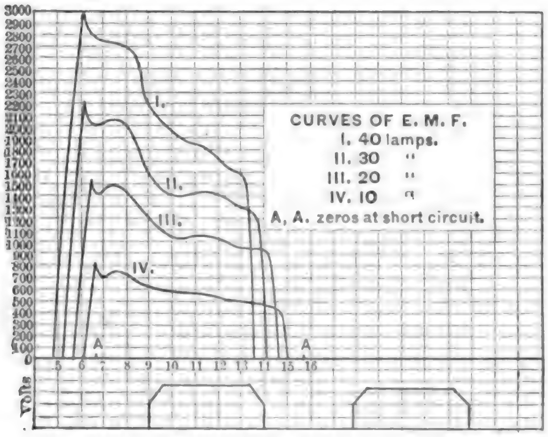

Fig. 10.

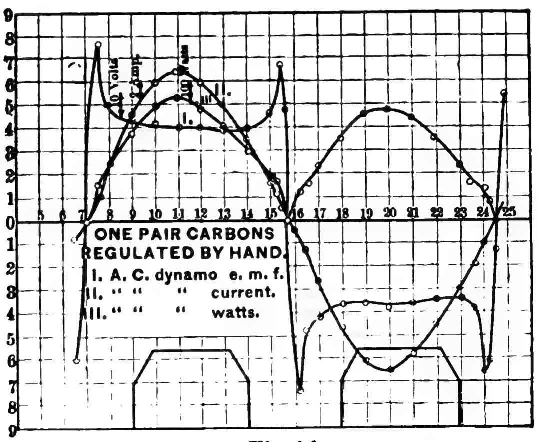

Fig. 11.

current were found by taking the square root of the mean square of 36 ordinates of a curve, representing a complete cycle. Although the current lag was very small, the product of the values of current and E. M. F. obtained as above did not give the watts. The watts were obtained by plotting a curve, the points of which were the products of the instantaneous values of E. M. F. and current; then integrating by a planimeter. Dividing the value of the watts thus obtained by the current, we obtained a value of the E. M. F. which was usually about seven volts lower per lamp than the corresponding value obtained from the square root of the mean square. This difference was no doubt due to the extremely high values of the E. M. F. when the current was very low, as the negative work was negligible. To distinguish between the two values we have called the one obtained from the square root of the mean square, the "actual" E. M. F. while the one obtained by the second method has been called the "effective" E. M. F., it alone being effective in doing work on the circuit.

It is very much of a question in our minds as to whether the square root of the mean square, obtained from the rectangular E. M. F. curves for arc lamps, gives the actual E. M. F., but for the lack of a better term the values thus obtained have been called the "actual" E. M. F's.

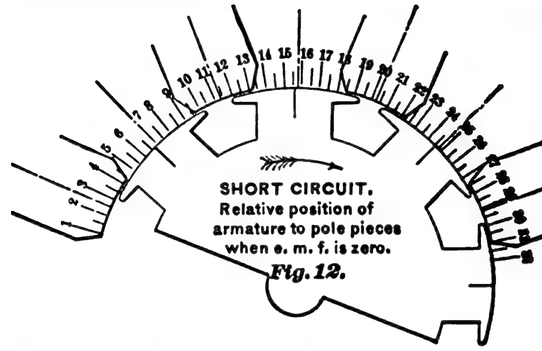

Fig. 12.

For arc current values we have assumed the square root of the mean square to be correct, and if not actually the case, they are certainly very close approximations, as the current curves are practically sine curves. The exact values of E. M. F. or current are of little consequence, however, except as a matter of interest, since the electrical output in watts is known, this alone being required to determine the efficiency.

In conclusion we can simply state that our investigations have shown, that the dynamo, aside from being very efficient and of most excellent regulation, is, as stated at the beginning, an extremely novel and interesting type of machine.

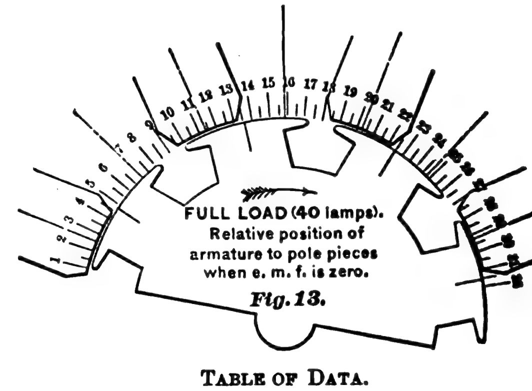

Fig. 13.

TABLE OF DATA.

	√Mean sq. of E. M. F.	Volts per lamp "Actual."	√Mean sq. of Current.	Volts per lamp "effective."	Mean Watts electrical.	Watts excitation.	Mean Watts by dynamometer.	Efficiency.

TRANSFORMER EFFICIENCY.

[144.] In your last issue I see from Mr. Swinburne's answer to my criticism in the issue of Sept. 6 of your paper, that he accepts my statement, "that the maximum value of the primary current in a transformer must occur before the impressed E. M. F. reaches zero, and this the more, the more load is thrown upon the transformer."

But I can not yet fully agree with Mr. Swinburne that for open secondary circuit this difference of phase is vanishingly small. For an ideal transformer indeed, that is, a transformer which wastes no energy at all in the iron, the energy consumed by the primary current would be rather small for no load, and therefore the difference of phase in this case negligible. For instance, in the transformer tested by Prof. Ryan this energy amounts to .4 watt; therefore, considerably greater than the .05 watt Mr. Swinburne suggests.

But in the same transformer the primary current expends 95.7 watts for the reversals of magnetism in the iron, and, if we assume as a very rough approximation—but one which will give us a fair idea of the operations going on—the work consumed by hysteresis to follow the sine-law, too, then we would have to expect, because of hysteresis, a shifting of phase given by the equation:

$EC \cos \omega = 96.1$ watts,

where, $E = 1030 =$ the primary E. M. F.

$C = .147 =$ the primary current.

Therefore the angle of shifting phase:

$\cos \omega = .635;$

angle $\omega = 50$ degrees,

and the maximum value of the primary current, if following the sine-law, would have to occur about 40 degrees before the impressed E. M. F. reaches zero, below a potential of about 900 volts.

Though this is only a very rough approximation, it is fairly well shown in the diagrams referred to. Such an angle of 40 degrees I can not allow to be negligible.

I am very glad to corroborate Mr. Swinburne's second remark, that the whole discussion was produced only by a mutual misunderstanding.

As it was said in those papers that the secondary current of the transformer gives back energy to the primary circuit, it was certainly not meant that this energy was stored up in the secondary circuit as electrostatic charge, as Mr. Swinburne suggests, but the term "current" was used with the meaning modern science attributes to it, not only considering what is going on inside of the wire, but also including the electro-magnetic disturbance outside of the wire, that is, the magnetic field of the secondary current; and it is this magnetism, which stores up and gives back energy to the primary circuit.

If it had been thought possible by the authors of those papers that somebody might misconstrue this, as Mr. Swinburne did, they very likely would have been more precise and would have put it perhaps like this:

"In the transformer there are three circuits, the primary electric circuit, the secondary electric circuit, and the magnetic iron circuit. During a part, greater or smaller according to the load, of each period the primary electric circuit gives off energy to the magnetic circuit, where it appears as potential energy of magnetism; during the other part of each period the magnetic circuit gives back energy to the primary circuit, in the form of an E. M. F. induced in the same direction as the instantaneous value of the primary current.

"The magnetic iron circuit transfers energy to the secondary circuit, either all the time, or, if there is self-induction in the secondary circuit, only during a part of each period; while during the other part of the period the secondary circuit gives back to the magnetic transformer circuit a part of its energy, which was stored up in the outside magnetic field, causing the self-induction.

"In regard to the electric transformer circuit, the magnetic transformer circuit during a certain part of each period must be considered as belonging to the primary electric circuit, during another part of the period to the secondary, and generally to both electric circuits.

"The transfer of energy from the primary electric circuit to the magnetic circuit, and back, has been plotted in these curves referred to."

That a magnetic field is capable of storing up a rather large amount of energy, is shown by numerical calculation.

Let $F =$ magnetomotive force, in ampere-turns,

Let $M =$ magnetism (number of lines of magnetic force).

Then the potential energy stored up in the magnetic circuit $F\,M$ is:

$$H = 10^{-8} \int_0^M F\,dM \text{ joule.}$$

where F and M are connected by the well known curve of magnetization:

$$M = \mathfrak{f}\,(F).$$

If for an approximation, we assume:

$$M = \frac{F}{R}$$

where R = const. = magnetic resistance (reluctance), then we get:

$$H = \frac{10^{-8}\,M^2}{2\,R} = 10^{-8}\frac{F\,M}{2} \text{ joule.}$$

In the transformer tested by Prof. Ryan, we have:

$M = 3850 \times 63.3 = 243700.$

$F = .21 \times 675 = 142.$

Therefore,

$H = .173$ joule,

transferred to and fro 550 times per second.

The last point Mr. Swinburne referred to in your last issue, I did not mention at all as an answer to his criticism, but only as a remark to Prof. Ryan's assumption, that the resistance of an incandescent lamp is dependent only on the effective current: it merely refers to an analytical treatment of this question, which proved that this assumption, though not absolutely true, can certainly be considered correct enough for all practical and also scientific researches. CHAS. STEINMETZ.

YONKERS, N. Y., OCT. 30.

SWINBURNE'S HEDGEHOG TRANSFORMER.

[145.]—I have read Mr. Tesla's article in your issue of the 24th ult. with great pleasure, and will, with your permission, deal with it point by point. First, he thinks it will be difficult for me to point to estimates of transformer efficiencies with the iron loss omitted. Prof. S. P. Thompson's book on dynamos is deservedly well known and appreciated. Mr. Tesla will find the efficiency of a transformer worked from copper loss only in the last edition. The efficiency given is 97.2 per cent. The question of loss in iron has only come prominently to the front within the last year or so. Some American makers are, I think, ahead of us in this matter.

Mr. Tesla thinks 10 per cent. loss in iron an excessive estimate. Nobody could doubt the absolute accuracy of a statement in a Westinghouse advertisement, so we have authority for saying that the efficiencies of the four leading American makers average below 90 per cent., and no doubt this loss is mostly in the iron.

If circuits can be arranged so that transformers are cut off when light is not wanted, the advantage of the Hedgehog form of open circuit transformer is not so great. I quite agree with Mr. Tesla about this. In many cases I think it would be well to use an automatic switch, which cuts the transformers out when not wanted. As I am pecuniarily interested both in the Hedgehog transformer and the drop switch, I may be biased, but I cannot be accused of partiality in saying that I do not think any of these methods is a real solution of the problem, and that transformers stuck about houses are only a makeshift, and in the future we must distribute at low pressure from substations.

Mr. Tesla goes on to say that according to my arguments a transformer could be made most efficient with no iron. This, uttered in jest, is true. The only drawback would be expense in copper, unless the frequency were enormous. This was mentioned in my British Association paper, last year. Mr. Tesla goes on to say that to reduce the loss in iron to one-tenth I must use one-tenth of the mass of iron, and the same induction. I agree with him. But he thinks that if you remove three sides of a closed iron circuit, leaving an open circuit, or simple core, that the iron is more strongly magnetized than before. This is obviously wrong; in fact, the removal of three sides and replacing by air increases the magnetic resistance of the circuit, if I may again use this unscientific analogy. As a matter of fact, the induction in the iron varies inversely as the cross section and frequency and directly as the electromotive force. The "magnetomotive force" adapts itself to produce the necessary induction. If Mr. Tesla will look up curves of loss by hysteresis he will find it does not vary as the square of the induction.

Mr. Tesla next argues that if you arrange, say, four 50 light hedgehogs in a square you get a closed iron circuit, and the exciting current goes down, so that the loss by it is reduced. This is so. The loss due to the exciting current is small, under two watts, so in the four transformers the saving is, say, eight watts. You thus get a closed circuit 200 light transformer with a higher efficiency than an open circuit 50 lighter. Replace it by an open

circuit 200 light transformer and you get a higher efficiency still. We are sending the Westinghouse Company a 50 lighter to test. This size has a full load efficiency of 96.75 per cent. The constant loss in it is 20.5 watts. Taking Mr. Tesla's loss of less than 6 per cent., say 5 per cent., in iron, the saving in a 50 lighter always on is more than 100 watts, say 100 watts. If no switch is used, this goes on all day. The cost may be taken at, say, 5 cents per 1,000 watt hours, or 12 cents a day; 12 cents a day amounts up to $44 a year, so the transformer would pay its first cost in less than two years. In a few weeks the Westinghouse advertisement will read: "It will pay you to throw away our converters and substitute the Hedgehog make."

I cannot be in error as to the motives for shortening the magnetic circuits in closed circuit transformers, as I have not mentioned it. I said that the closed circuit was adopted to reduce magnetic resistance. If Mr. Tesla will look up my British Association papers, last year and this year, he will find that I have at least given some attention to the design of closed circuit transformers, and to the qualities of different kinds of iron.

I am glad to hear Mr. Tesla was the first to advocate open circuit transformers. I have no such claim; Messrs. Gaulard and Gibbs were before me, and I have only worked out a particular form.

Some day I hope I may meet Mr. Tesla without a revolver and convert him.

J. SWINBURNE.

WIMBLEDON, ENGLAND, October 10, 1890.

CORRESPONDENCE.

BOSTON.

Electricity Supplanting Oil in Cambridge.—Electric Railway Pole and Wire Regulations.—The Electric Elevated Railway Plan.—The British Iron and Steel Institute in Boston.

THE Cambridge City Council last evening voted to substitute electric lights for the oil lamps now in use in the Belmont district and wards 1 and 4.

At a meeting of the Board of Alderman, an order was passed that the committee on rules report on the advisability of providing in the rules or standing regulations that all permits for the location of street railway tracks, the erection of poles or posts for electric wires, and the construction of underground conduits, that the rules shall contain a condition that the work must be completed during the municipal year; also that a public hearing on the same shall be given. A petition was received from the West End Company praying that it might be allowed to lay a double track from the terminus of its lines in Dorchester to Ashmont, and was referred to the committee on railroads. The following order, passed by the Board Aug. 18, was rescinded: That all permits for the erection of poles for the support of wires hereafter issued shall provide that such poles shall be of the "Providence" pattern. Alderman Wilson moved a reconsideration, and the question was assigned to the next meeting.

The West End Street Railway Company has removed its engineering department from the Milk street office to the central power station in Albany street.

The hearing by the street commissioners on the proposed extension of Harrison avenue to Summer street and Hawley street to Water street for the elevated railroad, was continued in the council chamber at city hall yesterday morning, the remonstrants having an opportunity to set forth all their objections, which were confined chiefly to the amount of property to be destroyed. The hearing was adjourned till Saturday, Nov. 1st.

The Thomson-Houston Electric Company had the pleasure this week of entertaining the members of the British Iron and Steel Institute, accompanied also by Mr. H. M. Massey, electrician to the Queen, in Boston and Lynn. Mr. G. W. Davenport accompanied the party from New York to Boston, and in this city they were joined by a representative number of gentlemen from the Thomson-Houston Company and escorted to Lynn, where they were shown through the factories of the Thomson-Houston Electric Company and the Thomson Electric Welding Company. Electric welding formed the chief thing of interest, and the visitors were shown in operation the process of welding bars, cables, chains, rings, tubes and shell projectiles. At noon lunch was served in the drafting room, after which the visitors returned to Boston, and special electric cars were provided to take them in a "rapid transit" trip to Chestnut hill. At 7:30 p. m. there was a banquet at the Vendome, and the diners were guests of the Thomson-Houston Company. Capt. Eugene Griffin, general manager of the street railway department of the Thomson-Houston works, presided. At his right was John Alleyn, at his left, Mayor Hart. The other gentlemen at the table of honor were: Prof. Thomson, Gen. Francis A. Walker, Prof. Geissler, of Germany, Mr. Hawksley, Edward Atkinson, H. A. Pevear, W. H. Massey and W. Duff Bruce.

Mr. Griffin spoke briefly, extending a hearty welcome to the visitors, and introduced Mayor Hart, who welcomed the visitors to Boston. Sir John Alleyn replied for the iron and steel men, and expressed his great satisfaction at what he had seen. Mr. Griffin introduced Prof. Elihu Thomson, and there was a hearty hand-clapping. Prof. Thomson spoke briefly of the progress of the science of electricity and its relation to iron and steel, and predicted that in 20 or 30 years perhaps electricity would operate nearly all the railroads.

Prof. Geissler also addressed the meeting in German.

BOSTON, MASS., Oct. 31, 1890.

ST. LOUIS.

New Electric Railway Work.—Double Carbon Lamp Suits.

THIS month witnessed the successful inauguration of electric power on the main line of the Lindell Railway Co. from Third street to Grand avenue, the route being Washington avenue, Fourteenth street, Gratiot street, out bound, and Papin street; in bound, Eighteenth street and Chauteau avenue to Grand avenue. The Vandeventer avenue section, a new road lately acquired by the Lindell Railway Co., is also in successful operation, and gives the Lindell Co. a direct line to the Fair Grounds. This section was completed and in operation in time to handle the immense crowds of visitors to the Fair, and proves to be a valuable acquisition to the Lindell Railway Co. This most successful inauguration of electric power is due to the thorough and unstinting financial policy carried out by Mr. Geo. D. Capen, president of the company. The remaining portion of the main line from Fourteenth and Washington avenue to Vanderventer avenue will be ready for operation as soon as the engines arrive and can be set up, everything else being in readiness and waiting.

The East St. Louis Electric Railway Co. are laying track and setting poles on Collinsville avenue and Broadway. The first section of the road to be put into operation will extend from the Levee to the National Stock Yards. Connections will be made with Wiggins ferry boats and also with the Bridge Electric Railway. A temporary power station is being fitted up at the old Thomson-Houston arc light station on the levee, which has been abandoned by the Municipal Electric Light Co. since it passed into their ownership. A permanent power station will be erected on ground adjacent to the Citizens' Electric Light Co.

The Belleville and East St. Louis Electric Railway have secured a controlling interest in the St. Clair County Turnpike Road and will construct an electric railway 14 miles in length from Belleville to East St. Louis. The route of the turnpike will be used throughout a greater part of the way.

In the suit of the Brush Electric Co. against the Municipal Electric Light and Power Co., for infringement of patents on double carbon arc lamps, the plaintiff has filed a motion for a preliminary injunction.

ST. LOUIS, Oct. 26th, 1890.

CHICAGO.

Electric Lighting in Hyde Park.—The Electric Fountain.—Electric Railway Work.

THE Hyde Park Thomson-Houston Electric Light Company have now begun to supply the residences in that neighborhood with incandescent lamps run from their newly built station located at Fifty-third street and Illinois Central Railroad. This is somewhat of a new departure, it being the first plant in Chicago constructed specially to furnish electric lights for illuminating residences. The residents of this beautiful and wealthy portion of the city, who have suffered so long with the wretched quality of the gas they have had to put up with, have now an opportunity of obtaining brilliant illumination without the accompanying disadvantages of gas, such as dirt, heat and danger from fire.

The concluding display for the season of the electric fountain at Lincoln Park took place last week and was witnessed by several thousand people. The immense column of water, with its ever-changing hues and possessing in turn all the colors of the rainbow, shot into the air for more than an hour to the extreme gratification of the onlookers. The display ended at 8:30 o'clock.

The South End Electric Railway has recently been incorporated with a capital of $100,000, by Charles E. Loss, F. B. Dyke and C. J. Wood. Mr. Charles E. Loss has been largely identified with the construction of street railways and has made a specialty of electric roads. Amongst others he built the electric road at Pullman, and the Calumet Electric Street Railway, now in operation between Ninety-fifth street and South Chicago via Stony Island avenue and Ninety-third street. This company now proposes to build a system of lines through the section of country west and north of Lake Calumet and operated by electricity.

The unanimous consent of the property owners of the frontage on Michigan avenue from Ninety-fifth to 116th streets, on Ninety-fifth street and Michigan avenue to Stony Island avenue and on 103rd, 111th and 115th streets, from Michigan avenue to Lake Calumet, has already been secured. An ordinance will be imme-

diately introduced in the council for a franchise to operate the electric system on the thoroughfares named. It is intended to connect the territory on the ridge with the Pullman electric lines at 115th, 111th, 103rd and Ninety-fifth streets, and also to connect at the latter with the Calumet electric street railroad for South Chicago.

A syndicate of Chicago and Hammond capitalists who have large interests in the Calumet River basin are contemplating an electric line connecting South Chicago, Hammond and East Chicago. It is stated that they have control of a new motor invented by Theodore M. Foote, of Boston, which will be used. The lines as projected will be built north on Homan street in Hammond, and will be extended north between Wolf Lake and Lake George to connect with the Ewing avenue line at South Chicago. Branch lines will be built on a number of streets in Hammond. A cross-line on Gostlin street will connect Hammond and East Chicago. The Hammond council have passed an ordinance giving the new company the necessary street franchises but under such conditions that it cannot be accepted till some changes are made. This railway when completed will be part of a chain of street railway lines, running from Chicago to the southern limits of Hammond.

CHICAGO, Oct. 31, 1890.

UNIVERSITY NOTES.

HARVARD.

The courses in electrical engineering open this fall with still larger attendance than last year; in fact, the introductory ones are almost overcrowded. Ever since electrical engineering was made a separate course instead of occupying a subordinate position in the department of mathematics and physics, there has been a marked increase in the number of students at the laboratory. There is also a constantly growing interest in the more abstruse courses of mathematics and physics. These courses have always stood high, and are becoming more and more popular, especially with graduate students.

During the summer vacation the heating and ventilating apparatus in Sever Hall have been looked over and improved, much to the gratification of the teachers and students who use the class rooms. Among the improvements is an electric regulator in each room, which shuts off the steam or lets it on, according as the temperature rises above or falls below 70°.

The students of Harvard have long suffered from the lack of a suitable reading room for evening use. The authorities do not dare to put lights into the present room on account of the risk of fire. So the students have formed a committee to canvass the whole college and alumni to raise $150,000 to $200,000 with which to build a fire-proof addition to the present library building. This new part will, of course, be lighted electrically, and can be used evenings.

The opening meeting of the Electric Club was held October 16. Seven new members were elected. Three more papers have been added to the club's library, *The Scientific American* and its Supplement and the *Elektrotechnische Zeitschrift*. G. T. P.

SIBLEY COLLEGE OF MECHANICAL AND ELECTRICAL ENGINEERING, CORNELL UNIVERSITY.

The non-resident lecturers for the ensuing year have been elected as follows:—Prof. Mendenhall, Prof. S. P. Langley, Alexander Graham Bell, W. A. Anthony, Captain R. W. Hunt, Mr. James Allen, Mr. Holloway, Eckley B. Coxe, Chas. E. Emery, Dr. C. B. Dudley, Prof. Elihu Thomson, F. J. Sprague, Mr. Rothwell and Mr. E. D. Leavitt.

At the last meeting of the University trustees, $50,000 was appropriated for new apparatus and machinery for Sibley College.

Prof. R. H. Thurston has been elected "membre correspondent" of the "Ecole Supérieure de l'Industrie Nationale," Paris, in recognition of his services to science in presenting to English speaking engineers the work of the elder Sadi Carnot.

The senior Electrical Society has elected officers as follows:—President, H. M. Willson; vice-president, W. E. Lindsay; secretary, E. E. Williams. At the last meeting an interesting address on "Practical Electric Work," was given by instructor Geo. W. Shepardson.

F. C. Perkins, '91, has been elected an associate member of the American Institute of Electrical Engineers.

Mr. Andrew Carnegie was present at the recent meeting of the University trustees.

Prof. Carpenter is soon to make a running test of a locomotive on the L. V. R. R.

W. A. Ballard, '93, is on the editorial staff of the *American Manufacturer and Iron Age*, Pittsburgh, Pa.

E. S. Bowen, '90, is engaged at Chicago with the firm of McIntosh, Seymour & Co.

F. F. Goodwin, '90, is with the Thomson Welding works, at Lynn, Mass.

S. G. P.

LEGAL NOTES.

THE CONSTITUTIONALITY OF THE ELECTRICAL EXECUTION LAW.

The first motion to secure final action from the Supreme Court of the United States on the question of the constitutionality of the New York electrical execution law was made in the Supreme Court, at Washington, on Oct. 27, in the case of the Japanese, Jugigo, under sentence of death in New York. It was moved that the case be advanced and set down for a speedy hearing.

The point raised in the case is that the Kemmler execution demonstrated that killing by electricity is a cruel and unusual punishment and as such is prohibited by the Constitution of the United States. The court took the papers.

THE BRAGG DEVICE FOR HITCHING UP FIRE HORSES.

At Indianapolis, Ind., on Oct. 29, Judge Gresham of the Federal court decided the suit of Walker & Olters, of Terre Haute, charging infringement of patent in the use of the Bragg fire alarm device. The invention consists of a gong and a contrivance that unfastens the halters of the horses and drops the harness upon them by electricity when an alarm is sounded.

Several years ago the plaintiffs purchased the right to make and use the device in a number of States, and sought to introduce it into a number of Fire Departments. The owners then discovered that, without authority from the patentee, the device was used by nearly every city in the Union having a paid Fire Department. Suit was entered in 1887 to enjoin the city of Terra Haute and to recover damages, and Judge Gresham to-day decided in favor of the plaintiffs. Suits will now be filed against every city in which the invention is used.

METAL AND SUPPLY MARKET.

CHANGES MADE BY THE TARIFF.

The changes in the tariff made by the McKinley bill will effect materials used in electrical interests as follows:

Aluminum, formerly free, increased to 15 per cent. ad valorem. It was proposed to make this much higher.

Brass bars or pigs, old, yellow metal fit only for remanufacture, no change.

Copper, ores, reduced from 2½ cents to 1½ cents.

Old copper for remanufacture, reduced from 3 cents to 1 cent a pound.

Copper in plates, bars or ingots, not manufactured, reduced from 4 cents to 1¼ cents.

Copper in rolled plates, rods, pipes, sheathing, remains at 35 per cent. ad valorem.

Lead remains practically unchanged.

Tin remains at 4 cents a pound.

Zinc in blocks or pigs is increased from 1½ cents to 1¾ cents a pound.

Old zinc, for remanufacture, increased from 1¼ to 1¾.

Chromic acid, 6 cents per pound instead of 15 per cent. ad valorem.

Bichromate of potash remains the same at 3 cents per pound.

Nickel, etc., per pound, 10 cents, reduced from 15 cents.

Electrotype plates remain at 25 per cent. ad valorem.

Thin blown glass is increased to 60 per cent. ad valorem, from 45 per cent.

Mica is raised from the free list to 35 per cent. ad valorem.

Blue vitriol or sulphate of copper reduced from 3 cents to 2 cents.

Sal-ammoniac changed from 10 per cent. ad valorem to ¾ cents specific.

Sal-soda and soda ash remain at ¼ cent.

Caustic soda has been reduced from 1½ cents to 1 cent.

Sulphuric acid is increased from free to ¼ cent a pound.

Wire and wire rods are reduced ¼ cent a pound, where they are not covered. Where they are covered with cotton, silk or the like, they are increased 1 cent a pound. Flat steel wire is increased from 45 to 50 per cent. ad valorem.

The schedule shows that of the articles mentioned the tariff on 44 per cent. has been reduced materially, while it has been increased on 28 per cent. and unchanged on 28 per cent.

Parts made of porcelain, such as switch bases, socket details, etc., promise to be dearer, and the manufacturers in this country are likely to have a large amount of business thrown into their hands. It is claimed that the German article will practically be excluded from the market.

It is also claimed that a stimulus will be given by the tariff to the manufacture of fine instruments.

The general belief even among the many opposed to a higher tariff is that the springing up of many new factories and shops requiring electric light and power will have a good effect on electrical industries.

TRADE. NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT

THE NASSAU CAPSULE BATTERY, THERMOMETER AND BELL OUTFIT.

A CONVENIENT source of current for the numerous purposes to which electricity can be applied in the household, goes far towards popularizing and hastening the introduction of many important devices tending to health and comfort. To meet this demand,

FIG. 3.—NASSAU BATTERY AND BELL OUTFIT.

there has recently been brought out by the Nassau Electrical Co., of this city, a neat little chloride of silver cell, which is shown in actual size in the accompanying engraving. The zinc case acts at the same time as one electrode and from the centre projects a silver wire constituting the other electrode. The case is filled with the exciting electrolyte in the form of a jelly and the whole is hermetically sealed.

The cell so constituted can evidently be placed in any position and connected directly with the terminals of an apparatus without running an inch of wire.

One of the applications to which it has been put is in connection with an alarm thermometer, shown in Fig. 2. The rising

FIGS. 1 AND 2.—NASSAU CAPSULE BATTERY AND ALARM THERMOMETER.

above, or falling of the temperature below, a certain point, closes a circuit and rings the bell and calls attention to the fact. The little cell is directly attached and when the alarm is not required the battery can be turned off by means of the switch shown.

Fig. 3 illustrates the application of the cell to a bell outfit. Here the cell is completely concealed in the case of the push button.

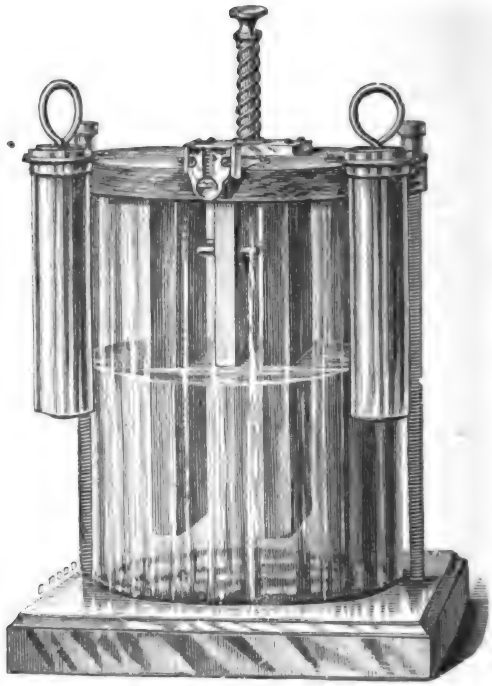
Numerous other application of a like nature will suggest themselves to our readers. The cell has an E. M. F. of over one volt, and gives over two amperes on short circuit. When worn out by continued use the cell can be withdrawn and replaced by a new one.

AN ELECTRIC CIGAR LIGHTER.

THE easy and cleanly manner in which light can be produced by the electric current makes the application of the latter preferable wherever it can be resorted to. A neat electric lighter for cigars, where dynamo current is not available, is that recently brought out by the Barr Electric M'f'g Co., of 17 and 19 Broadway, which is illustrated in the accompanying engraving. It consists of a single bichromate cell, the zinc element of which is fixed to a rod which passes through the cover and which is normally pushed upward by a spring so as to raise the zinc above the level of the fluid. By pressing the rod downward, the zinc is immersed, and the current established passes through a fine platinum wire, heating it to incandescence. A mere touch of the lighter ignites the alcohol at the tip.

A single charge of the chemicals, costing only five cents, is sufficient to afford 5,000 "lights" running from 30 to 60 days.

The arrangement has also been adapted as a domestic electric lighter by the addition of a small alcohol lamp, which, after being ignited, can be used as a torch, thus avoiding entirely the use of



THE BARR ELECTRIC CIGAR LIGHTER.

matches. Still another use to which the cell can be put is that of furnishing current for a domestic medical battery. Several other combinations, such as a cigar and domestic lighter, have also been constructed.

WESTINGHOUSE LIGHTING WORK.

The Brush Electric Light Company, of Baltimore, Md., has received the contract from the municipal authorities of that city to light the streets and public buildings for a period of five years. The contract calls for eight hundred arc lights and five thousand incandescent lamps. The Brush company operates the Westinghouse alternating current arc and incandescent systems of electric lighting.

The Westinghouse Electric and Manufacturing Company has concluded a very excellent record of contracts for the month of October. During the first three weeks of that month the company had orders for the furnishing of alternating current incandescent electric lighting apparatus approaching a capacity of 25,000 16 c. p. lamps. This is a very good showing in itself, though the contracts for arc light apparatus, street railway apparatus and electric mining appliances are not included in this.

Contracts for central station alternating current incandescent apparatus were received from the following places: Evanston, Ills., 750 lights; Baltimore, Md., 6,000; Elmira, N. Y., 1,500; Oswego, N. Y., 750; Durango, Col., 750; Lincoln, Neb., 1,500; Orange, N. J., 750; Uxbridge, Mass., 750; Tampa, Fla., 750; Cohoes, N. Y., 750; Manchester, N. H., 1,500; Amesbury, Mass., 500; Aransas Pass, Tex., 750; New Cumberland, W. Va., 750; Mason City, Ills., 500; Havana, Cuba, 750; Rich Holl, Mo., 750; Clearfield, Pa., 500.

Among the places where Westinghouse alternating current arc apparatus was installed during the month are: Oswego, N. Y., 60 lights; Clearfield, Pa., 25 lights; Washington, Pa., 60; Norwich, N. Y., 25; Baltimore, Md., 250.

THE U. S. ELECTRIC RAILWAYS CO.

The U. S. Electric Railways Co. is a new corporation that has recently been incorporated, and has established itself in comfortable quarters at 10 Wall street, N. Y. The company primarily is an engineering company, and will contract for and build electric railways, steam plants, power plants, and do all work connected with the complete installation of electric railways of any system. It will negotiate the sale of street railway bonds, and give special attention to the reorganizaton of street railway companies desiring to equip with electricity.

The president of the company is Mr. Wolstan R. Brown. Mr. W. L. Clark will act as their counsel, and Lemuel Wm. Serrell will be the general manager of the company.

The ability of the gentlemen associated together in this enterprise is well known to be the very best, their financial backing is solid and very strong, and we cannot but predict for them a very bright and prosperous future in the wide and important field of work they have undertaken. Mr. Serrell is particularly well known to our readers as a rising young electrical engineer, whose work in the stationary motor and electrical railway field has been of the highest class. He has made a specialty of power work for several years, and has published not a few valuable articles of a practical nature on various features of this great new department of applied electricity.

ELECTRIC EXHIBITS AT THE AMERICAN INSTITUTE FAIR.

The electrical exhibits this year, while not as numerous as in former years, owing no doubt to the many large exhibitions in different parts of the country which have taken the time and attention of exhibitors, nevertheless embrace a great deal that is of interest. The attendance this year has been up to that of former years.

The C. & C. Motor Co. exhibits a 50 light compound wound dynamo operated by a White & Middletown 8 horse-power gas engine.

The Chalmers Spence Co. show a full line of asbestos goods for all purposes.

The Safety Electric Construction Co , 45 and 47 Wall St., who control the Creamer automatic steam pump trap, have one in operation.

Clark Electric Co.—The exhibit of the Clark Electric Co., 192 Broadway, attracts considerable attention. They show a tasty stand on the main floor, which contains their arc regulator and automatic safety device for continuous and alternating currents. They also have an arc lamp in their ornamental fixture for interior lighting burning on a 110 volt incandescent circuit.

The D. Frisbie Co., 112 Liberty St., have an elevator, operated by their special elevator engine, which carries passengers to the top of the building.

Andrew P. Brown, 7 West Twenty-eighth St., shows his electric leak detector, an apparatus designed to give an alarm the moment an overflow of water occurs, thereby averting damage.

Kirkwood Grate Bar Co., 187 and 189 Mercer St., exhibit the Kirkwood patent shaking and dumping grate.

The Crosby Electric Co., 87 and 89 South Fifth avenue, have a very effective display of their well known dry battery. The numerous uses to which this battery can be put are shown by its operating a motor fan, lighting small incandescent lamps, and in telephone and burglar alarm work. They also have the Hussey blue stone battery.

New York Leather Belting Co., 84 and 86 Gold St., show a full line of their different kinds of belting.

The Metropolitan Electric Signal Co., 45 Broadway, exhibit their "Telecall" for use in factories, stores, banks, hotels, steamships, etc.

The Vulcan Smoke Preventing Patent Grate is shown by the Vulcan Manufacturing Co., of 47 Dey St.

Chas. A. Schieren & Co. show their perforated electric belt, and full line of belting material, for electric light plants, etc.

The American Link Belt Co. exhibit their link belt.

"Litofuge," the well known boilor compound, is in the corridor.

Himmer & Anderson show their dry battery and cigar lighter.

THE AFFAIRS OF THE HARRISBURG CAR COMPANY.

The special committee of five, Messrs J. Wister, S. C. Gilbert, G. M. McCauley, G. K. Reed and W. W. Card, have recommended that the Commonwealth Guarantee Trust and Safe Deposit Co., of Harrisburg, be appointed receiver for the Harrisburg Car Co. The Board of Directors has accepted the recommendations of the committee, and the plan will be duly carried into effect.

OTTO GAS ENGINES IN ELECTRIC LIGHTING.

Messrs. Schleicher, Schumm & Co., of Philadelphia, now have their hands full keeping even with their orders for gas engines, many of which are used for isolated plants and central station work. A number of instances have occurred in Philadelphia, where isolated plants using the Otto gas engine have been installed because of the inability of the parties to get service from the electric light companies—the municipal restrictions on overhead wires being the obstacle. It is a significant fact that the gas engine is coming into use more prominently since the custom of gas companies also running electric light plants has been in vogue, in which cases the superior economy of the "Otto" over a separate engine outfit shows up finely.

THE BABY ELECTRIX SWITCH.

We illustrate in the accompanying engraving, the "Baby" Electrix switch, which is just being brought out by the Star Elec-

The Baby Electrix Switch.

trix Co., Phila. It is about the smallest made and embodies all the excellent features of their larger 10 amp. switch. The contacts are of soft metal, wearing bright by use, and they are finished in fancy colors to match interior finish.

THE FITCHBURG STEAM ENGINE CO.

A fine steam plant installed at the Watervliet Arsenal, Troy, N. Y., by the Fitchburg Steam Engine Co. has just been started. The plant consists of one 250 h. p. duplex engine, three horizontal tubular double-riveted steel boilers, a feed water heater, a steam pump and an injector, together with various accessories. The engine consists of two horizontal variable automatic cut-off engines, arranged as a pair, with one shaft common to both. The cylinders are each 16¾x36 inches. The contract specified that the engine must develop not less than 250 horse-power, under 80 pounds of steam. The boilers are each of 100 horse-power. The trials have been a complete success.

FREDERICK PEARCE.

Mr. Frederick Pearce, successor to the old established house of Pearce & Jones, at 79 John street, N. Y., has now a scheme for inducing "Young America" to become interested in electricity, which promises to be successful. Mr. Pearce has taken a 6 c. p. Edison lamp, made up a little outfit for a small battery to light same—a battery lasting a couple of hours on continuous work—the whole being neatly packed and sold at such an attractively low figure as will fairly tempt the price from a student of electricity.

THE NATIONAL WIRE MANUFACTURERS.

The New York Insulated Wire Company, 649–651 Broadway, this city, have received an order for wire to be used in the Executive Mansion at Washington, D. C. As the company have also furnished the wire for the Statue of Liberty, the Washington Monument, the State, War and Navy Departments, they begin to feel that they are entitled to the name of the National Wire Manufacturers.

The Carnegie Music Hall, Fifty-seventh street and Seventh avenue, is now very nearly completed. It is a very attractive and imposing building, constructed principally of Milwaukee pressed brick. It is built from the plans of architect Wm. B. Tuthill, 52 Broadway. Chas. H. Davis is the engineer in charge. A feature of the Carnegie Music Hall will be the lighting arrangements. It will be lighted throughout with electricity, the Thomson-Houston system of electric lighting being employed. There will be 4,000 incandescent lamps. The wiring of the building for these lamps is to be done exclusively with the Grimshaw white core wire, manufactured by the New York Insulated Wire Company, at a cost of about $15,000. The new *World* building is wired almost entirely with the New York Insulated Wire Company's popular specialty.

ELECTRIC MOTORS IN PENNSYLVANIA MINES.

The Sumner Hill mines, at Woodville, Pa., have just been equipped with a complete electric plant of mining machinery. The power plant consists of one Westinghouse Junior engine, one 30 h. p. three-wire, four-pole Westinghouse alternate current generator, six Hercules coal mining machines, a twelve-foot fan with a capacity of 30,000 cubic feet per minute, centrifugal pump, etc. The mining machines and the pump are operated by 3 h. p. Tesla motors. The entire equipment has been furnished by the Westinghouse Electric and Manufacturing Company.

A careful record of the work of the mining machines in the Willock mine, which is also operated by Westinghouse electric mining appliances, shows that from July 1 until August 8, each cut represented about one and one-tenth tons of coal. It was found that it was impossible to keep the rooms cleaned up fast enough of the coal that was brought down, to give the machines a chance to test their full capacity. Each machine is doing the work of from twelve to fourteen pick miners.

THE CENTRAL ELECTRIC CO., CHICAGO.

The Central Electric Company's new fixture and electrolier department is now complete, and adds materially to the showy appearance of their already handsome store. This company are showing a piece of plain Okonite wire that was placed in the Lumber Exchange Building at Minneapolis five years ago, and has been used continuously ever since. The wire was stapled to the fire-proofing and plastered over, and is now apparently in as good condition as ever. Okonite seems to become more popular with architects and electric light men each year, and has so far withstood the severest tests that have been applied to it. The Central people have a stock of fully two million feet in their warerooms, and try to maintain it at about that figure as a reserve.

MR. EDISON EXPLOITING CANADIAN NICKEL MINES.

A special dispatch from Ottawa, Canada, of Oct. 29, says:—"Thomas A. Edison is the latest American who has turned his attention to the Sudbury nickel district. Officials of the Canadian Geological Survey state that the inventor will soon begin to develop mining properties adjacent to the mines owned by the Standard Oil Company. Mr. Samuel G. Burn, the expert sent out by Mr. Edison, was here a few days ago. It has transpired that the inventor has bonded thousands of acres near Sudbury on various sections. The outcropping of nickel is very promising. Mr. Burn confirmed the opinion of the Geological Survey that the Canadian nickel region is the richest mining district in the world. The Edison people claim to have discovered a process by which the nickel ore can be treated very inexpensively, leaving a larger margin of profit. The astonishing statement is made that every dollar invested in the mines brings a return of $4 profit per month. Mr. Burn has already examined various mica mines, the product of which will be utilized for electrical purposes.

EUREKA TEMPERED COPPER.

The Eureka Tempered Copper Co., of North East, Pa., have received the following from W. M. Ramsey, assistant superintendent Federal Street and Pleasant Valley Passenger Railway Co., Pittsburgh: "In reply to your inquiry concerning our experience with tempered copper, would say that, after a year's use, we can heartily endorse it, and recommend it for all descriptions of bearings and for electrical purposes, such as commutator bars, trolley wheels, etc., etc."

THE ELECTRIC CONSTRUCTION & REPAIR CO.,

205-207 Canal street, Chicago, will do general construction work, giving special attention to street railway construction. Several employés of the late well-known Sprague Electric Equipment Company have been retained for this department, and will be under the immediate charge of Mr. W. Sharpe, thereby ensuring good work and modern methods of construction. Mr. C. M. Barclay, who represented the Sprague Electric Railway & Motor Company for several years in Chicago and the West, and who also was secretary for the Sprague Electric Equipment Company, is the general manager, and Mr. W. A. Kreider, secretary, and his wide mechanical knowledge will be of great service to the company. Recognizing the difficulty street railway companies encounter in having repairs done in a prompt manner and at a reasonable cost, they have equipped a repair department where armatures and field coils of any system will be rewound or repaired. The repair department is under the management of Mr. J. G. Hart, who has had many years' experience, and whose work is well known.

The company has secured premises with power in the new Springer Building, 205 Canal street, corner of Jackson, facing the river, thus being situated in close proximity to the centre of the city, and the various railway depots.

J. G. BRILL'S ELECTRIC CARS.

The J. G. Brill Company, Philadelphia, is busy with orders for electric street railway cars and trucks. This company is equipping the Missouri street railway of St. Louis, the Toledo electric railway, of Toledo, O., the Ann Arbor street railway, of Ann Arbor, Mich., the Memphis electric railway, of Memphis, Tenn., and also equipping roads for Wilkesbarre, Pa., Syracuse, N. Y., and Cleveland, O., and is making six storage battery cars to be used in Dubuque, Ia., and five storage battery cars for the Electric Traction Company, of New Orleans, La., which are fitted with a system of handling battery trays from the ends of cars. A notable fact is that every order at the works at present is for electric street cars.

THE "UNIVERSAL" ARC LAMP FOR INCANDESCENT CIRCUITS.

The "Universal" Arc Lamp Co., of 16 and 18 Broad street, and 49 West 22nd street, where the lamps can be seen, are bringing out a line of arc lamps intended for direct current circuits. They give a steady, noiseless light of great purity, and can be adjusted for circuits having a pressure from 100 to 125 volts, using from 8 to 9 amperes. When burning two in series, the resistance is coiled around the chimney at the top of each lamp, within which the carbon rod is suspended, thereby rendering any additional resistance unnecessary.

The company have also brought out the "Universal" theatrical lamp, for stage purposes, knocking out the old calcium lamp very effectually, besides being easy and economical to run. Outfits are furnished, ready to operate, at the shortest notice.

"AJAX" SWITCHES FOR HEAVY CURRENTS.

Mr. C. S. Van Nuis, of 74 Cortlandt street, has just issued a very neat and handy little pamphlet on the subject of "Ajax" switches. It contains one of the best and pithiest discussions of the essential points in heavy current switches that we have ever seen, and we heartily endorse its remarks on current carrying and breaking capacity. Mr. Van Nuis has embodied in his switches not only great experience, but much reflection on cause and effect and remarkable ingenuity in the adaptation of means to ends; and the result is that he has already, in so short a time, made them a standard article in the market. It may be hoped and expected that he will continue his good work in this field, and even try his hand on one or two other details that still need attention in electrical lighting and power equipment.

LIGHTING THE BRIDGEPORT MACHINE TOOL WORKS.

E. P. Bullard, proprietor of the Bridgeport (Conn.) Machine Tool Works, has put an electric light plant into his works. It consists of a 35 horse power high-speed engine and a 380 incandescent Edison dynamo. The fly wheel of the engine connects by means of an Evans friction pulley direct with the dynamo. Mr. Bullard estimates that this plant, which cost him about $3,000, will save him $600 per year, over the use of gas. His works are very large and have only been fairly well lighted.

ST. PAUL TRADE NOTES.

THE ELECTRICAL ENGINEERING AND SUPPLY CO. has recently been formed with C. A. Daigh as president and general manager and Morgan Brooks, secretary and treasurer. The company has been laying in a stock of general supplies, and is now ready for business, having already received a number of orders.

THE WOODBURY, MERRILL, PATTEN AND WOODBURY AIR ENGINE.

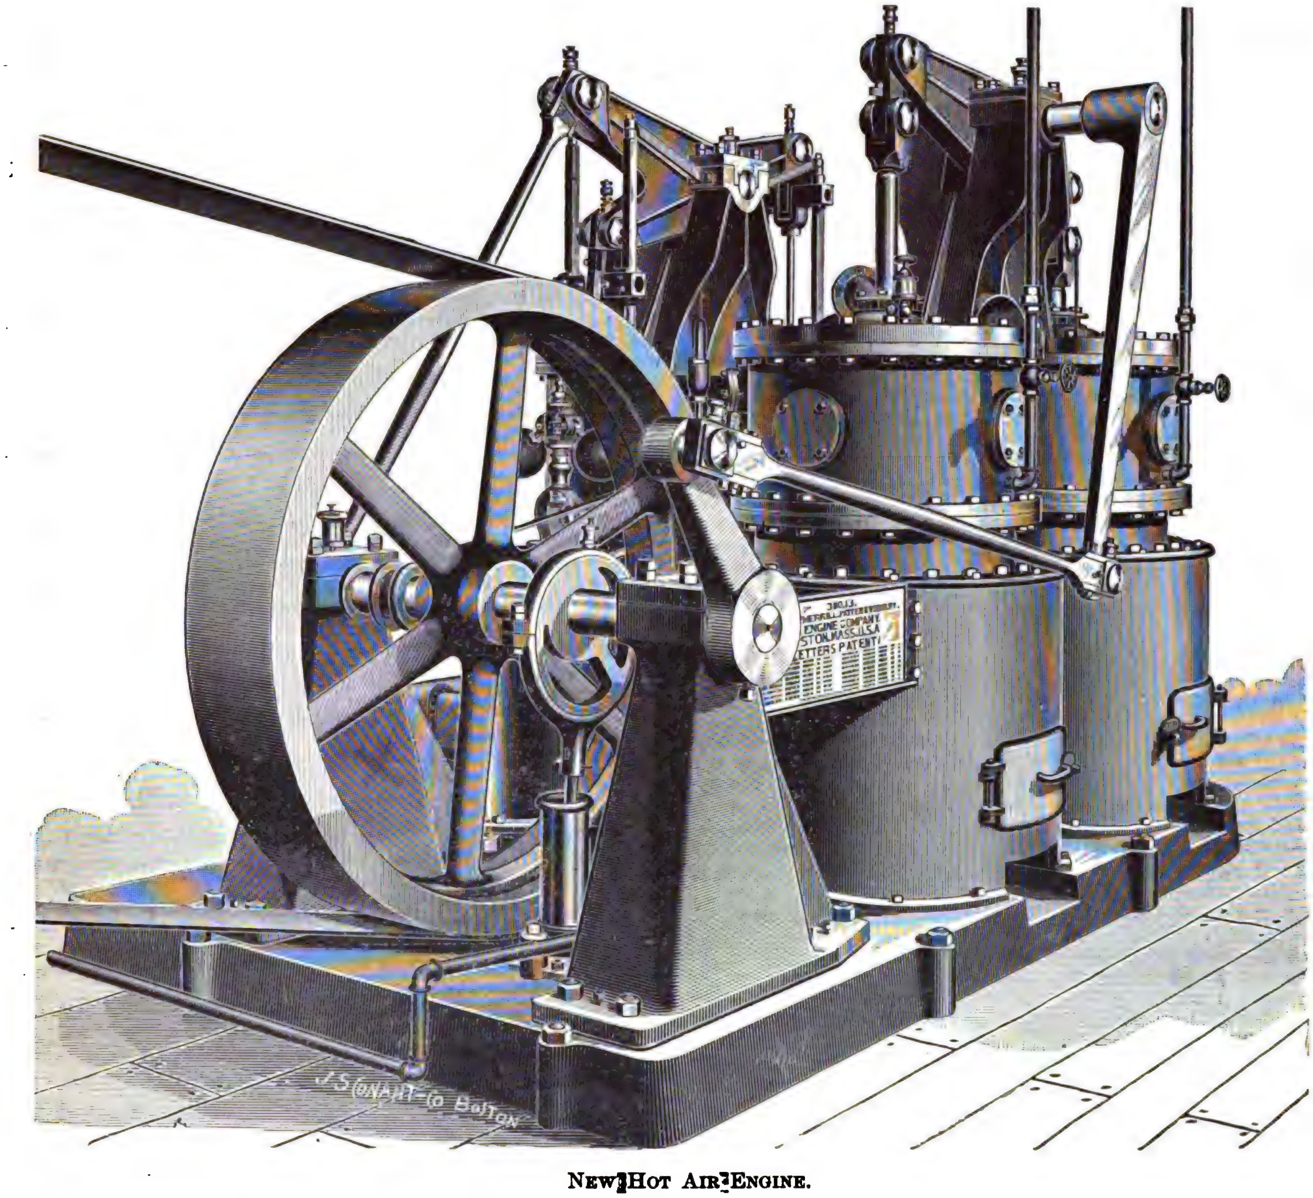
The high economy as well as the ease with which hot air engines can be operated, as compared with steam engines, has long made this type of prime mover the subject of study and experiment, but up to the present their construction has been limited to engines of but comparatively small powers. Indeed it may not be generally known that the great inventor, Ericsson, spent a large part of his time on the perfection of hot air engines, and that a large number of small engines of that type are in daily use for various purposes, such as pumping water, etc.

The application of the well known principles of thermo-dynamics to a hot air engine of larger power has, after a long series of experiments, led to the construction of the engine illustrated in the accompanying engraving, which is now built by the Woodbury, Merrill, Pattten and Woodbury Air Engine Co., of Boston. An engine of 10 h. p. is now on exhibition, driving blast fans and a lathe at the Fair of the Massachusetts Charitable Mechanics Association, and as it embodies a number of novel features, a description of it will be of interest to many of our readers using power.

The essential features of the engine are a heater, regenerator, and cooler, which three in combination are termed a reverser. The engine illustrated is composed of two reversers and two double acting working cylinders. It is not an exhausting engine; therefore, it has neither admission nor exhaust valves. Each reverser is provided with a reverser heater, placed within a furnace; a generator, composed of wire cloth of great superficial area, extending from the cooler to the bottom of the reverser heater; a cooler, composed of a large number of thin copper tubes, which are surrounded by water; and a displacer piston, having metallic packing rings, and adapted to reciprocate within the cooler.

In the operation, the alternate raising and lowering of the temperature of the same mass of air is accomplished as follows: In the upward stroke of the displacer piston, the mass of air in the cold chamber above the piston is forced, First, through the cooling tubes, in its downward passage, through which the temperature of the air is not materially changed. Second, the air enters the regenerator, and in its passage through the same it absorbs heat which has been imparted to the regenerator. Third, the air then passing over the heated surface of the reverser heater, thereby becoming further heated, enters the hot chamber below the displacer piston.

The temperature of the air in the cool chamber is about 120° F., and the temperature of the air in the hot chamber is about 600° F.



New Hot Air Engine.

In the downward stroke of the displacer piston, the mass of air is forced, First, to the regenerator. Second, the air enters the regenerator, and in its passage through the same, it deposits thereon the greater portion of its heat. Third, through the cooling tubes, where its temperature is reduced to about 120° F., and then into the cold chamber above the displacer piston. Therefore, at each upward and downward stroke of the displacer piston, the temperature of the same mass of air is alternately raised and lowered.

The alternate raising and lowering of the temperature of the displaced air (in both reversers) generates a power in accordance with the well-known laws of the expansion of gases, which power is developed by the working cylinders, as follows: While one displacer piston is making its upward stroke, and is heating and expanding the displaced air, thereby producing a pressure which is exerted against the bottom of the working piston of the working cylin-

der directly opposite the reverser, and against the top of the working piston of the working cylinder diagonally opposite; the other displacer piston is making its downward stroke, and is cooling and contracting the displaced air, thereby reducing the pressure against the bottom of the working piston, of the working cylinder directly opposite the reverser, and the top of the working piston of the working cylinder diagonally opposite. Thus each working piston is subjected to differential pressures, which are alternately reversed as the displaced air is alternately heated and cooled.

The engine is designed to run at an initial air pressure of 45 pounds and at a speed of 115 revolutions per minute. A test recently made by Mr. George H. Barrus, the well known engineer, showed a consumption of 1.54 pounds of coke per indicated h. p. per hour and 2.37 pounds per brake h. p. per hour.

We may add that a number of these engines have been in operation, one of them for several years, and that one of 35 h. p. is now in daily operation driving the machinery in the elevator and machine works of Messrs. Moore & Wyman, of South Boston. The effort is being made to introduce these engines for electric lighting purposes.

THE REGISTER AT THE "ELECTRIC EXCHANGE."

The register at Alexander, Barney & Chapin's Electric Exchange in the Telephone Building, 20 Cortlandt street, this city, shows a long list of visitors during the past week. Among the names appear those of:—E. H. Clark, Long Branch, N. J.; Rudolph Schmidt, Rochester, N. Y.; C. A. Nichols, Springfield, Mass.; J. Pinckney Smith, New Orleans, La.; A. D. Newton, Hartford, Conn.; M. E. Baird, Windsor, Conn.; W. C. McIntire, Philadelphia, Pa.; A. H. Hayes, Newark, N. J.; Romeyn Boyden, H. E. Harrington, Hartford, Conn.; J. F. Noonan, Paterson, N. J.; J. H. Shay, Chicago, Ill.; J. W. Packard, Warren, Ohio,; J. W. Peale, Wm. Whitney Munroe, O. S. Carr, Greenpoint; C. F. Pilen, New Jersey; Leo Daft, New Jersey; W. R. Eckart, San Francisco; George W. Davenport, Boston, Mass.; P. L. Saltonstall, Boston, Mass.; Wm. H. Temple, Fred. H. Whipple, Geo. W. Adams, Boston, Mass.; W. R. Bennett, Hoboken, N. J.; J. H. Bunnell, C. R. Huntley, Buffalo, N. Y.; Wm. M. Brock, Paterson, N. J.; Frank Wheaton, Paterson, N. J.

The firm have just secured the valuable services of Mr. David Chalmers, whose long experience in the electrical supply business and large circle of acquaintance, renders him a very desirable acquisition. He has already entered upon his new duties.

WESTERN TRADE NOTES.

The Electric Merchandise Company, of Chicago, have issued a very complete supplement to their regular catalogue containing handsome illustrations, descriptive matter, and prices of Sprague material for electric street railways. All the various adjuncts of the system, including axle brasses, armature bearings, motor and dynamo brushes and holders, pinions and gears commutators, fibre insulators, switches, etc., are tastefully arranged and their constructions clearly shown in the cuts. Parties operating the Sprague system should not fail to send for one of them.

The "Canvas Jacket" patent woven insulated wire, handled by The Illinois Electric Material Company, The Rookery, Chicago is enjoying a rapidly growing popularity amongst users of high grade moistureproof wire. Fresh testimonials are coming in fast, all in high terms of praise of its high insulation, resistance to abrasion and great toughness and tensile strength. The "Murray" overhead trolley switch is another meritorious specialty handled by the above company, and is meeting with approval by railroad men, and fresh orders are coming in all the time. The handsome souvenir pencils which they are giving away on application are rapidly vanishing, and those who have not already written for one should do so without delay.

The Great Western Electric Supply Company are just transferring their business to a new company of the same name but organized under the laws of the State of Illinois. Mr George Cutter, the able manager of the company, has sold out his interest to the new company, and will accept the managership of the new company, who are to be congratulated on this connection, as the immense business now being done by the company is almost entirely due to the untiring energy and perseverance of Mr. Cutter and to his large personal influence and widespread acquaintance amongst the electrical fraternity all over the country. His knowledge of the supply business and its many details is very extensive, and under his experienced management the greatest success is sure to accrue to any concern with which he is connected.

The Charles Munson Belting Co. are manufacturing a 60-inch belt for Akron, O., and a 48-inch one for Toledo, O., for the electric street railway plant. They are also making a 54-inch belt for Milwaukee, to be used for railway work.

The Knapp Electrical Works, Franklin street, Chicago, have just brought out a large and handsome catalogue of their numerous supplies and specialties. The book contains some 230 pages replete with fine cuts, ample space being allowed for each article and its accompanying reading matter to make a clear and prominent display. The famous Grimshaw white core and other wires and cables, connectors, cleats, pins, cross arms, railway supplies, insulators, rubber specialties, belts, fixtures, switches, lamps, sockets, annunciators, telegraph and testing instruments batteries and all kinds and classes of electrical supplies are prominently shown, and the whole arrangement of the apparatus is most complete and thorough, forming a fund of information which no purchasers of electric supplies should be without; and all should make early application for a copy.

The Central Electric Co. are to be congratulated upon the acquisition of Mr. George W. Vernor, who takes charge of the bookkeeping department. Mr. Vernor has been secretary of the Southern Electrical Supply Company, at St. Louis, for the past year, and is already well known to the electrical trade.

Mr. Charles E. Brown, of the Central Electric Co., has just returned from an extended trip of over eight weeks' duration. Mr. Brown reports business good, and brings home some nice orders for improved Candee wire.

Mr. James A. Lounsbury, so well and favorably known amongst the electrical fraternity of Chicago, as one of the managing engineers of the National Engineering Bureau, has severed his connection with the Bureau, to accept the position of electrician to the Thwing Electric Co., of this city.

Mr. W. H. Harding has been appointed manager of both the South Side Electric Light Co. and the Central Electric Light Co., of Chicago, and has his offices at 185 Dearborn street. The two companies operate the well known Ft. Wayne Electric Company's system. No better selection could have been made, as Mr. Harding is a man of immense executive ability in running a central station and thoroughly conversant with all the detail of this work.

Mr. W. C. Lyman, 49 Michigan street, Chicago, has just completed an enormous exhaust head for 20-inch exhaust pipe for the Chicago Edison Co. This is one of the largest ever constructed, and the mammoth exhaust head makes a most imposing show outside his shop.

J. Lang & Co., 44 Michigan street, Chicago, have put in two of their well known switches, each of 1,000 amperes for two new dynamos in the Chicago Edison Co's. station. They are also supplying the United Electric Traction Co. with all their large switches. Last week they shipped four 3-pole 250 ampere and six single pole 250 ampere to Bloomington. Ill., for street railway work.

Mr. James H. Garrett, one of the corps of engineers of the N. W. Thomson-Houston Co., who has been building the electric street railway in Streator, Ill., has resigned his position with the above company, and accepted a similar one with the Anaconda Smelting Co., of Anaconda, Mont.

NEW ENGLAND TRADE NOTES.

The Gethins Electrical Manufacturing Co. of Boston, manufacturers of the well known Gethins gravity cell, have become selling agents for the Sorley storage battery, and have become sole agents for their sale for phonograph purposes. Of late the Gethins company have been selling large quantities of the Gethins cells for charging storage batteries to run phonographs, and the New England Phonograph Company have adopted the cell for primary battery purposes.

The Standard Company of Vermont have sold a 500 light plant to the Worcester Woolen Mills, Worcester, Mass., and a 300 light plant to the Carolina Mills Company, Carolina, R. I.

The Bird and Sloane Electric Construction Co., of Boston, formerly Bird and Sloane, have been organized under the laws of the State of Maine, with a capital of $30,000, and have taken offices at 624 Atlantic avenue. Messrs. Bird and Sloane have been doing quite a large business in various electric construction work, and have taken this means to provide more capital for their increasing work. The officers of the company are:—Thomas J. Howe, president; Roswell P. Smith, secretary, and John F. Polsey, treasurer.

PHILADELPHIA TRADE NOTES.

Chadbourne, Hazelton & Co.—The Wenstrom Consolidated Dynamo and Motor Co., of Baltimore, made no mistake when they selected as their exclusive selling agents Messrs. Chadbourne, Hazelton & Co., of Philadelphia, who have recently so flooded the company with orders that something had to be done at once to meet the demand. At a recent meeting of the board of directors of the Wenstrom Company, in Baltimore, it was decided to rent a temporary factory at once pending the completion of the new factory now building. It is expected that the ew factory will be fully equipped in about three months.

THE
Electrical Engineer.

VOL. X. NOVEMBER 12, 1890. No. 132.

LIEUT. FISKE'S POSITION FINDER.

IN a recent issue[1] we described the valuable range finder of Lieut. Bradley A. Fiske, by which a gunner is enabled to know accurately the distance of the object which he is firing at. This instrument can be applied in many situations on land and on board ship, but

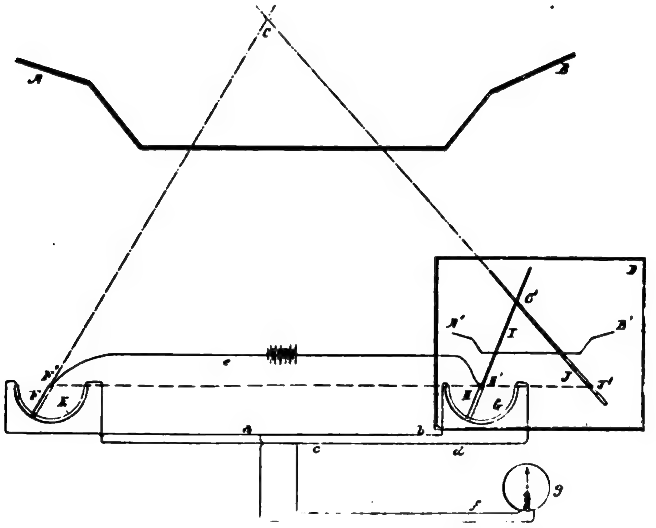


FIG. 1.—DIAGRAM OF FISKE POSITION FINDER.

presupposes, of course, that the gunner is able to sight directly upon his target. In modern fortifications, however, the tendency to the employment of what are known as disappearing carriages is becoming stronger every day and hundreds of such carriages are already employed in sea coast forts abroad.

In these forts the guns are loaded below the level of the parapet and when ready to fire are raised into firing position, usually by a hydraulic ram. This method of operation evidently protects those charged with the loading of the gun while the operation of loading is in progress; but it is evident, that by the means heretofore at hand, it has been impossible to sight the gun while depressed behind the parapet. True, the range could be determined beforehand by means of the range finder so as to permit the gun to be given the correct elevation before raising to fire, but this gives no indication of the true direction of the object to the concealed gunners, and hence deprives them of an essential factor in the pointing of the gun.

What was wanted, therefore, was some means by which the gunner could obtain both the range and direction of the object, with regard to the gun as a central point, in other words, their relative position. It is this which Lieut. Fiske has now accomplished, and in virtue of which the gunner is enabled to locate on a chart, drawn to scale, the exact position of a distant object which he has no means of seeing, but which is being sighted on by two observers placed at any distance, well protected from the fire of the enemy and unobscured by smoke.

The new position finder may be said to be a simplification and amplification of the range finder. It embodies, first, a telescope moving over an arc of conducting material and which is directed upon the distant object; second, a pivoted pointer moving over a like arc of conducting material in a Wheatstone bridge circuit with the first-named arc; the arrangement being such that when the alidade arm attached to the telescope on the first arc, and the pointer on the second arc stand at the same angle, the circuit is balanced. The pointer arm moves over a chart representing the area which includes the position of the distant object on a reduced scale. On this chart there is a simple pivoted arm which can be trained directly upon the object; or the arm may be mechanically controlled by a telescope directed upon the object so that it will make with the other arm an angle equal to that made by the lines of sight drawn from the two telescopes to the object. The position of the object is then shown by the intersection of the electrically directed pointer and the mechanically directed arm upon the chart.

In the accompanying illustrations, Fig. 1 is a diagram showing the general arrangement, and Fig. 4 is a similar diagram showing the chart D in different position. A B represents, for example, the parapet of a fortification. The distant object is supposed to be located at C; and it is the position of this object which is to be determined upon a chart D, on which the fortification line A′ B′ appears on a reduced scale. E is an arc of conducting material and F a telescope or arm pivoted at one end at F′ with its free extremity moving over, and making contact with, the arc E. G is an arc similar in all respects to the arc E and located in proximity to the chart D. H is an arm pivoted at H′ and having its free end sweeping over, and making contact with,

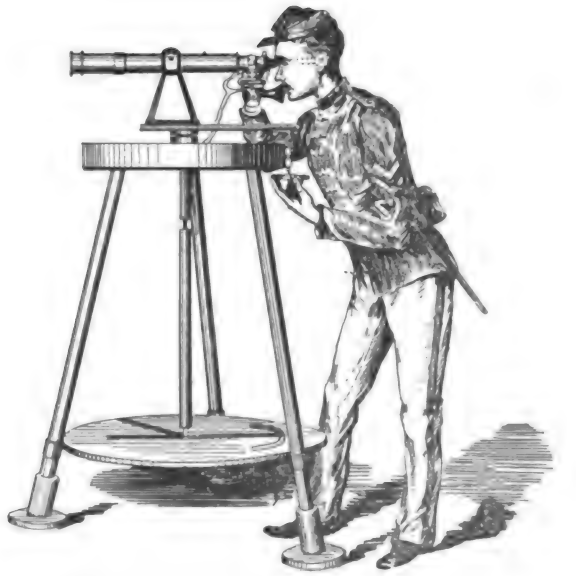

FIG. 2.—FISKE POSITION FINDER IN USE.

the arc G and carrying a pointer I. a, b, c, d, are members of a Wheatstone bridge connecting the arcs E and G. E is a loop including the battery, and *f* the loop including the galvanometer *g*.

Now it will be obvious that when the arm H is set upon its arc G at the same angle to the line H′ F′ as the arm F upon the arc E, then the bridge will balance and the gal-

1. THE ELECTRICAL ENGINEER, Oct. 1, 1890.

vanometer will indicate zero; and hence, inasmuch as the telescope F points to the actual object C, so the arm H will point to the corresponding position of the object C or C′ on the chart D. Pivoted upon the chart D at J′ is an arm J, which arm may be provided with a telescope or alidade, so that it may be directed upon the object C, the arm J being long enough to make intersection with the arm I.

If then the arm J is trained directly upon the object, inasmuch as the line H′ J′ joining the pivots of the arms I J on the chart D corresponds to the base line F′ J″ extending between the distant stations, and as the angle C′ H′ J′ equals the angle C F′ J′, it follows that the intersection of the arms I and J at C′ indicates the position of the object C upon the chart D. The chart being drawn to scale and laid off in divisions of known dimensions, it then becomes easy to

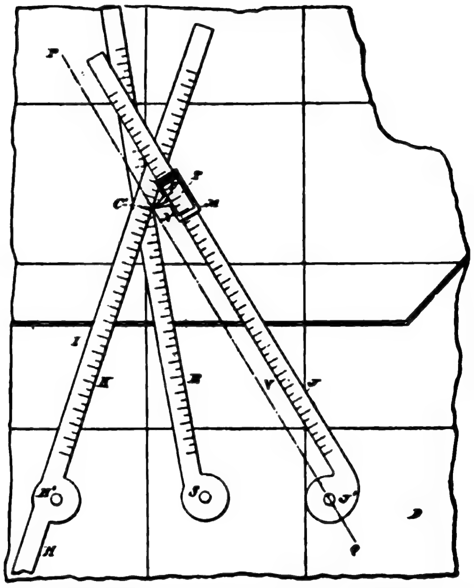

Fig. 3.—Intersecting Pointers, Fiske Position Finder.

recognize at a glance both the bearing and distance of the object C from any given point on the chart.

In actual practice Lieut. Fiske has adopted the form of apparatus represented in Fig. 2. This consists of a tripod supporting an upper platform which carries the standard upon which is pivoted the telescope. Extending downward through the platform is a shaft which turns with the telescope and standard. An arm is carried by the shaft and moves over a lower table on the upper surface of which is marked the chart. The arm is set parallel to the telescope; so that when the telescope is directed upon the object, the arm will also be directed upon the object. This parallelism of arm and telescope, however, is not essential. Carried upon the lower table is another arc and a second arm. The intersection of the two arms over the chart, as already explained, shows the position of the distant object; and the apparatus of Fig. 2, as indicated in Fig. 1, is located at one station, while the arc E with its telescope F is located at another distant station.

Referring now to Fig. 4, it will be seen that in this case the line H′ J′ on the chart D, while corresponding, as before, to the base line F′ J′, does not coincide with that line, and hence that the arm J is itself not directed upon the object. This represents the condition before referred to when the arm J is not set parallel to the axis of the telescope M, but at an angle thereto; this angle being such that the angle H′ C′ J′ will continue the same as the angle F′ C J′ despite a change in relative position of the chart D; such as indicated in Fig. 4.

In Fig. 3 is represented a construction of the intersecting arms I and J, which is especially adapted for the uses before detailed, and which allows of the actual intersecting point being determined with great accuracy. It will be obvious that with a chart laid out on a small scale and using arms I J of sufficient width or thickness to give them rigidity, the exact point of intersection of lines drawn through the pivot centres of the arms will be difficult to determine; and there may be considerable error in regarding the apex of any one of the four angles made by the intersecting arms as the true point indicated. In the device shown in Fig. 3, this source of error is practically eliminated; and in addition other advantages are secured.

The arm I has one edge K on a line passing through the pivot centre H′. On the arm J is a slide M, which carries a pointer N, projecting from the edge V; the extremity of this pointer being upon an imaginary line drawn through the pivot centre J′ and indicated by the dotted line P Q. It will be obvious that the point on the arm I indicated by the pointer N, will be the exact point of intersection of lines drawn through the pivot points H′ J′. The arms I, J are graduated lineally to conform to the scale of the chart D; so that the distance of the object from both separated stations can at once be read. Thus, on the rod I may be read the distance H C′ which is that of the object from the station at which is located the telescope F, Fig. 1; and on the rod J may be read the distance J′ C′, which is the distance of the object from the station at which is located the chart D. If it be desired to determine the distance of the object from any intermediate station between the two mentioned, a third pointer R may be placed in position between the two arms I J, and situated in the same relation thereto as the intermediate station is to the two extreme stations. The distance from the pivot point S of this arm to the point C′, the place of intersection of the edge of the arm with the point of contact of the edge K of arm I, and the apex of the pointer N, shows the distance of the object from the pivot point S, and hence from the intermediate station. The slide M is moved along by hand. It is provided with an opening T, through which the scale marks on the arm J may be read, and to allow this reading being

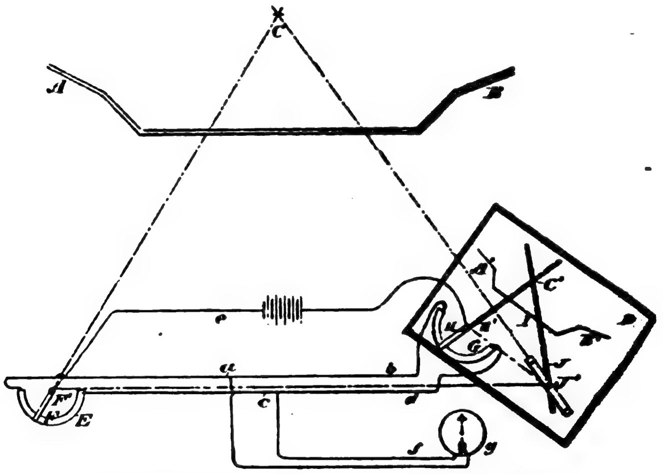

Fig. 4.—Diagram of Fiske Position Finder.

made, there is a central mark U made on the pointer N which comes into coincidence with any one of the scale marks.

Telephones are fitted to the telescopes in the same way as in Lieut. Fiske's range finder. This arrangement of telephone and telescope overcomes one great difficulty always found heretofore with observers widely distant from each other; that is, the difficulty of maintaining both lines of sight on the same point. This difficulty, when the target is partially covered with smoke, as in the case of a war-ship firing her guns, has been considered almost insurmountable, since the smoke would cover, at times, the very part of the ship at which the telescopes were directed. The telephones, however, enable two observers to agree instantly upon what point to direct their telescopes, and enable them to change the point as often as the circum-

stances of the battle require. The instruments are constructed of aluminum, bronze and iron, and require no care except an occasional cleaning.

Lieut. Fiske's position finder at Fort Hamilton, New York Harbor, has now been exposed to the elements for two months without any covering or protection of any kind. At a recent trial, the average error in determining the positions of objects distant between a mile and a quarter and three miles, was about one-third of one per cent.

BRADLEY'S SELF EXCITING GENERATOR.

In our last issue we described a type of machine designed by Mr. C. S. Bradley specially as an alternating motor, in which advantage is taken of a novel arrangement to obtain the torque reaction between field and armature. We are now enabled to describe another interesting machine of the same inventor, designed as a slow speed self exciting generator.

This machine, illustrated in the engraving, Fig. 1, may be considered to be a combination of Mr. Bradley's multipolar continuous current machine with an inductor of the same general type as the continuous current armature, the two being cross connected in a reverse manner, as shown in Fig. 2.

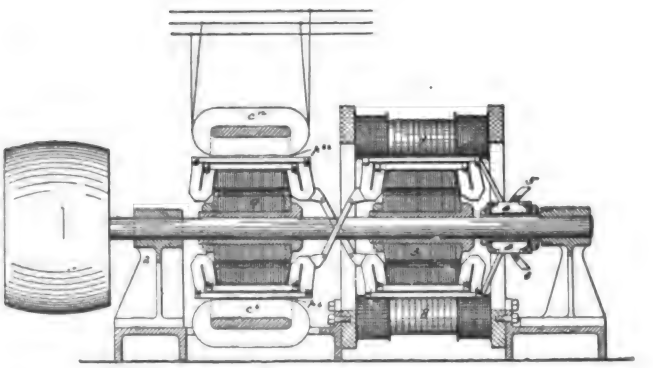

FIG. 1.—BRADLEY'S ALTERNATING GENERATOR AND MOTOR.

In the operation of such a machine, assuming the continuous current armature 3 to be driven in the direction indicated by the arrow on the pulley of the machine, current is induced in the winding of armature 3, and as the latter rotates while the polarity induced therein by the field remains stationary, it is evident that the polar lines thus set up in the armature-core travel, relatively, in a direction opposite to that of the movement of the armature itself. The connectors which are arranged between the armature 3 and the inductor 9 cause this rotation of the polar line which is now induced in the inductor 9 by the currents passing from armature 3 (owing to the reversal of one pair of the connectors), to change direction, and the propagation of the polar line now takes place in the same direction as that of the movement of the inductor itself. Consequently the actual speed of propagation of the polar lines in inductor 9 will take place at double the speed actually given the rotating shaft; that is, if the armature is rotated at the rate of five hundred per minute the polar line will traverse the body of the inductor 9 in the same direction at the rate of one thousand per minute.

Arranged around the inductor 9 is a stationary ring of laminated iron, the inner surface being notched, Fig. 3, and in the notches are wound the even number of coils, coils c c^2 c^3 c^4, etc., as shown in Fig. 4.

These coils may be connected to an external circuit in either of two ways, according to the character of alternating currents desired in the latter. They may either be connected all in series with the external circuit for a single alternating current, in which case the number of coils would be only one-half that shown in Fig. 4; or, as shown in Fig. 4, alternate coils may be connected in series and the terminals of each of the two circuits thus formed connected to the two external circuits 10 11 and 11 12. In the latter event the rotation of the polar line in the inductor 9 will set up in the two external circuits alternating currents with the phase of one-quarter of a period behind that of the other, so as to adapt the currents circulating in the external circuits for use in motors requiring currents of different phase. By suitably arranging the ring and its contained coils with reference to the number of poles in

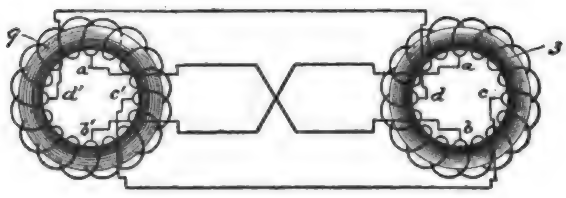

FIG. 2.—CROSS-CONNECTION OF ARMATURES.

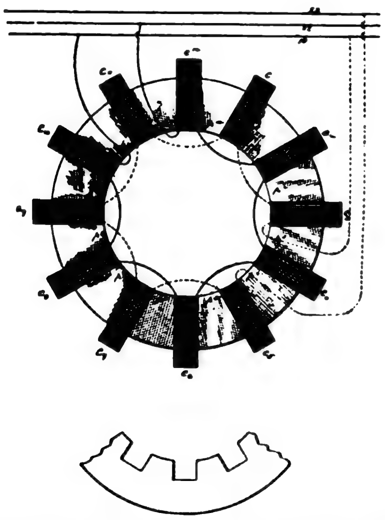
the inductor 9 the difference of phase between the currents in the two external circuits may be caused to correspond with any desired lag.

Considered as a generator, Mr. Bradley claims that it has the advantage of producing rates of alternation at comparatively low rates of speed. In the machine illustrated, if the armature 3 rotates at one thousand revolutions per minute, the six poles in inductor 9 will rotate at the rate of two thousand per minute, and, the annulus having six coils in series, the external circuit will have produced therein six alternations for every revolution of the armature 9, the result being twelve thousand alternations per minute in the external circuit. Another advantage when the machine is used as a generator is the total absence of contact rings and brushes between the coils of the alternator and the



FIGS. 3 AND 4.—BRADLEY'S ALTERNATING GENERATOR.

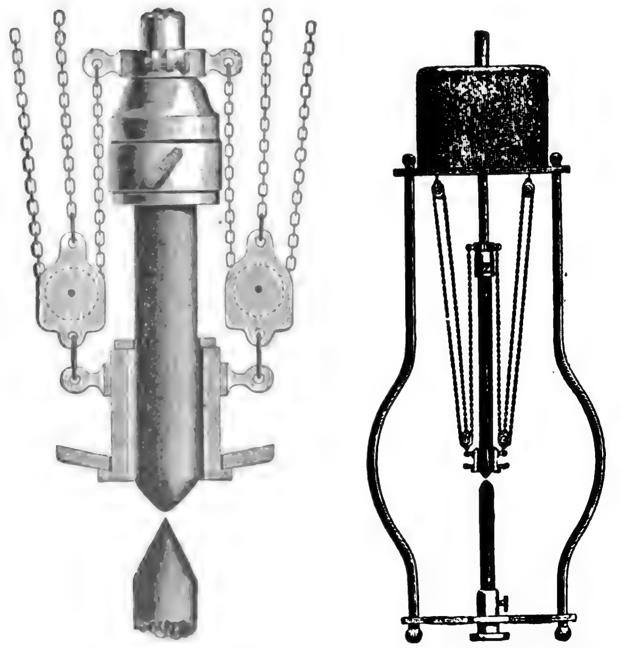
external circuit. Obviously the machine will operate as a motor when the coils c, c^2, etc., are supplied with alternating current from an external circuit.

BRITISH WEST INDIAN CABLES.

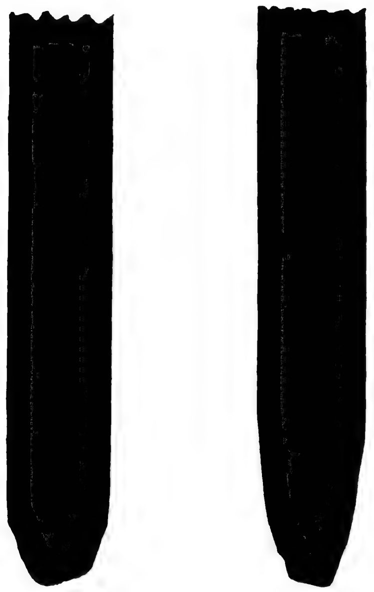
It is stated that in connection with new plans for fortifying the British West Indies, cable communications are to be established between all the islands. The ends of the cables in Jamaica, St. Lucia, and Bermuda will come into the forts. These cables will tap the main Halifax cable. They are under no conditions to connect with American wires.

THE HAZELTINE ARC LAMP CARBON SHIELD.

MANY of our readers readily recall the time when arc light carbons were sold at the rate of $1 a dozen and were not even then considered excessive in price. Since those pioneer days, there has been a continual diminution in the price of carbons, but with the enormous increase in the number of arc lamps burning nightly, the total expenditure involved amounts to many hundreds of thousands of dollars annually. It has, therefore, been the aim of many to increase as much as possible the life of the carbon on the one hand, or to increase its illuminating power with the same expenditure of electrical energy. These attempts have resulted in the application of various devices, either mechanical or as ingredients of the carbon itself, but, so far as we are aware, scarcely one of these methods has come into practical use, the pure carbon of to-day being still universally employed. The advent of a simple device by which an actual economy in the operation of the arc lamp is effected will, therefore, be of considerable interest, and for that reason we desire to call the attention of our readers to a simple and effective device of the kind due to Mr. W. B. Hazeltine, Jr., of the Hazeltine Electric Co., of St. Louis. This device, which is illustrated in the accompanying engravings, Figs. 1 and 2, consists simply of a sleeve of refractory material, forming a protective shield, or tip, which is freely suspended so as to hang in close proximity to the tip and the upper carbon close to the arc, the suspension device being so arranged that the sleeve is automatically maintained at its proper position near the arc. The effect of this simple arrangement, as has been shown by actual experience, is that the life of the carbon is practically doubled, so that an ordinary eight-hour carbon is able to burn 16 hours without retrimming. The exact action to which the saving in carbon and increase in life is due has not yet been fully analyzed, the fact remaining, however, as described. The shape of the carbon when protected by the shield is modified somewhat from that usually noted. Thus, in Fig. 4, is shown the tip of an ordinary positive carbon; and in Fig. 3, a tip which has been protected by the Hazeltine shield. It will be noted at once that the latter is considerably blunted, and the carbon shows a considerably larger crater than the unprotected one. The economical advantages gained by this device must be apparent. In the first place, not only may a large saving be effected in the carbon bills, but another important item, the cost of trimming lamps, may be reduced in almost the same ratio. A further attribute of the shield consists in the fact that it acts as an automatic cut-out whenever one or the other of the carbons is consumed, thereby preventing the destruction of the carbon holder, it being impossible, of course, for the holders to approach nearer to each other than the length of the shield. Aside from the economy in carbons and trimmer's services, it is pointed out that the convenience to customers of having their lamps trimmed every other day, instead of every day, as at present, will no doubt have the effect of increasing the popularity of the arc lamp. Besides, the consumption of the carbon is so complete that very little carbon dust settles at the bottom of the lamp, so that cleaning may also be deferred to the same time as trimming. We may add that the Hazeltine shield has been tested by Mr. James I. Ayer, superintendent of the Municipal Electric Light and Power Co., St. Louis, operating 3,000 lights, who, after a careful trial, fully corroborates the inventor's claims, which are also attested by the Western Electric Co., in whose factory a similar test was recently made under the supervision of Mr. C. A. Brown.



FIGS. 1 AND 2.—THE HAZELTINE ARC LAMP CARBON SHIELD.



FIGS. 3 AND 4.—CARBONS BURNED WITH AND WITHOUT HAZELTINE SHIELD.

FIVE-WIRE DISTRIBUTION.

THE five-wire central station at Königsberg, the first of its kind in Germany, will shortly come into operation. The total capacity of this station is at present 600 h. p. There are two groups of engines and dynamos, each comprising two triple-expansion engines, and four dynamos. The larger group which has to do the regular evening work consists of two 200 h. p. triple-expansion Schickau engines, each driving two 64 kilowatt dynamos. During the few hours of heaviest work, when two-thirds of the 8,000 lamps are alight, this group will be assisted by the smaller one, consisting of two 100 h. p. engines, each of which drives two 32 kilowatt dynamos. The fall of potential in the leads amounts to 10 volts at full load; the mains and distributing leads are all placed in Monnier conduits. The network is calculated for the supply of 24,000 lamps. Accumulators are used and special devices have been arranged to prevent them from being placed in the charging circuit before the right tension is reached. During their discharge, if their E. M. F. should fall, additional cells are automatically switched in. Any difference in the voltage of the different parts of the network is shown by a specially-constructed differential voltmeter.

THE MANUFACTURE OF KERITE INSULATED WIRE.

ONE of the first pioneers in the insulated wire industry, in this country, was Austin Goodyear Day. Mr. Day, who died but a short time since, was born at West Springfield, Mass., in 1824. Early in life he showed a decided bent for science and invention, and eagerly embraced the opportunity which was offered him, when he was only seventeen, of entering the India Rubber factory established by his cousin, Chas. Goodyear, at Woburn, near Boston.

Here he occupied a position as correspondent and bookkeeper, but with untiring industry he studied all the peculiarities of india rubber, devoting himself to the acquirement of an intimate knowledge of its physical and chemical properties, and the various processes of manufacture. At Woburn Mr. Day assisted at an important event in the history of rubber manufacture in this country, namely, the vulcanization of the first two or three yards treated by Hayward for Goodyear. He continued in Goodyear's service for several years, his strong bent for practical work securing him employment at various factories, at all of which he assisted greatly in perfecting the process of vulcanization. In 1851 he struck out for himself in an original line of investigation, and conducted a long series of experiments in the treatment of rubber with various materials, such as substitutes for magnesia, gums, resins and bituminous substances, and finally succeeded, by effecting a combination of rubber under the prolonged influence of a high degree of heat, in producing the first hard rubber made in this country.

A few years later, in 1853, Mr. Day made a great stride in improving the manufacture of rubber, and gave an immense impetus to the business by the invention and perfection of a process for cleaning the crude rubber. At that time Para rubber was the only kind used, as the rubber from other parts of the world was so much adulterated with foreign substances, dirt and impurities that its treatment could not be profitably undertaken. The price of Para rubber was so high that the development of the industry was necessarily hampered and restrained by the excessive cost of manufactured articles. Mr. Day's cleaning process rendered the treatment of impure or adulterated rubber a matter of ease; rubber from Africa, the East Indies and Central America then competed with the Brazilian product, and the cost of manufactured articles was reduced by about fifty per cent.

Fig. 4.—Exterior of Kerite Factory, Seymour, Conn., and a Corner of the Vulcanizing Room.

By 1854 Mr. Day had made so much progress in the industry to which he had devoted his energies that in that year he was enabled to buy a factory of his own, on the site of the present Kerite works at Seymour, Conn. By selling to the Boston Belting Company the rights to use his cleaning process he largely increased his capital, and was in a position to carry on the manufacture of hard rubber penholders and pencils as a business, while at the same time pursuing, with exhaustless vigor, his investigations and experiments in processes and combinations.

He applied himself with great earnestness to the perfection of the cleaning process, and for this and other reasons he postponed taking out patents for his inventions relating to hard rubber, as he wished to make them applicable to all kinds of commercial rubber, whereas without the cleaning process hard rubber could only be manufactured from pure gum brought from Brazil. Mr. Day's inventions had a very marked effect on the prices obtained for the different grades of rubber. In 1853 that produced in Africa and the East Indies sold for from 12 to 15 cents per pound, while the Para quality was quoted at from 30 to 40. So rapid was the rise in price, that before the cleaning process

FIG. 1.—AN EARLY STAGE IN MAKING KERITE.

had been very widely adopted Para rubber had advanced to from 75 cents to $1.00, and but for its introduction would have risen to $1.50. This great increase in price made an imperative necessity of what Mr. Day's cleaning process had only just rendered possible—the use of the cheaper grades—but so great was the demand for rubber goods that the price, even of these poor qualities of the crude article, rose steadily, and in 1864 reached 70 cents per pound. As an instance of the rapid multiplication of the uses found for rubber goods, it may be mentioned that in 1853 Mr. Day cleaned 55,000 lbs. of rubber, and in 1859 500,000 lbs.

Many of the difficulties in the manufacture of rubber having been overcome, and the processes reduced to a systematic and scientific train of operations, the manufacturers naturally began to turn their attention to the adulteration of the raw material with a view to cheapen and improve it. In their efforts to do this combinations of various substances were made with rubber, vegetable and mineral oils being used to some extent though with only negative results. A compound made by combining these materials in their natural state with rubber was too adhesive to permit of proper working, and the various ingredients had to be worked separately.

Having met with such signal success in other branches of the rubber industry, Mr. Day attacked this problem with the same earnestness and determination that he had brought to bear on those already solved. He made a long series of experiments with the set object of overcoming the obstacles which had hitherto presented themselves to other workers, the goal in view being the production of a compound which could be combined with rubber. The final result of these investigations was the discovery, or rather the building-up, of Kerite, the material which forms the subject of this article.

In the production of Kerite Mr. Day had solved the problem of finding a substitute for rubber in the shape of a compound which could be worked with it by machinery. He prosecuted his experiments at Seymour with great assiduity, and having made a discovery he applied himself with untiring industry to perfecting the new material. During the three years from 1867 to 1869 he made between two and three thousand experiments in different combinations of materials, and tabulated no less than 350 formulæ for making crude Kerite. As may be imagined, a vast number of different substances had to be experimented with, including the whole range of vegetable and mineral oils, bituminous gums and resins, sulphur, acids, alkalies, earths and mineral oxides.

Mr. Day at once applied his newly-discovered Kerite to the insulation of electric wires, an industry then in its infancy in this country, and his productions in this line met with prompt acceptance among the telegraph companies, who were at that time almost the only users of insulated wire. He soon saw that he had embarked in an industry which offered a profitable field and one capable of wide development, promising a rapid natural growth with the increase of electrical applications in the industrial arts. Accordingly he gave himself up to studying the manufacture of insulated wire, and in order to profit by the experience acquired in the old world where this branch of the art had long ago reached a high pitch of excellence owing to the multiplication of submarine cables, the construction of which has always remained in England, he paid a visit to Europe in 1870 and spent nearly two years there, during which time he acquired much information regarding the state of the rubber and cable industries. In 1872 Mr. Day returned to Seymour, and with his increased knowledge of the peculiarities of insulated wires and cables, as well as of the needed improvements in his crude Kerite and its combination with rubber, he started in to organize his wire and cable factory on a systematic and scientific basis.

Since then the record of the Seymour factory has been one of uninterrupted prosperity, and Kerite wire is so well known all over this country that in many companies the word "Kerite" is printed on forms as a conventional name for insulated wire.

No doubt many users of Kerite will, after reading the brief foregoing sketch of its inventor, be interested in following this material through the various stages of its manufacture, as explained and illustrated herewith.

FIG. 2.—PORTION OF THE GRINDING AND CLEANING PLANT.

In the accompanying illustrations, Fig. 1 shows the department where the first operation in making Kerite is performed. In the large cauldrons are mixed the various materials of which the crude Kerite is composed. These materials are several in number, but how many, what they are and in what proportions they must be mixed in order to attain the desired result it is scarcely necessary or proper to specify here. Suffice it to say they are thoroughly incorporated for several hours at a high degree of heat.

When the mixture has reached the correct stage of this process, which is easily recognized by the men who keep a careful watch over each cauldron, it is run out into a fresh cauldron, in which it is subjected to a different degree of heat for a short time and then allowed to cool. By this operation a chemical combination of certain of the components of the mixture is effected and the manufacture of the crude Kerite is then complete. The compound is run out in slabs or thick sheets, rolled up and stowed away in dry store-rooms for some time before being mixed in with the pure rubber, as Kerite, like good wine, improves with age. In the next department, illustrated in Fig. 2, a large, well-lighted shop, the inquisitive visitor to the Kerite factory is shown the grinding and cleaning plant for treating the pure rubber and ridding it of impurities, and the rolls and without further acquaintance they are indissolubly united by means of an elaborate ceremony performed by the heavy steam-heated rolls which line the room. The rubber is made soft and plastic by being passed through the rolls a number of times and the crude Kerite is treated in the same manner; they are then brought together and the operation is repeated time and time again until the materials are so thoroughly incorporated together that they form a dark chocolate-colored homogeneous mass in which it is impossible to distinguish any sign of one ingredient preponderating over another or of one portion failing to become properly mixed in with the rest.

This part of the process completed, the full-fledged Kerite insulating compound is made, and it is then transferred to the wire-covering department to be applied to the

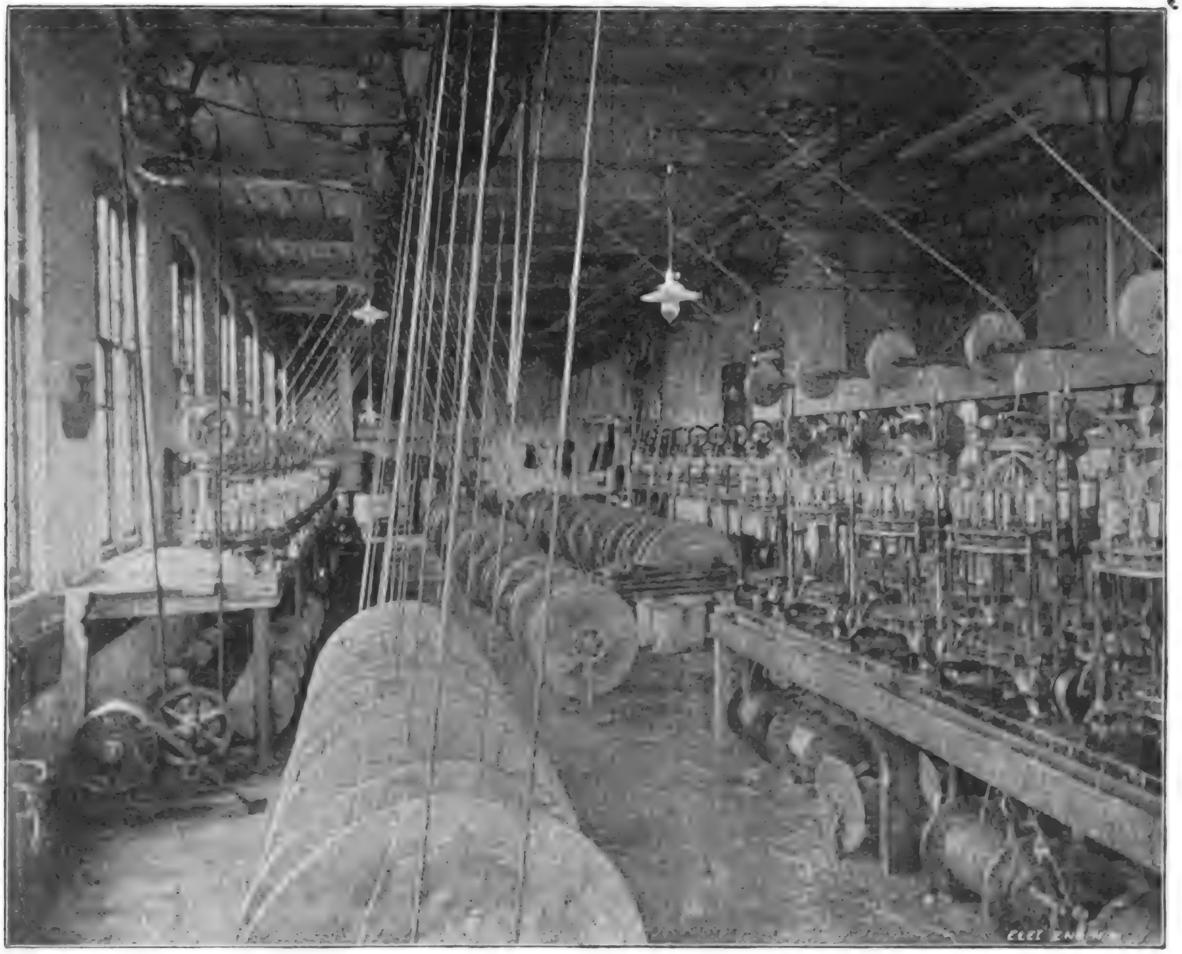


FIG. 5.—ONE END OF THE BRAIDING ROOM.

calenders for incorporating the crude Kerite with the rubber to make the final compound.

The grinding-machine for cleaning the rubber is of very ingenious construction. It consists of two heavy steel rollers studded over their entire surfaces with diamond-shaped projections. The rollers are so arranged that as they revolve the diamond-shaped studs of one fill up the spaces between those of the other. As can readily be imagined the rubber gets very thoroughly ground and purified in this machine, and there is no chance of any impurities escaping its very pressing attentions. After the rubber has been ground and cleansed in this manner it is hung up in the shape of long, thin, crinkled sheets, which look for all the world like so many alligator skins, in a dry loft, where it is left for many weeks to allow it to become thoroughly dry before being mixed with the compound.

At the appropriate time the rubber and the crude Kerite are introduced to each other in the calendering room and

wires. A view of this part of the process, showing three of the covering machines in operation, is given in Fig. 3.

The compound, in the shape of thick slabs or sheets, is brought to an operative stationed at the bench in the background, by whom it is cut into long strips and fed into a straining machine which forces it through a die-plate having a number of exceedingly small holes. This strainer arrests any particles of foreign matter that the compound may have picked up in course of transit from one shop to another, or from handling, and the compound emerges in what might almost be termed chemically pure condition. Bearing the appearance of a mass of uncanny, writhing worms it is now transferred to the covering machine, into which it is fed by the operative in charge. The covering machine is exceedingly ingenious and at the same time of simple construction, and it is a perfect marvel of compactness. The body of the machine stands at right angles to the line taken by the wire in passing through it and in the

space of a few inches the wire is provided with a well-fitting covering of insulating material.

The plant is arranged as follows:—The wire, which has been previously tinned by a special plant arranged for that purpose in another part of the factory, is wound on a light iron drum about four feet in diameter, which is mounted immediately behind the covering machine. This consists of a cylinder into which the strained compound is fed, and in which it is forced along by a screw until it reaches another and smaller cylinder attached at right angles to the main one. The wire enters this small chamber through a tiny hole and leaves it at the opposite end through a circular die, by means of which the amount of insulating compound to be applied is regulated. As it travels through the chamber the wire gathers its coating of compound, which is laid on with perfect evenness, securing exact centrality of the wire and smoothness of the insulation. On emerging from the die the wire travels along a short wooden trough and is coiled into the vulcanizing pan. This pan is of iron, about nine feet in diameter and six or eight inches deep; it is mounted on a small trolley in such a manner that the men who coil the wire down can, by a very slight effort, keep the pan revolving all the time, which, of course, greatly facilitates their work. As the wire is coiled down in the pan it is covered up with powdered soapstone and is then ready for vulcanizing. One of these large iron pans holds several miles of wire, and the whole operation of applying the compound to the wire is one of the most systematic and expeditious that we have inspected. It is all performed in an exceedingly small space as regards the flooring occupied by the plant and with a minimum expenditure of time and labor. In watching this process it is especially noticeable that one of the axioms of insulated wire manufacture is carefully borne in mind. Every hand that touches an insulated wire during its manufacture is a potential source of injury, and if the hands are many it is next to impossible to trace the defects and place the responsibility for them where it belongs. In the manufacture of Kerite wire, as we have pointed out above, the handling is reduced to the least possible amount. The

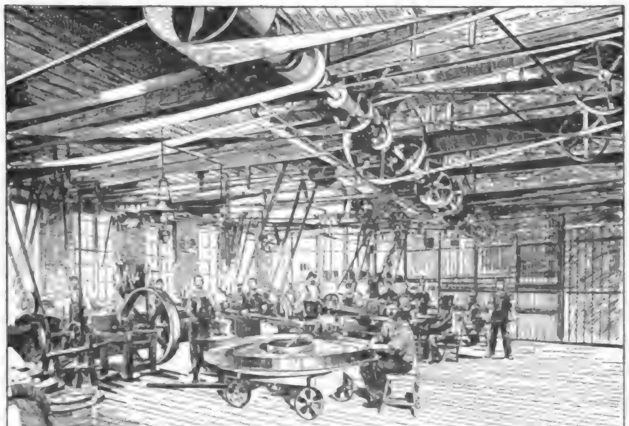

FIG. 3.—A GLIMPSE OF THE INSULATING DEPARTMENT.

wire passes from the covering machine along a trough filled with powder directly into the vulcanizing pan; the pan being revolved by hand no appreciable strain is placed upon the wire when in this delicate, new-born state, and the men in charge merely guide the wire so as to keep the turns slightly apart and each well coated with the soapstone. So deft do they become, after a little practice at this work, and so thoroughly do they seem to understand the susceptibility of the wire, that they barely handle it, guiding it to its place with the lightest touch possible. The machines through which the compound passes, such as the strainer and covering machine, are, of course, steam jacketted in order to keep the compound warm and plastic, consequently after leaving the die it is naturally still somewhat soft, and only by virtue of this careful treatment can large amounts of "faultless" wire be turned out.

When sufficient wire has been coiled into the pan this is wheeled away on its trolley to the vulcanizing room, a portion of which is shown in Fig. 4. Here a cover is fastened down over the pan and it is swung bodily into a large vulcanizing chamber of brickwork lined with iron and provided with a heavy iron cap which is bolted on by substan-

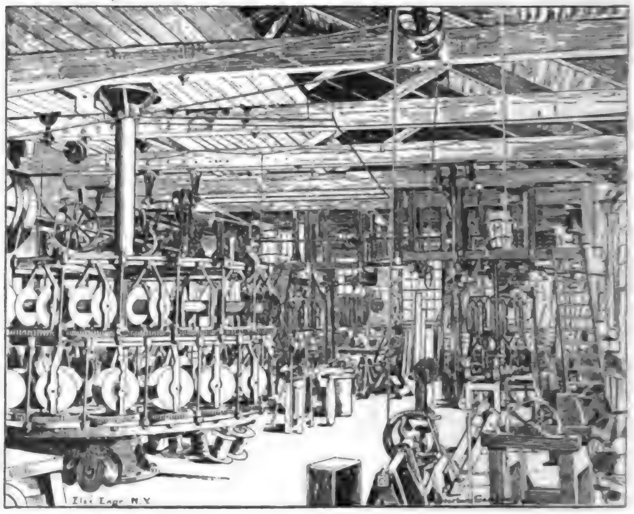

FIG. 7.—ANOTHER VIEW IN THE ARMORING AND CABLING DEPARTMENT.

tial screws and nuts. Live steam is circulated in the vulcanizing chamber for several hours, at the end of which time the manufacture of Kerite wire is complete. The pan is then taken out and the wire is wound off on reels, which are submerged in a large shallow tank placed just outside the testing room. The wire is all tested with a delicate reflecting galvanometer and a battery of about 200 volts before being made up into cables or sent out of the factory; and, as can readily be understood from the above description of the covering process, it is an exceedingly rare occurrence for a defective coil to be revealed.

A large proportion of the wire turned out receives additional protection in the shape of braiding and preservative compound, so that a visit to the braiding-room, a portion of which is illustrated in Fig. 5, is next in order. This department is on the second floor of the factory and contains a large number of the ingenious braiding machines, which are sufficiently well known to need but slight description. The light iron drums of wire are placed underneath the benches which support the braiding machines; the wire passes up through the machines where it is braided and impregnated with preservative compound, and then over a system of pulleys to a wooden spool, on reaching which it is complete and ready for shipment. The wire travels comparatively slowly, and as it is in the air for a considerable distance between the braiding-machine and the wooden spool, the outer covering of braid and compound is perfectly dry by the time the wire is wound up. The whole operation is entirely automatic; if a single thread breaks the braiding machine stops and the wire travels no further until the rupture is made good. This busy department with its large number of machines is constantly in full swing and many miles of wire are braided every day.

The factory at Seymour has built up an enviable reputation, now of many years standing, for the excellent work turned out in the line of submarine and aerial cables; in fact, until quite recently Kerite submarine cables stood practically alone in the market, and even now they enjoy a

conspicuous place in public favor by reason of their all-round excellence of manufacture. Submarine cable engineering on a large scale has been pretty well monopolized on the other side of the water; it is an industry extremely technical in its nature and largely dependent on the experienced skill and care of all hands employed in it. Although Mr. Day did not aim his ambitions at ocean cable work he realized that there were sufficient rivers, bays, and other stretches of water in and about this country to cause a demand for short submarine cables, and, always quick to seize an opportunity, he at a very early date laid out his factory to supply this demand. Consequently he and his workmen acquired ample experience in the construction of submarine cables long before most of the insulated wire factories in this country had sprung into existence, and so well is this fact recognized by other companies in the same business that it is no uncommon occurrence, when orders for submarine cables are obtained by some of them, for the wires to be sent to Seymour to be armored.

In Figs. 6 and 7 are views of the large shops containing the big "sun-and-planet" armoring machine, and several smaller cabling machines for laying up aerial cables and the cores for compound submarine cables. This is one of the most important departments in the Seymour factory, as cable of all classes, aerial and submarine, is constantly being manufactured, and Kerite cables are to be found overhead and under water in all parts of the country. Much of the machinery used here, as in the other departments, is peculiar to this factory and has been constantly altered and improved during the many years' experience of the treatment of insulated wires and cables that those in charge of the work can boast of.

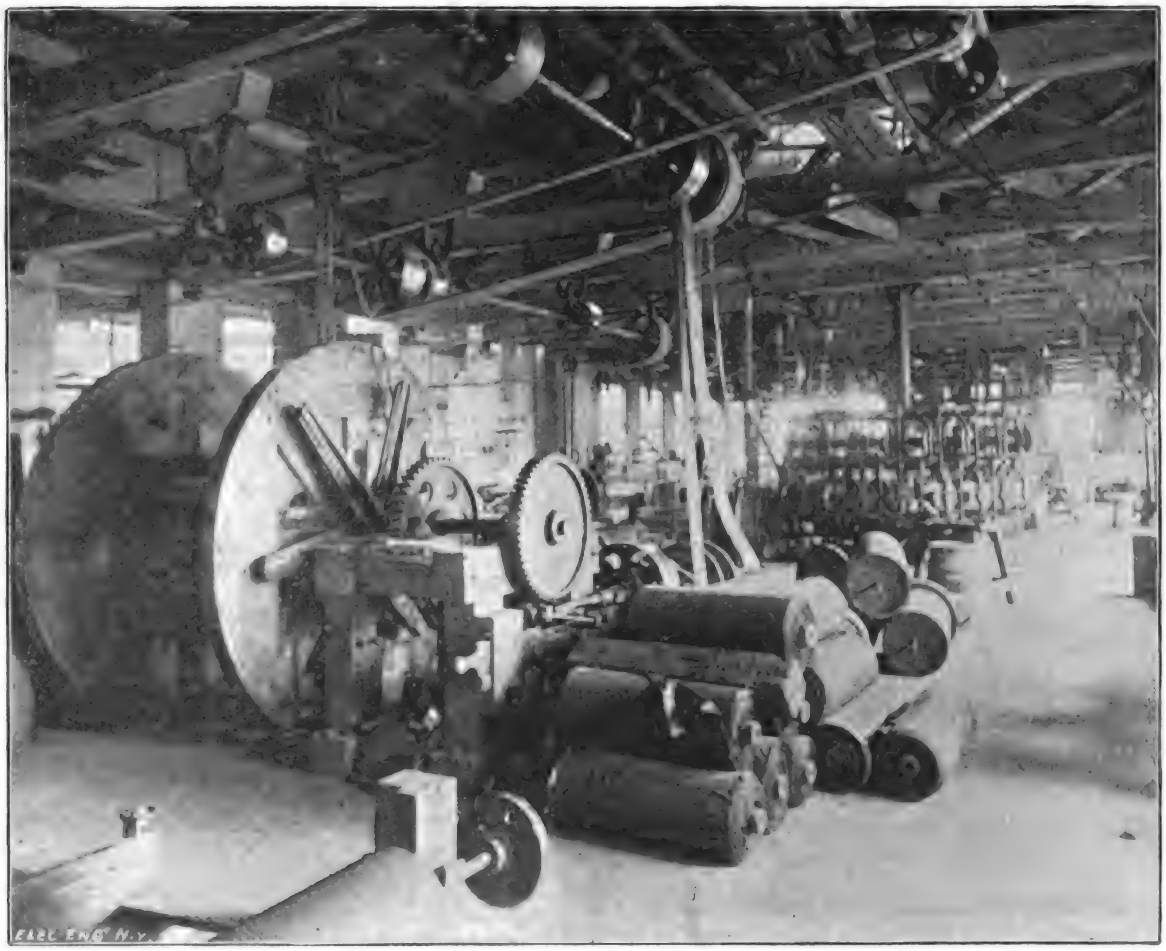

FIG. 6.—VIEW IN THE CABLING AND ARMORING DEPARTMENT.

Another important branch of the work done at Seymour is the manufacture of Kerite tape for making joints in insulated wires. This tape is a special production of which the proprietors of Kerite feel particularly proud, a feeling in which they are justified by the long record of good and useful service which the tape has achieved since its introduction. A great deal of experimenting has been done, in the years gone by, to make this very necessary adjunct to electrical construction the perfectly reliable material that it is, and special machinery has been designed for its manufacture. The tape is made with the same compound that is used for covering wires, the compound being employed for this purpose in its unvulcanized state. By means of a very heavy calendering machine of special design rolls of cloth of a particular texture and suitably prepared so as to be perfectly dry and free from any foreign matter are impregnated with the compound under the influence of steam heat and heavy pressure. So thoroughly is this part of the process carried out that it is difficult to tell whether the cloth is impregnated with Kerite or the Kerite impregnated with cloth; the result is practically a fine sheeting of unvulcanized Kerite strengthened by means of the textile fabric. The cloth is rolled up on a light drum and cut into the proper width for tape, which is then wound off on little wooden spools. This Kerite tape is a prime necessity for making waterproof joints in vulcanized insulated wire and it possesses the peculiar property of self vulcanizing by exposure to the sun and atmosphere. Joints made with this tape in the most exposed situations, have been known to last in perfect condition for many years. The manufacture of the tape goes on continually at Seymour and many thousands of rolls are sent out every year.

We have already shown how Mr. Day devoted his whole time to the study of rubber and how he was led to the discovery of Kerite, which thenceforth claimed his entire attention and caused him to acquire a knowledge of the technique of another industry—that of the manufacture of wire and cables. In this he was assisted by two very able lieutenants, Mr. A. G. De Wolfe and Mr. W. R. Brixey, the former of whom is now on the retired list, the latter in active command of the factory. Mr. De Wolfe was with Mr. Day when the manufacture of insulated wire was first begun at Seymour and to his mechanical ingenuity are due many of the appliances and machines used in the various processes of insulating and cabling. Mr. De Wolfe is thoroughly familiar with the entire work, root and branch, and has every detail at his fingers' ends. Since 1858 he has been engaged in studying the needs of an insulated wire factory, and almost since the same date he has been occupied in supplying them, as far as improvements in the permanent plant and processes are concerned. Much of the machinery now in use at Seymour was originally designed by him, and by him improvements have from time to time been made, both in his own inventions and in the machinery which has been adopted from outside.

Mr. De Wolfe is now well advanced in years and has retired from active work, but he pays almost daily visits to the factory, enjoying all the pleasure an inventor feels when watching the creations of his brain and fingers doing nimble service and turning out useful products. A chat with this veteran is a pleasant feature of a visit to Seymour, as he is surcharged with an inexhaustible fund of information on a variety of subjects, and a good listener can get a number of useful "pointers" from him in the course of a short talk.

Mr. W. R. Brixey has been the superintendent of the factory for upwards of ten years. Originally a nautical man, Mr. Brixey has brought all a sailor's ready resource and love of neatness and order to bear on the organization of his work at Seymour. Having originally a strong bent for mechanics, he very quickly mastered the processes in which mechanical work plays an important work; his sailor's training was a good preparation for the acquirement of general knowledge, and with a natural faculty for "catching on" to new ideas quickly he soon learned all that Mr. Day and Mr. De Wolfe could teach him, and in six months was as much at home in the factory as if he had been brought up there. That Mr. Brixey thoroughly understands the art of securing the best possible results with the least expenditure of space and labor is plainly apparent from a very cursory examination of the factory at Seymour. Those who can judge of the extent of the business done in Kerite wires and cables would naturally expect to see a very large factory and a great number of hands at work. As a matter of fact the works, although commodious, are by no means of startling size and the operatives employed are not so numerous as to crowd each other; which goes to show that scientific management, high-class machinery and intelligent organization are able to do a great deal in getting the maximum benefit out of the minimum of space and manual labor. Mr. Brixey thoroughly understands this and also appreciates the value of careful supervision of all branches of the work, down to the smallest detail. He is works-manager, engineer and electrician all in one, being a superintendent in the full sense of the word; and while he remains at Seymour there is no fear of any falling away from the standard of excellence so long maintained by the products of the Kerite factory.

In the foregoing description we have endeavored to give some idea of the manufacture of Kerite wires and cables and of the workers who have been, and are, prominently connected with this industry, one of the oldest established in American electrical circles. Some points have necessarily been omitted, but to do adequate justice to such an interesting theme would require more space than we can devote to any one subject. We have no doubt, however, that many of our readers who seldom have an opportunity of watching the evolution of insulated wires will have accompanied us in our ramble through the Kerite factory with a great deal of interest and profit.

Our thanks are due to Mrs. A. G. Day and to Mr. G. B. Prescott, Jr., general agent for Kerite, for the facilities placed at our disposal in the preparation of this article.

ON THE CONDUCTIVITY OF SOLID AND FUSED SALTS.[1]

BY L. GRATZ.

The data hitherto published on the conductivity of solid and fused salts differ for each salt when determined by different observers. The author was extremely careful to keep the salts at constant and accurately measured temperatures. The salts were fused in a small porcelain crucible 2.8 cm. high and 2.2 cm. diam., heated equally in a sand bath. In the salt were placed stout square, platinum electrodes of 2.25 square cm. surface. The electrodes were freshly platinized before each test. To prevent cooling of the electrodes by conduction of heat through the connecting wires, about 20 cm. of the latter were also put in the same bath. The resistance of the salt was measured by the alternate current and an electro dynamometer. The capacity of the crucible was determined by a solution of magnesium sulphate. All readings were taken with decreasing temperatures in order to obtain greater constancy.

In spite of the fact that many of the salts on solidifying showed porosity, a general agreement was found between the results for the same salt in the solid and fused state. With some salts, just at the point of fusion, a remarkable change occurs in the volume or in their conductivity; with others, the conductivity alters rapidly at a temperature below the fusing point; and with a third group, a steady change only is observed. It appears, therefore, that the only difference between salts in the solid and fused state is due to an action of an electrolytic nature, as Warburg has already proved in the case of glass and crystal. Clausius' theory, therefore, that in solid bodies the molecules oscillate about a position of equilibrium, but cannot separate from their own group, cannot be accepted. The idea of a sharply-defined difference between solids and liquids must also be abandoned as it seems to have no existence in nature. Liquid molecules exist in every solid, even when the latter show no approach to the softened state.

1. From Wiedemann's *Annalen*, Vol. 40, No. 5.

THE BROWN ELECTRIC LEAK DETECTOR.

It is not generally known, though it is nevertheless a fact, that property aggregating many thousands of dollars is destroyed or damaged every year in this city alone by overflows or leaks from the hydrants, bath or toilet rooms, as well in business apartments as in private houses. Unlike damage in the case of fire, there is no insurance for this class of loss, which is thus irretrievable. A safeguard against such loss is therefore eminently timely, and has been worked out in a very simple manner by Mr. Andrew H. Brown, of this city.

The apparatus, which is now being exhibited at the

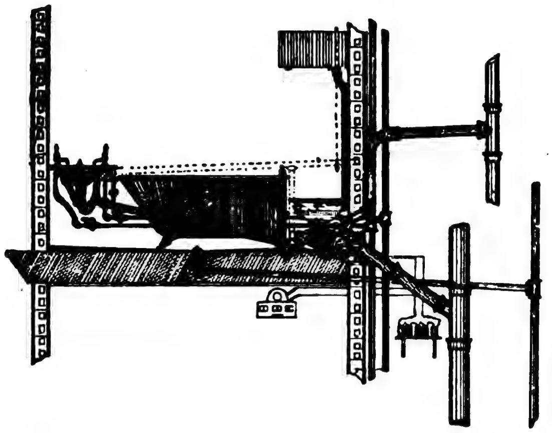

Fig. 1.—The Brown Electric Detector of Water Leaks.

American Institute Fair, where it attracts much attention, consists of a simple circuit closer acted upon by the presence of water and connected with an annunciator which locates the leak at once.

The accompanying engraving, Fig. 1, shows the application of the leak detector to a bath or toilet room. The circuit closer is shown full size in Fig. 2. Its operation is exceedingly simple. When any of the pipes, couplings, joints or valve glands leak, or an overflow occurs on any floor, the water drips into the pan or safe, and flows into the bucket valve of the detector. When the quantity

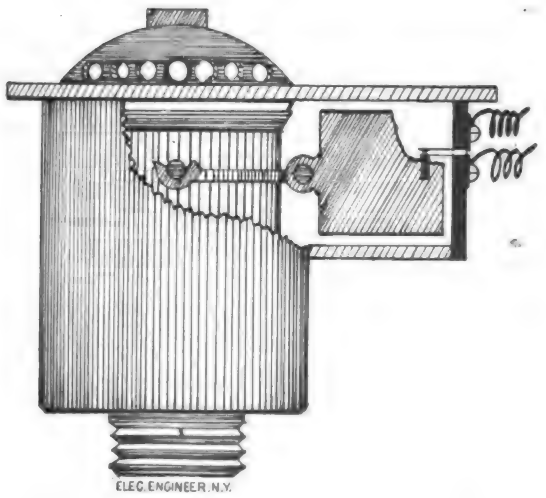

Fig. 2.—The Brown Electric Detector of Water Leaks.

equals a tablespoonful the valve falls by the weight of the water and brings the free end of the lever against the contact points in the annunciator circuit, closing the circuit to the annunciator; this rings an alarm, and at the same time indicates in which room, apartment or floor the leak has occurred, so that preparations can be made, or measures taken to stop the leak.

With this arrangement the usual "safe waste" pipe may be dispensed with, so that a considerable reduction in the expense for the plumbing equipment of a house may be effected.

IMPROVEMENTS IN ELECTRIC RAILWAY CAR DETAILS.

BY T. C. FRENYEAR.

If allowed a little space I should like to call attention to the bearing which Dr. W. L. Allen's admirable paper, read before the American Street Railway Association and published in The Electrical Engineer of Oct. 22, has toward the appliances of The Short Electric Railway Co., with which he seems not to be familiar; especially as some of the difficulties he mentions have been recognized and overcome in the Short system.

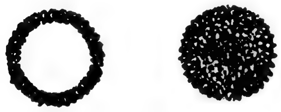
Dr. Allen says: "We want gear of some material that will be reasonably durable, and at the same time noiseless," and "To overcome the noise, it is necessary either to have the gear covered and running in oil, or to have the gear of wood or the pinion of rawhide." There is nothing to wear like steel, and it is therefore preferable to use steel gears and pinions, if the noise can be stopped. Rawhide pinions wear out very quickly, wooden gear teeth have yet to prove whether they will long stand the very hard usage to which street car motor gearing is subjected. But a *wooden web* between the steel hub and steel rim of the gear wheels has proved to be a sure preventive of noise, and has made it possible to retain the longest lived gearing known. In the Short system the teeth are also made very large so that it is impossible to strip the gear, and a form of construction is used which makes it possible to take up the wear of the gearing, thus further lengthening its life.

The chafing of the armature wires, which Dr. Allen speaks of as being a fruitful cause of burn-outs, is entirely prevented by the use of the "ring" armature, as in it each bobbin is separate and there is no bunching of wires.

Burning out from "grounds" is also prevented by insulating the motor from the truck. The practical value of these devices is evidenced by the freedom from repairs wherever they have been adopted.

COPPER OXIDE FOR STORAGE BATTERIES.

Our readers may already be aware that for some time past numerous important experiments have been carried on by Messrs. Justus B. Entz and Montgomery Waddell in



The Entz and Phillips Storage Battery.

adapting copper oxide for use in the storage battery. For this purpose they employ a tube of woven copper wire which is filled with copper oxide, as shown in the accompanying illustrations. In the employment of pure copper oxide, however, trouble has arisen from the lack of coherency of the material.

To avoid this, therefore, Mr. Entz, in connection with Mr. Wm. A. Phillips, has recently modified the composition by combining with the oxide of copper a small portion of sulphur, and then heating the mixture. The sulphur is thoroughly mixed with the oxide and then applied to the woven copper wire. The whole is then heated to burn off the sulphur, but in so doing the oxygen of the oxide of copper is absorbed to form the SO_2, leaving the oxide in a reduced or partially reduced state on the support. The heating then being continued, the exposed portions of the particles of the mass are reoxidized, while the unexposed portions at the juncture being protected from the air remain metallic and serve to hold the mass together. The sulphur, when used in this manner, therefore acts as a binding, toughening, or hardening agent without being actually present in the mass after the treatment.

The oxide of copper thus formed has about the same consistency and qualities as the resultant mass of the first process above mentioned.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 150 *Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers*

VOL. X. NEW YORK, NOVEMBER 12, 1890. No. 132

If an invention at once takes a place in the arts as a practical thing, or if it so clearly embodies a great step forward that the inventor or others are incited to develop it to a practical or pecuniarily profitable application, it constitutes a progress, and the purpose of the law is satisfied.—J. J. Storrow.

THE ECONOMY OF THE ELECTRO-DEPOSITION OF COPPER.

THE high economy called for in the many devices requiring the employment of copper, whether in the form of wire, of rods or of bars, has, during the last decade, served to bring the electrolytic refining of copper into considerable prominence. As a result, a number of works have gone into operation both in this country and abroad in which many tons of refined copper are deposited daily from copper matte, the residue remaining in the tanks being generally re-smelted to obtain the gold and silver contained in it. The continuance of this method of obtaining refined copper, as well as the presence of unmistakable signs that it is rapidly gaining in favor, would appear to be sufficient proof of its economy from a financial standpoint, and hence we are not surprised to note the formation abroad of various companies to exploit the new Elmore process of copper deposition, in which a dense and tough deposit is obtained by the action of a burnisher, maintained in continuous contact on the freshly deposited surface. We are, of course, not concerned in the slightest degree with the financial policy adopted by the exploiting company, but note that in a leading editorial, the London *Electrical Review* attacks with customary vigor and incisiveness a report made by Dr. John Hopkinson to the Elmore directors, and attempts, by certain calculations, to show that the actual cost of production of electrolytically refined copper is much understated.

While we do not doubt that Dr. Hopkinson is well qualified to sustain any statements made by him, it appears to us to be a duty to point out some errors into which our contemporary has fallen, and which, if allowed to go uncorrected, might be cited against the establishment of future works of this character.

Before we proceed, however, it might be well to point out the fact that our contemporary's errors are largely due to its close confinement to the text-books on the subject. However valuable these may be, and are, in other departments of applied electricity, their data on the electro-deposition of copper from copper matte is exceedingly meagre and indefinite, due no doubt to the secrecy with which these processes are still surrounded by their operators. Enough, however, is known in America, at least, to set at rights the obvious miscalculations referred to.

Unmindful of the fact that operations of this nature are carried on continuously night and day, our contemporary takes the figure of Rayleigh and Roscoe, that 1 ampere deposits .0050478 grain of copper in one second, and figures out that to deposit, say, 20 tons in *one week of* 60 *working hours,* would require a current of

$$\frac{20 \times 7000 \times 2240}{.0050478 \times 60 \times 60 \times 60} = 287,620 \text{ amperes.}$$

It goes without saying that by working the plant, as is done in regular practice in America, 24 hours per day instead of 10 hours, as assumed by our contemporary, a proportional reduction to nearly $\frac{2}{5}$ of the above figure will give the same deposit of copper, with a corresponding reduction in the number of generators, vats, etc., required.

Then taking John T. Sprague's figure of 18 amperes per square foot of surface, our contemporary figures the size of plates required to be

$$\frac{287,620}{18} = 15,976 \text{ sq. ft.} = 127 \text{ ft.} \times 127 \text{ ft.}$$

The fact has evidently escaped our contemporary that *both sides* of the depositing plates are employed in practice, so that the 15,976 sq. ft. of plates would be divided by 2 with a corresponding saving.

Our contemporary then goes on to calculate, or rather speculate on, the number and size of the tanks required to deposit 20 tons of copper, on the assumption, first, that working tanks in series confers no benefits whatever, and, secondly, that each vat requires 1 volt to accomplish deposition.

As regards the benefits of working in series, it may be remarked that, theoretically, any amount of metal can be deposited with a given power, disregarding the counter E. M. F. of the depositing vats, which is usually small in a properly arranged plant of this nature. But the limiting quantities are evidently, on the one hand, the cost of power, and on the other, the cost of vats, copper under treatment, buildings, etc. With relatively high cost of power the number of vats may be advantageously increased, and it may be stated generally that to obtain an increased deposition with a given power, the number of vats must be increased in the square of the desired ratio of increase. The question here is, therefore, merely one of determining the limiting point of relative economy.

But the assumption that it requires 1 volt per vat to obtain deposition involves a most serious error, when we con-

sider that the results of actual practice demonstrate that .5 volt, and less, is ample to afford deposition. Based on the assumption of 1 volt, our contemporary figures that it requires .5 h. p. hour to deposit 1 pound of copper. Still assuming the necessity of employing one depositing tank, it remarks, that "if the working E. M. F. were less than 1 volt, then the cost would be proportionally less, but this, on the other hand, would involve a great increase in the size of the depositing tanks to enable the required current to pass." The fallacy of this argument, in the light of what has just been said, is obvious.

But perhaps the best proof of the errors into which our contemporary has fallen is to be found in its own citations of the results accomplished at one or two refining works of this nature. Thus it mentions the case of the North German Works, in which 1 pound of pure copper is obtained with an actual consumption of .4 h. p. hour against the .5 h. p. hour, theoretical. But the figure cited is by no means the best which can be obtained, and we know, "of our own knowledge," of actual cases where 1 pound of refined copper is being deposited with a consumption of .33 h. p. hour, delivered from the engine pulley.

As the industry of copper refining by electrolysis, already well established in this country, is likely to be considerably extended in the near future, it has not seemed out of place to controvert statements, which, in view of our contemporary's well recognized standing as an authority, are apt to mislead, with serious results.

INCREASING THE LIFE OF CARBONS.

ALTHOUGH comparatively little has found its way into print on the manufacture of carbons for arc light purposes, it may be stated as a fact that this vital part of the lamp has been the subject of as much study and research as any other portion of arc lighting taken as a system. It was recognized from the very first that the expense due to the consumption of carbons, including the trimming of lamps, was a large item in the cost of maintenance of arc light stations, and that the prolongation of the life of a carbon was a matter of considerable importance. The early attempts to increase the brilliancy of the arc by an admixture of various mineral earths, was therefore soon abandoned, being found detrimental to the life of the carbon. It was soon recognized—and has since been verified by actual practice—that independent of the process, the purest and most homogeneous carbon has the longest life. Still, the ever-restless mind of the inventor has continued to seek improvement, and as such the device due to Mr. W. B. Hazeltine Jr., referred to on another page, is worthy of the most serious consideration by all users of arc light lamps. The well-substantiated claims made by the inventor leave no doubt in our minds that a distinct advance has been made in the art, and one which cannot fail to have a corresponding influence for good upon its progress, affecting as it does, not only the producer, but the consumer as well. A short time ago we illustrated and described the Saunderson arc lamp "wick," in which a cavity in the carbon is provided with a small reservoir of oil. It would be interesting to know what has become of that device for increasing brilliancy. In the meantime, the Hazeltine device may be welcomed as a very practical means of increasing the longevity of the carbon, and of diminishing the cost of attendance.

ELECTRO-OPTICAL MEASURING INSTRUMENTS.

THE frequent corrections which are necessary to obtain standard readings from electric measuring instruments embodying permanent magnets or dependent upon the action of the earth's magnetism, make it an object of importance to seek some substitute which, having equal accuracy, shall at the same time be more constant in its indications. Such a method seems to be at hand in utilizing the phenomenon of the rotation of a beam of polarized light by the current. The application of this phenomenon for the purpose described, though hinted at, seems up to the present to have received no serious consideration, and hence the contribution of Mr. A. E. Kennelly on this subject, to our columns, will serve to draw attention to a subject which is well worthy of consideration. In the application of the phenomenon to the construction of optical ammeters and voltmeters, Mr. Kennelly shows the various factors which enter, and the limitations to which such an instrument is subject. While Mr. Kennelly does not claim for this type of instrument a place among practical every-day apparatus, the results obtained by him seem certainly to justify the claim that it possesses distinct advantages for laboratory use as a standard, not only on account of constancy, but because of its ease of manipulation. We hope that some of our instrument manufacturers may take up this subject in a practical way.

Defects in Ship Wiring.

ANOTHER instance of poor wiring, or faulty insulation, on shipboard, is reported in the daily papers this week, and the fact that the fire was only a little one, promptly extinguished, does not render the case less grave. Such "accidents" ought not to happen. As both the steamers recently concerned were wired in England, we cannot speak positively as to the wire used or its quality, but it is evident that either the wire or the construction work was bad. Perhaps neither was as good as it should be. In view of the special conditions of exposure at sea, these wires should be of the best quality, and they should certainly be run through the waterproof and fireproof "conduits" now a standard commodity for purposes of safety. In matters of this kind the traveling public has the right to expect that resort will be made to every measure and means of protection known in electric lighting. And the rules to be observed are not in any sense exacting.

Insulated Wires and Cables.

ONE of the most interesting articles in this issue is that which describes and illustrates many of the processes devised and employed by the late Mr. A. G. Day, in the manufacture of insulated wires and cables. We are glad thus to pay a tribute to the memory of one who did so much in this country to develop and perfect the difficult art of insulation, upon which to-day in fact the whole electrical industry depends. The pithy paper read by Mr. Fred Degenhardt, before the Chicago Electric Club, shows how vital to efficiency and success good insulation is.

ON THE BEST DIMENSIONS FOR STANDARD OPTICAL AMMETERS AND VOLTMETERS.—I.

BY A. E. KENNELLY.

ATTENTION has recently been called to the application of the optical galvanometer to the measurement of current strengths, utilizing the electro-optical laws of Faraday, Becquerel, Wiedemann, and Verdet.

The advantage possessed by the method is its almost complete freedom from local magnetic disturbances to which galvanometers as a class are subject, and also its capability of rendering current strengths in absolute measure from purely geometrical data, having given a good rotatory polarization apparatus of the saccharimeter type, and a pure chemical medium for the light to traverse, with a reliable electro-optic constant. Such an instrument is unfitted for practical indicators of current or E. M. F. in engineering practice, and can at present be only used advantageously for standard measurements. In these, however, it possesses a very fair degree of accuracy, and a convenience in manipulation second only to that afforded in the use of the gravitational measurers of Sir Wm. Thomson. It is proposed to discuss the conditions that lead to the best construction of the instrument as these apparently have not yet been published.

The liquid medium generally adopted is bisulphide of carbon, which can be obtained in the requisite degree of purity without difficulty, which possesses a high, though by no means the highest, specific rotary power among liquids, and which has probably received the most careful determination of that power under the title of the "Verdet Constant."

It will be advisable to examine mathematically the best conditions for securing the greatest amplitude of rotation for any given current, and the limitations to which that amplitude is subject. The practical formulas for determining the best winding for the various classes of instruments will then directly follow.

Let c be the current flowing through the helix; (amperes).
" e " E. M. F. acting on the helix, or the p. d. between its terminals, assumed steady; (volts).
" r " resistance of the helix; (ohms).
" l " length of the helix; (centimetres).
" a " internal radius of the helix; (centimetres).
" b " external radius of the helix; (centimetres).
" m " mass of the helix; (grammes).
" n " number of turns in the helix per centimetre of its length.
" N " total number of turns in the helix or $l\,n$.
" σ " specific gravity of the conductor in the helix.
" d " diameter of the conductor; (centimetres).
" D " diameter of the covered wire.
" v " magnetic potential difference between the ends of the helix axis of the liquid column, in absolute measure.
" φ " "Verdet Constant," or the rotation in the medium of a plane polarized series of luminous vibrations with given frequency, for unit electro-magnetic p. d., expressed in minutes of arc.
" θ " observed angle of rotation; (minutes).
" ρ " resistivity of the conductor at working temperature; (ohms per cubic centimetre).
" h " heat developed by the current in the helix per sq. cm. of its external surface per second; (watts).

Then the fundamental electro-optic law is :—

$$\theta = v\,\varphi. \qquad (1)$$

To a first approximation, very nearly accurate for a long thin helix,

$$v = \frac{4\,\pi}{10}\,c\,N = \frac{4\,\pi\,e\,n\,l}{10\,r}. \qquad (2)$$

The correction for the reduction in magneto-motive force due to the influence of the free solenoidal poles is a simple one. It can be deferred for the moment if it is remarked that in virtue of this correction, the actual length l of the helix becomes a virtual length L where $L = l - \lambda$ and consequently equation (1) becomes strictly

$$\theta = \frac{4\,\pi\,n\,e\,\varphi\,L}{10\,r}. \qquad (3)$$

In what follows, the uncorrected length l only will be considered, since the correction is usually small, and can always be separately introduced.

Developing N and r of (2) in terms of the dimensions of the solenoid,

$$N = \frac{l\,(b-a)}{D^2}; \qquad (4)$$

$$r = \frac{4\,\rho\,l\,(b^2-a^2)}{D^2\,d^2}. \qquad (5)$$

This is on the assumption, realizable with care in practice, that the wire is uniformly and accurately wound on the solenoid without paper or other insulating material between the layers or turns. This assumption is involved in all that follows. Substituting in (1) and (2),

$$\theta = \frac{\pi\,e\,\varphi\,d^2}{10\,\rho\,(b+a)}. \qquad (6)$$

This shows that the amplitude of rotation obtainable from a helix for a given potential difference between its terminals, that is, when used as a voltmeter, does not in the first instance depend upon the length of the helix, but varies directly as the sectional area of the wire, and inversely as the mean radius of the winding. This means, that for a given winding space, the amplitude would increase indefinitely with the sectional area of the wire used in winding the instrument.

Practically, however, the limit is reached owing to the strength of the current in the helix, and the heat that current would generate during the measurement. This heat not only alters r, and affects to a certain extent the specific rotary power φ, but also interferes with the working of the apparatus by setting up differences of density in the liquid column, thus refracting, scattering and obscuring the beam of light. A jacket of insulating and circulating water if inserted between the tube and helix, would certainly act as a shield, but would by no means add to the convenience of the instrument, while it would tend to reduce its effectiveness in another direction by increasing the radius of the helix. In any case the variation in r due to any considerable rise of temperature would interfere greatly with the use of the apparatus for standard measurements. It therefore becomes necessary to so limit d that the heat generated may escape from the surface of the helix without materially raising its temperature or that h may not exceed a certain limiting value.

This value is strictly speaking a function of a and b; but for practical purposes, we may fairly consider the limit to be $h = 0.02$ watt per sq. cm. for intermittent and measuring currents, and $h = 0.01$ for a helix that has to remain in circuit and sustain a permanent current.

Expressing d in terms of h and the general dimensions,

$$d^2\,D^2 = \frac{8\,h\,b\,\pi\,l^2\,\rho\,(b^2-a^2)}{e^2}; \qquad (7)$$

and

$$b = a\sqrt{1 + \frac{4\,m}{\pi\,q}\left(\frac{D}{d}\right)^2} \qquad (8)$$

where $q = \pi\,a^2\,\sigma\,l$, or the mass of the space within the helix if converted into copper.

Hence

$$d^2 = \frac{\sqrt{l}}{e}\sqrt{\frac{32\,h\,\rho\,m\,b}{\pi\,\sigma}}; \qquad (9)$$

and $$\theta = \frac{4\pi\varphi}{10}\sqrt{\frac{lm}{\sigma}} \times \sqrt{\frac{2h}{\pi\rho\sigma}} \times \frac{b}{a+b} \qquad (10)$$

The last equation shows that when the current in the helix reaches the heat limit, the rotation obtainable is independent of the E. M. F., varies approximately as the square root of the mass of copper in the winding, and also as the square root of the dimensional ratio $\frac{l}{a}$. In other words, the same amplitude should be obtainable from all well designed instruments whether ammeters or voltmeters, and it is almost useless with a given weight of wire to increase the length of helix, notwithstanding the greater surface obtained, if the internal diameter be increased in the same proportion.

Taking $\sigma = 8.95$, $\rho = 1.8 \times 10^{-4}$ as values for copper:

$$\theta = 250\,\varphi\sqrt{\frac{l\,m\,h}{a}} \times \frac{b}{a+b}. \qquad (11)$$

For the D line of the sodium flame φ is given by Lord Rayleigh and Koepsel at 18° C., as 4.20×10^{-2}, so that

$$\theta = 1050.\sqrt{\frac{l\,m\,h}{a}} \times \frac{b}{a+b}. \qquad (12)$$

For intermittent currents and $h = 0.02$,

$$\theta = 1.485\sqrt{\frac{lm}{a}} \times \frac{b}{a+b}. \qquad (13)$$

For permanent currents, and $h = 0.01$,

$$\theta = 1.050\sqrt{\frac{lm}{a}} \times \frac{b}{a+b}. \qquad (14)$$

It is difficult to make l more than one metre, if only from the absorption of light in so long a column; it is also difficult to make the internal diameter of the helix less than 1 cm.; hence the practical limit of $\sqrt{\frac{l}{a}}$ may be estimated at 10. Again, a fair maximum for m would be 10,000 grammes, or 22 pounds of copper, and with the superior limit of the fraction $\frac{b}{a+b}$, namely, unity, we have for intermittent currents $\theta_{max} = 1485'$, or 24° 45′,
and for permanent currents $\theta_{max} = 1050'$, or 17° 30′.

These are then the approximate maximum amplitudes that can be practically obtained with any instrument of the class, although theoretically, there is no definite limit, as shown by equation (12).

It might be possible to double the amplitude of rotation by arranging a mirror at one end of the tube and causing the light to traverse the length of the liquid column twice in succession, but this is not only inconvenient, but probably needs an increase of illumination and of internal radius.

It is also to be regretted that no simple and definite standard of illumination can yet be adopted with a higher frequency than the sodium flame. Thus a monochromatic flame radiating violet light of the wave length G would more than double the amplitude of rotation. The effect might also be greatly increased by surrounding the tube with a bundle of annealed iron wires, but troubles would follow from residual magnetism, while the instrument would cease to give results directly in absolute measure from the indeterminate rate of change in the permeability of the iron.

Assuming the above then to be the practical limits of amplitude with instruments operating at their maximum capacity, the degree of accuracy obtainable depends only upon the degree of precision with which the amplitude can be measured. With a good polarimeter, and particularly with a repeating circle to eliminate errors of eccentricity, the limit of precision on steady currents should certainly not exceed 2′ of arc, and in fact when repeated measurements can be made, a mean rotation can always be found whose probable error is less than 1′; so that the degree of precision at full capacity attainable is certainly 1 part in 750, and probably 1 part in 1,500 with care and under the most favorable circumstances.

The best windings for such instruments may next be considered, and first for voltmeters.

Voltmeters.—Suppose the length of the helix given, the internal radius a, and the total mass of wire m to be wound, the maximum voltage to be measured being also given. It is to be remarked that the degree of precision in the observations with any instrument diminish as the current measured descends below the maximum current, so that they work best at full load.

The diameter of the wire to be used can be found from equation (9). In solving it a trial value can be given by estimation to the fraction $\left(\frac{D}{d}\right)^2$, and if this value should be found inaccurate by the result, the formula should be used again with the adjusted value. As an example, let it be required to determine the best winding for a voltmeter to operate at a maximum limit of 130 volts, the length of the helix being 62 cms. between flanges, and its radius 1.1 cm., allowing 10 pounds of wire in the helix, and a heat limit of 0.02 (intermittent currents).

Assuming $\left(\frac{D}{d}\right)^2 = 1.2$, formula (8) gives

$$b = 1.1\sqrt{1 + \frac{4 \times 10 \times 453.6 \times 1.2}{3.142 \times 3.142 \times 62 \times 1.21 \times 8.95}} = 2.277$$

Then by (9) $d^2 = \frac{\sqrt{62}}{130} \times$

$$\sqrt{\frac{32 \times 0.02 \times 1.8 \times 10^{-4} \times 4536 \times 2.277}{3.142 \times 8.95}} = 12.46 \times 10^{-4};$$

or, $\qquad d = 3.53 \times 10^{-2} = 0.0139''$.

When covered, this wire would have, say, a diameter of $0.017''$, so that $\left(\frac{D}{d}\right)^2$ would be 1.474. Repeating the reckoning with this value in place of 1.2, b becomes 2.468, and $d = 0.0142''$, in this case practically the same result.

The amplitude to be expected from the instrument at 130 volts would be, by (13),

$$= 1.485\sqrt{\frac{62 \times 4536}{1.1}} \times \frac{2.468}{2.468 + 1.1} = 519', \text{ or } 8° 39'$$

±, subject to correction for polar influence.

ELECTRICAL FOG SIGNAL.

Experiments with the Andrews electrical fog signa have recently taken place at Bowes Park, on the Great Northern Railway, in the presen e of a large number of railway engineers and directors. In this system an insulated rail is laid down parallel with the ordinary rails; and the current is conveyed to the engine by means of a metallic brush affixed to the footboard. There is an illuminated dial fixed on the weather-board of the engine, with a miniature signal and a gong to direct the attention of the driver to the sign given on the engine. In the signal-box are other miniature signals showing the signalman that the driver has received correctly the signal. The signal may be brought into action by the signalman immediately upon a fog coming on, simply by moving a switch.

UNDERGROUND ELECTRICAL WORK.[1]

BY FRED DEGENHARDT.

To Charles Augustin Coulomb no doubt belonged the honor of discovery of that most essential necessity of modern electricity, insulation. He it was, during the latter part of the last century, who developed the fact that the momentary dissipation of electricity was proportional to the degree of electrification at the time, and that when the charge was moderate, its dissipation was not altered in bodies of different kinds or shapes.

The temperature and pressure of the atmosphere did not produce any sensible change, but he concluded that the dissipation was nearly proportional to the cube of the quantity of moisture in the air.

In examining the dissipation which takes place along imperfectly insulating substances, he found that a thread of gum-lac was the most perfect of all insulators, as it insulated ten times as well as a dry silk thread, and that a silk thread covered with fine sealing-wax insulated as powerfully as gum-lac, when it had four times its length. He found that the dissipation of electricity along insulators was chiefly owing to adhering moisture, but in some measure also to a slight conducting power.

History, as far as the writer knows, is silent as to the first attempts at insulating wires commercially, for electrical purposes,

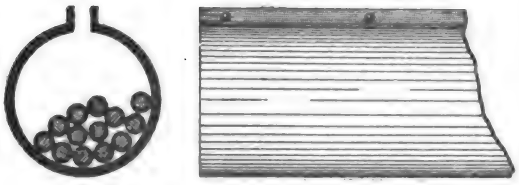

FIG. 1.

but as these remarks apply entirely to underground construction, we will refer only to the earlier efforts in that line, accepting at once the conclusion that wires had perforce been insulated. In 1829 Prof. Henry used insulated wire for experimental work.

It was during the year 1852 that Prof. Morse first conceived the idea of underground transmission of electricity, and among his earliest plans we have a suggestion of the conduits of to-day, and as these drawings are of historical importance, I have produced two views, as shown in Fig. 1, which will clearly illustrate the general similarity of ideas, covering a lapse of fifty-eight years.

Prof. Morse adopted the underground plan without experi-

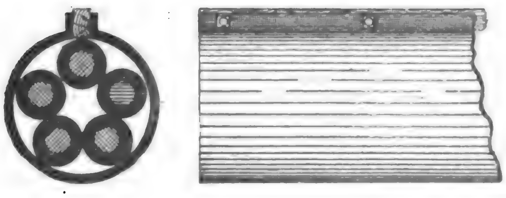

FIG. 2.

ment, not knowing the disastrous failures that had followed like attempts in England, and, strange as may seem, the very work in this line in this country, to-day carries with it the ear-marks of fifty years ago, and Morse's first cable was a bunch of five wires, lead encased. Prof. Morse's first cable was laid from Baltimore to the Relay House, seven miles distant, and the failure of this cable all but sealed the fate of underground electrical work; and while referring to these earlier experiments, I cannot refrain from a mention of the first attempts at overhead construction, simply that by comparison, we may show that at the present day, underground as well as overhead work has been perfected only after much cost and study. The first overhead insulation adopted on the line built by Prof. Morse, shows how rudimental were the conceptions of men at that period. The insulation consisted simply of two plates of glass, between which the wire, after wrapping well with cloth, saturated with gum shellac, was placed and over which a wooden cover to protect from rain and press the glass upon the wire, and keep it in place, was nailed. Fig. 3 will illustrate. (This was before the door-knob era.)

It is not necessary to further cite the history of experimental underground electrical conduction or construction. Enough that the problems involved came thick and fast, and the modern applications of electricity seemed for a time to have stamped the success of the underground branch of the business as an impossibility, but as each day proved the utility of the new agent, the fact also became apparent that we would soon be walled in by a network of wires, and at this period popular clamor arose, and Necessity once more became a fond mother, and her child, Invention, brought forth in turn a multitude of offspring, among which were some that had merit, and others which had none.

It is safe to say that underground work slumbered for a period of twenty years from the date of Prof. Morse's first experiments. When, in the city of Chicago, an objectionable pole line had been placed through a prominent residence portion of the city, the citizens of that particular section banded themselves together and selected a committee who waited upon Prof. Barrett, of the

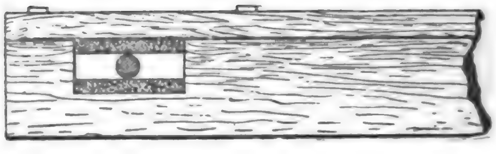

FIG. 3.

City Telegraph Department, of the City of Chicago, and stated their grievances.

The Professor told them that the line might be placed underground but that the city did not furnish the means for so placing it. After momentary deliberation, the gentlemen composing the committee volunteered to defray the expenses, and the poles were removed, and thus the first underground work was started in the city of Chicago. Eight hundred and forty feet of 2-inch wrought iron pipe was laid about three feet below the surface, the exterior of the pipe being first treated with a liberal amount of tar and linseed oil. In this pipe two insulated wires were placed. These wires are in service to-day, and are giving as good service as the day they were placed underground.

From this date on the underground question was agitated in the city of Chicago, and in the year 1883, the Common Council passed an ordinance requiring all electric conductors to be placed underground. In accordance with this ordinance, the various companies doing business in the city, after exhausting all means to evade it, adopted various systems for placing their wires under-

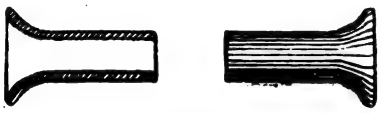

FIG. 4.

ground, and to-day the wires so placed underground embrace all branches of the service, viz., telegraph, telephone, police, fire-alarm, electric lighting and power. In 1883 a franchise was granted to the Sectional Electric Underground Co. to build underground conduits for commercial purposes. This company built about seven miles of conduit in the business district of the city, and rented space in the same, for $1,000 per mile per duct, per year, the city being allowed the use of one duct, free of charge.

The cables laid underground in the city of Chicago are placed in conduits of various kinds, viz., iron pipe laid in the earth without other protection; iron pipe laid in concrete; iron pipe, cement lined, laid in concrete and multitubular blocks of bituminous concrete about four feet long. Man-holes in many cases, are

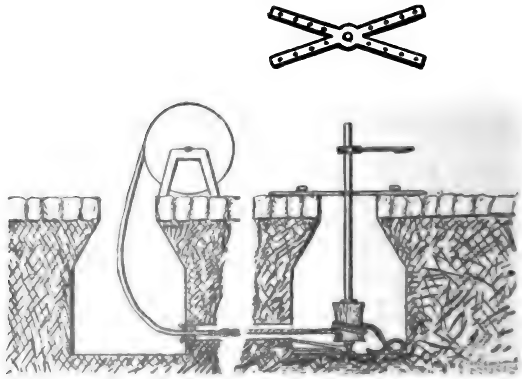

FIG. 5.

built circular in form, and in other cases, rectangular shaped, the latter averaging 46 inches in length by 40 inches in width, and are from four and one-half to nine feet deep, with double iron covers, one of which is set below the grade and made water-tight by packing, the other set on a level with the street.

The iron pipe used for conduit is thoroughly reamed at the

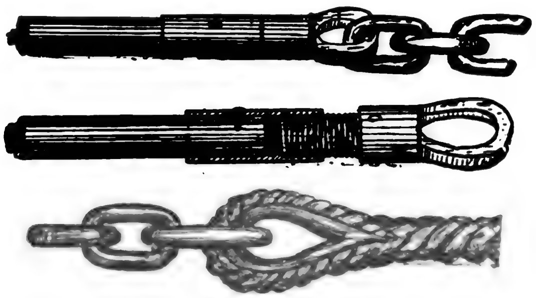
1. A paper read before the Chicago Electric Club, Nov. 3, 1890.

ends, thus removing the burr. Conduit is laid with a pitch or difference of grade from six inches to one foot, so as to draw into the man-holes, thus disposing of all drip from condensed moisture.

The usual specifications for underground conductors, for the purposes of arc lighting, may, perhaps, not be out of place, and I give them herewith: The insulation resistance should not be less than 500 megohms per mile, and the insulation should not materially deteriorate for the space of two years after being in service on an electric light circuit having a voltage of from 2,500 to 3,000 volts, and a current of from 9 to 12 amperes, or a voltage of from 900 to 1,200 volts, and a current of from 18 to 20 amperes.

The early method of preparing the trench for underground work, was to plough a furrow and place the conduit and the insulated wires in the trench thus made. To-day the tools and accessories are quite a feature of underground work, for after the conduits have been made and the ducts placed in most perfect alignment, so that no obstruction may be offered to the introduction of the cables, a competent corps of men take charge of the drawing in of the cables into the ducts, and I have prepared some sketches of the most essential tools, which I show in the drawings, Figs. 6, 7, 8, 9 and 10.

Moisture is to-day, as it has always been, the worst enemy of perfect underground construction, and therefore, in selecting men for the difficult work of making joints, it is well to secure those men who are possessed of that sovereign virtue, sobriety,



FIGS. 6, 7, 8.

and instill into their minds the fact that it is not how many joints they can make, but how well they can do them.

This class of men should be well paid and fostered, and I believe should be under the supervision of some one higher in authority than a mere boss line man. I am afraid that many, like Prof. Morse, tried the problem without experiment, and depleted pocket-books are silent reminders of that fact. But underground electrical construction is here to-day, and here to stay, and the success that now attends it is as signal as was its failure fifty years or more ago. Electrical currents of infinitesimal potential are no more easily conducted than are those electrical giants of four or five thousand volts. To-day the user of the cables for electric lighting simply tells the manufacturer of the potential, that he wishes to carry over his lines underground, and lo! the cable is forthcoming, and with it a guarantee. The telephone manager tells you that he must have a cable with an electro-static capacity that must not exceed a given number of microfarads, and that it

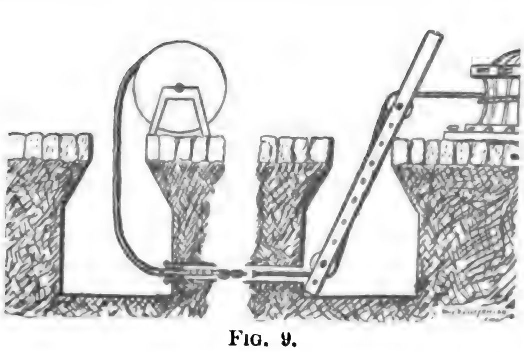


FIG. 9.

must contain so and so many conductors, and that its insulation must be so high and no higher, that all the conditions must be met within a given space, and the wires must be twisted in pairs, so that they can be formed into a metallic circuit if they wish, and your manufacturer goes at once to work and evolves a cable that meets these most exacting requirements. Thus on, through the whole list, transmission of power, telegraph, arc or incandescent lighting, it matters not, you simply make known your wants, aye, even whisper them, and twenty bright and active workers stand ready to take your orders, and deliver the results you desire.

Pardon my return to statistical information, but in the progressive city of Chicago alone, there is at present in successful daily operation the following enormous amount of underground electrical cables and wires, the telegraph companies alone using no less than 650 miles of wire. The Chicago Arc Light and Power Co. operate 140 miles of arc light cable and 30 miles of ducts. The city of Chicago 174 miles of arc light cables, 1,264,-430 feet of conductors, made into cables from 5 to 25 wires each, and 65 miles of single wires. The city has 20,441 feet of conduit

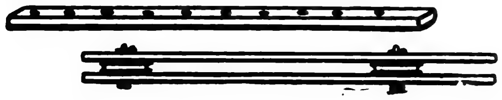

FIG. 10.

or about 100,000 feet of ducts otherwise than of iron pipe, and of the latter they have 478,087 feet used for conduits. The Chicago Telephone Co. have in operation at this date, 6,080 miles of wires, in the form of cables, or 32,102,400 feet of conductors. Their conduit system consists of 67,175 feet of main conduit, in which are 192,786 feet of duct. These conduits have a carrying capacity, when full, of 1,000,000 feet of cable, of 200 conductors. In addition to the above they have lateral conduits which measure 7,451 feet, and duct capacity in these laterals of 8,004 feet, and a cable capacity of a like amount. The Chicago Edison Company has 90 miles of conductors.

INSTITUTE DISCUSSION OF THE STANLEY ALTERNATING MACHINE.

The reading of the papers by Messrs Tobey and Walbridge and Mr. Thorburn Reid[1] on the new Stanley alternating arc machine was followed by an interesting discussion:

MR. WILLIAM STANLEY, JR., remarked that the papers referred to the regulation of a dynamo with which there is no external appliance to control the current. In applying an alternating potential to a circuit, there are two kinds of opposition to current flow. One kind is offered by the resistance of the circuit, determinate in the dimensions of the circuit, and the specific material of which it is composed, while the other is the opposition due to the shape of the circuit, that which we ordinarily call the self-induction of the circuit. Now the relation of these two oppositions to the flow of current is not exactly the same. The resistance of the circuit opposes the flow of the circuit at the instant the potential is applied. The counter-electromotive force of self-induction first delays the flow of current and then eggs it on, and the time that elapses between the application of a given potential to a circuit and the flow of current corresponding to any particular value of the potential is determinable by the ratio of the value of the self-induction to that of the resistance. Now, in the machine under discussion, we may consider that all that part of the circuit which is inside of the machine, viz., the armature coils, represents the self-induction part of the circuit. This portion, therefore, tends to delay the flow of the current for a while and afterwards to push it on. All that part of the circuit external to the machine may be considered to represent the resistance portion of the circuit. Now, it is evident we cannot change the number of turns of wire, or very well the number of revolutions of the machine when running; consequently we cannot change the value of the self-induction in circuit, and therefore the ratio of the self-induction to the resistance. The change of this ratio, by simply short-circuiting such arc lamps as we may wish to turn out, changes the time of the appearance of the current. It lets the armature of the machine get a little further ahead when one lamp is burning, when the maximum value of the current in the armature occurs; that is, it allows the armature pole to come up in front of the field pole, as shown in Fig. 10[2], and to oppose the field pole (the magnetization in the armature being directly opposite to that in the field), it keeps the lines of the field magnetism from passing through the armature. This effect is very beautifully shown by winding on the armature two circuits, one an arc circuit and another a few turns of wire connected with the voltmeter, both wound upon the same tooth. If the machine be short circuited, the magnetism is, as it were, blown out, and no potential is found upon the supplemental circuit. The whole regulation of the machine is due then to the fact that, as shown in Fig. 10, the time of the current flow has advanced, from the point AA of the horizontal line to the point near the numeral 5—13½. If we could put upon the field of the machine a separate circuit and as fast as we turned out the arc lamps that we wished to compensate for, put a current through that circuit, decreasing the field strength, we would obtain exactly the same results the machine attains by its own armature action.

MR. A. E. KENNELLY, in referring to the general idea embodied in Mr. Reid's paper, remarked that it was a method which is com-

1. THE ELECTRICAL ENGINEER, Nov. 5, 1890.
2. THE ELECTRICAL ENGINEER, p. 518, Nov. 5.

paratively new although not entirely so, of considering inductance in a dynamo not as a geometrical constant belonging to the wire or to the circuit, but as a function of magnetic resistance. Of course the two things were inseparably associated. The ordinary method, which is the shape method, which is supposed to be connected with the fact that an inductance is necessarily a length, is the original method. Any one who has tried to determine what the inductance of a coil is on theoretical grounds, or who has endeavored to follow the first formula given by Neumann for that determination which deals with an integral of little elements of length taken all around the circuit—each little part acting on every other part at a certain distance supposed to be measured or known and then multiplied by the cosine of the angle between those two elements—must feel that this treatment is exceedingly artificial and almost unnatural. He feels that although it yields a result which is correct, there is something there which suggests action at a distance, and not in a way in which nature herself must act. The other way, which deals with magnetic resistance, is a much more tangible one. It supposes a certain stress brought on the material, the resistance which that matter opposes to the magnetic force and the total effect of that resistance on the magnetic flux. The magnetic flux itself for unit current is then the inductance in the ordinary sense of the term. Consequently a method which will enable us to determine inductance from a simple conception of magnetic resistance must be immensely valuable, not only theoretically but also for the treatment of the most intricate problems which often present themselves for analysis. In continuous current machines, as Mr. Reid had pointed out, these reactions were few, comparatively simple, and more easily determined. In alternating current machines there are problems which baffle at present all the intelligence which can be brought upon them. Any means by which we can take a coil with any specified magnetizable environment and determine what the magnetic resistance of that circuit of environment will be, is most desirable; and he thought that any one who looks on this problem, however sadly he turns away from the fact that it is still a generally unsolved problem, must feel that there must be some means of attainment to this end, and of following out that plan by analysis.

MR. THOMAS D. LOCKWOOD referred to the fact that the very first machine employed for arc lighting, the "Alliance," was of the alternate current type and that likewise the first machine employed by Jablochkoff in his arc lighting system was of the alternating type.

MR. E. T. BIRDSALL inquired in what manner the efficiency was obtained from the curves of Messrs. Tobey and Walbridge's paper, and whether the efficiency takes into account the power used by the exciter?

MR. TOBEY, in reply, said that of the two values of E. M. F. and efficiency, the former were obtained first from the square root of the mean square; second, by taking the watt curve, the points of which were plotted from values obtained from the instantaneous values of current and E. M. F. These gave the instantaneous values of watts at different periods; then integrating the curve, they obtained the output in watts. In this manner, they obtained the value of the watts without determining either the E. M. F. or current. Dividing the watts by the current gave the second value of E. M. F. Of course the watts were the product of the E. M. F. and current, but were separated only as a matter of interest. The values of efficiency included the excitation. The method of getting these efficiencies was to divide the watts of electrical output by the sum of the watts by dynamometer, plus the watts of excitation.

MR. CHARLES STEINMETZ drew attention to the fact that while Mr. Reid assumed the magnetism of the field N to be constant, it was hardly ever so in practice, and in illustration of this referred to the variable nature of the exciting current as shown in the diagrams of Messrs. Tobey and Walbridge, there being fluctuations as great as 50 per cent. To complete the equations, there ought to be added to the term N, another factor, involving the amplitude of the variations of exciting current, and its angle of lag. He also thought that it would make a certain difference in the equations if the assumption of the constancy of magnetic resistance were abandoned, as not being quite true, and that here also another term ought to be added; but if this were done, the equations would become so complicated that it would hardly be possible to integrate them.

He saw the importance of this reasoning some time ago when testing a certain kind of alternator of about the same type as the new Thomson machine a short time before that machine was brought out. Here the induction was produced by changes of the magnetic resistance, and neither the armature coils nor the field coils were movable. By a calculation similar to the equations given, where he supposed the exciting current to be constant, and therefore the magnetomotive force of the field constant, also, he found an electromotive force of about 500 or 600 volts. But after experimenting with the machine, he obtained the very high voltage of 22 volts! (Laughter.) In this set of tests he used as an exciter the current derived from a storage battery of about 30 volts. Searching for the reason of this very curious phenomenon, and, suspecting the reaction upon the field current, he used an exciting current which was more likely to be constant, the current of a constant current dynamo, connected in series with a large storage battery and two transformers with open secondaries as choking coils, so that he was sure that very heavy self-induction and polarization straightened the wave of the exciting current. For exactly the same number of exciting turns and the same strength of current, and the same number of periods, the voltage of the dynamo rose to 160 volts. But this was still much lower than that calculated, so that this consideration seems to be rather important.

MR. THORBURN REID replied that he had gotten the equation (16) before it occurred to him that the field current would be variable; then, when he did think of it, he did not think it would be enough to amount to anything in changing the total magnetization. In regard to the change in the value of N, he saw that difficulty from the first. The saturation, of course, will change the value of N all the time. He concluded that the best plan would be to get an average value of N in different positions of the armature and for different values of the current. But as a theoretical matter to see how the machine regulates, he did not see how these two considerations would materially affect it.

MR. C. O. MAILLOUX remarked that the reactions of the magnetic field are constantly causing a succession of fluctuations, even in continuous current machines. If it is a shunt machine, that effect is only felt on the shunt circuit. If it is a series machine, it reacts over the whole circuit. Each time a section is commuted, or, in an alternating current, each time there is a reversal, there is a re-distribution of the magnetic field. Just previous to the time when the section is about to go out of circuit or is going to have its current reversed, there is a certain tension in the magnetism at, or about, the neutral line or at the space corresponding to the portion occupied by that coil that is ready to pass out; and at the very instant that the current is reversed in that section, there is a re-distribution. We have a certain relapse, so to speak, of the lines of force. Now this necessarily affects magnetic resistance since the path of the lines of force is altered in length. He had also had occasion to study this fluctuation in a more perceptible way, on a larger scale, in connection with the older form of machines formerly in use, with the old shuttle-wound armatures of the Siemens type. When they are used for producing continuous currents, we get, strictly speaking, not a continuous current, but a series of alternated impulses. We have really a large impulse in one direction followed by a smaller impulse in the opposite direction, in each case, so that the current is only relatively continuous in spite of the commutation. He had seen machines of that type, where, by putting another coil around the magnetic field an alternating current could be obtained which could be used for producing electric light, working transformers, etc., showing that in this case the oscillations or the wavy action taking place in consequence of the reactions of the armature on the magnetic field, were sufficient to determine a motion of a magnitude adequate to produce the induction of a current in a suitable circuit. In this connection he wished to invite those who study these matters from the mathematical standpoint to consider in connection with their treatment the fact that the elasticity of the lines of force themselves is a reactionary factor of importance in the phenomena taking place while currents are being induced by the cutting of lines of force. In expressing inductance we have to introduce the notion of velocity since the E. M. F. due to self-induction varies with the rate at which lines of magnetic force are cut. Now the notion of velocity must involve the consideration of the fact that the lines of force themselves are not passive during the operation of being cut; that they may yield one way; that there is a certain tension produced by the reaction of the current which would make them give way, as Mr. Stanley has so well said. Now in that case the velocity would evidently be affected and the rate of cutting would be reduced; while in the rebound they would fall back, and thereby increase the relative velocity or rate of cutting.

DR. M. I. PUPIN drew attention to the peculiar form of the curve which expresses the electromotive force; when arc lamps are introduced in the circuit it is evident that the form of the curve is entirely different from the form which obtained when there are incandescent lamps in it. Mr. Tobey had suggested that it was probably due to the change of resistance brought about by the cold air which is cooling off the carbon points, and the experiment which he devised to test this, seemed to prove his suggestion. But there was another way of looking upon this matter and that was this: We know that the current is conveyed between the carbon points by means of luminous carbon particles. The resistance between the two carbon points depends on the amount of this luminous carbon particles which pass between the points. Now, the amount of these luminous carbon particles depends on the strength of the current, just as in electrolysis the amount of an element deposited depends on the electric current. Therefore the resistance will change with the current. When the current is zero the resistance will have a maximum; and vice versa. In addition to that, we have, of course, changes due to the change in the temperature of the carbon point. Now, Messrs. Tobey and Walbridge introduced the flame of an alcohol lamp between the two points and observed that the sharp corners in the curve were modified, rounded off. But the flame is, comparatively speaking,

a very good conductor of electricity, so that by putting a flame between the two carbon points, in order to prevent, as they intended, cold air from rushing in, they had introduced a good conductor there and had prevented those large variations in resistance and had thereby prevented sudden changes in the electromotive force.

He did not agree with Mr. Kennelly's suggestion that it was desirable to introduce magnetic resistance in the definition of self-induction, so that we would have something tangible, whereas the definition of self-induction as given by Neumann was a mathematical one and intangible. His reason for this was that Neumann's integral for the coefficient of self-induction represents a certain physical quantity which can be measured. It refers to the electro-magnetic energy of the field, and energy is the best conception to have. He did not know what the magnetic resistance was. He could not imagine anything that could represent magnetic resistance, unless to establish first the relation between this quantity and the electro-magnetic energy. The integral of Neumann represents a certain amount of energy which we can measure in a great many ways. Referring to Mr. Steinmetz's remark that if we introduced N as variable we would obtain a differential equation which is not integrable, he did not agree with him in this particular case, for the simple reason that N would be a quantity which varied in a certain way and has two points of discontinuity during one revolution. It was a periodic function, having the same period as the machine, and every function of that sort can be represented by a series of sines and cosines. Besides, the curves obtained were practically sine curves; therefore, we have every reason to infer that the magnetic resistance will be a simple harmonic function, and that this is equal to a constant plus a sine function.

Dr. Cary T. Hutchinson did not see how Mr. Reid's equations differed from the ordinary well known forms based on the assumption of a sine curve variation and constant magnetic permeability. In their paper, the authors had given several diagrams of magnetic circuits, and based certain explanations upon those diagrams; in Figs. 4 and 5 the lines of induction pass through the armature and back entirely by air. Where was the return part of the circuit? It certainly was not completed through the air, as shown. Referring to the definition of the coefficient of self-induction, was not one of the simplest definitions: The number of lines of induction enclosed by the circuit? This, of course, included the case both of air and iron, and took into account very plainly the reluctance. Again, he did not see how the reluctance of the circuit could be a simple sine function, for the reason that the air gap formed the largest part and was constant.

Dr. Pupin replied that he did not say that it was the same sine function. He said magnetic resistance was a simple harmonic function. Of course, magnetic resistance was connected with self-induction, but it did not follow at all that the coefficient of self-induction will be a single sine function.

Dr. Hutchinson drew attention to the fact that Dr. Louis Dundan, of Johns Hopkins University, and two associates, had made some experiments of this kind nearly three years ago; the curves shown might almost be taken as tracings from some of theirs, and the description of the method and apparatus used in obtaining them applied almost verbally to their method and apparatus. This was the more remarkable, as neither in this paper, nor in Prof. Ryan's read before the Institute some time ago, and which was even closer to Dr. Duncan's than this one is, as both dealt with transformers, was there the slightest reference to their work. Their experiments were made on a Siemens dynamo using both open and closed circuit transformers. Nor did they find any difficulty in the direct use of a Thomson quadrant electrometer.

AN ELECTRICAL COMMISSION FOR WASHINGTON.

The President of the United States has appointed Lieutenant Francis R. Shunk, corps of engineers; Professor Henry A. Rowland, of Johns Hopkins University, and Andrew Rosewater, of Omaha, Neb., a board "to consider the location, arrangement and operation of electric wires in the District of Columbia, whether used for electric lighting, transmission of power, telegraphy, telephony or signaling, with a view to procuring as soon as practicable the construction of a safe and convenient system of conduits or subways, and the placing therein of all necessary electric wires along the streets, avenues and other public places and the removal of all unused overhead wires and their supports," as provided for in the District of Columbia appropriation bill of 1890.

The "Chicago Journal of Commerce," which has long been published as a blanket sheet, has now changed its form and appears in a "make-up" very similar to that of The Electrical Engineer, adding also a handsome cover. The change is decidedly one for the better in every respect, and serves to bring out the many excellent qualities of the journal in higher relief. We trust the Journal may enjoy great prosperity as a quarto.

EUROPEAN CORRESPONDENCE.

LONDON.

Newspaper Office Lighting.—An Explosion.—Underground Mains.—Dynamo and Engine Efficiency.—Lighting of Monte Carlo.—New Fog Signal.

An electric light installation for the new offices of the *Bolton Evening News* has been completed by Messrs. Ernest Scott & Co. It claims to be one of the most complete plants erected in newspaper offices; 300 16 c. p. lamps and one of 200 c. p. and 100 c. p., respectively, are supplied from two "Tyne" dynamos. Each machine is constructed to give an output of from 90 to 100 amperes at an E. M. F. of 105 volts, the speed being 900 revolutions. Gas engines are employed for the motive power. The switch-board is an enameled slate slab of 5 feet by 4, completing a handsome piece of work.

One of our leading daily papers takes account of an explosion which took place on board Earl Poulett's steam yacht while stationed at Portsmouth. On striking a light in one of the cabins to discover the source of a leak, a loud explosion took place. On the Earl and his engineer going on deck where the accumulators were kept for supplying light to the boat, it was found they had burst and were smashed to atoms. This, although a somewhat rare occurrence, has happened before; a similar accident took place not very long ago on the Barking Road tramway here, when the windows and light woodwork of the cars were broken. The former may be accounted for by the fact that although the accumulators were on deck they were provided with exceedingly small vent holes. Mr. Anthony Reckenzaun, having in mind this mishap, says that he experienced explosions with covered cells having vent holes, as early as 1882, and at different periods since. It is well known that if there is a sufficient supply of air or the cells are completely sealed or quite open at the top, there will be sufficient safeguards against mishaps of this description. Of course it is natural to suppose that overcharging of storage batteries must of necessity evolve hydrogen which, accumulated in a close atmosphere, will produce a most explosive compound.

We are likely to have some small quarrels here on the question of mains, between the Board of Trade and the vestries. On the former authority granting a provisional order to a company, it is naturally supposed that no further obstacles will be placed in the way. Vestries, however, do not thus look on the matter, and last week the secretary of the London Electric Supply Co. was summoned by the vestry of St. George, the Martyr, for cutting away a sewer for the purpose of laying mains. The matter was adjourned in order that the Board of Trade may take this as a test case.

Various tests have been published from time to time of the efficiency of Willans & Robinson's central valve engine combined with various dynamos. Last week a test was made with an engine combined with a large Edison-Hopkinson dynamo, made by Mather & Platt, and a result was obtained superior to anything previously reached, the figures being 86.7 per cent.

Monte Carlo will shortly be lighted by electricity, the central station being in course of erection. Two alternating current machines of the Zipernowsky type, A6, together with the necessary exciters and transformers are already set up, and a third machine will shortly be added.

A successful trial of a new fog signal has been carried out on the Great Northern Railway. It is the invention of Mr. Andrews, an electrician of Nottingham, and does away with the old fashioned and noisy fog signals. The principal features are an insulated rail laid down in parallel with the ordinary rail. The current is conveyed to the engine and signal box by means of a metallic brush affixed to the footboard. An illuminated dial is fixed on the weather-board of the engine, with a miniature signal and a gong to direct the attention of the driver to the sign given on the engine. The action is automatic and is not affected by the rate of speed of the train.

London, Oct. 28, 1890.

Town Lighting.—South London Railway.—City of London.—Electric Traction.—Progress in Vienna.—Edinburgh Exhibition.—Submarine Telephone Experiments.—Paris Telephone Service.—Bradford Electric Lighting.—Lighting in Coal Mines.—New Electrical Journal.—Mr. Lane-Fox's Patent.—The Old Students Association.

The corporation of Sunderland, after considering an exhaustive report on the electric lighting of the town furnished by the appointed committee, has decided to apply to the Board of Trade for a provisional order to enable it to supply electricity. It is estimated that 10,000 c. p. will be provided for. The towns of Southport, Exeter, and Whitby will be lighted from stations of the local authorities.

Something definite is at last to hand regarding the South London Railway, which, as I have mentioned previously, is the new electric railway running from London Bridge to Stockwell.

For months information has been vainly sought, but it seems that we are about to have our wish. The Prince of Wales is announced to formally open the railway next Tuesday, Nov. 4th, when everybody will have the opportunity of criticising the work which has been so jealously guarded.

The authorities controling that district in London known as the City, are advertising for tenders for the lighting of an area which includes all the principal publishing and newspaper offices. It is said this will be one of the most profitable parts, as the gas bills are enormous.

The North Metropolitan Tramway Company are anxious to place twelve electric cars upon their lines, but one of the vestries with its usual cry of "the infancy of electricity" has contrived to interpose many obstacles. The matter is to be referred to the County Council, and as this is a progressive body, I have little doubt as to the result.

There are not wanting many signs of progress in Vienna. A scheme has been submitted for a complete transformation of the tramway system, the major portion of the lines to be worked by electricity. It is also intended to construct an underground narrow gauge railway, which would cross the town in two directions, so that passengers would be able to journey from one side to the other in five minutes, a three minutes' service of trains being proposed.

The Electrical Exhibition of Edinburgh has been a financial failure. It is computed that the deficit will be about £30,000.

Heligoland has not long been in the possession of the Germans, but short as the time has been, it has enabled the Imperial Government to carry on interesting experiments of telephony in submarine cables which have been particularly satisfactory. Telephonic communication has been established between Heligoland and Cuxhaven, a distance of 46 miles.

The unsatisfactory telephone service in Paris is about to be improved. The government intends to centralize the wires in a large building which will be constructed in the very heart of the city.

A report recently issued by the Bradford Corporation considers the electric lighting in that town a great success. This is the only municipal body, with the exception of one, which has undertaken the responsibility of supplying electric light. The plant was laid down in September of last year. Since then there has been a constantly growing demand. To meet this, two more dynamos will shortly be placed in position.

Colliery owners here are very slow to utilize electricity, although when it is used it is a signal success. Last week, however, arrangements were begun by the Fife Coal Company for the introduction of the electric light into their pits at Leven, N. B., which will obviate the necessity of each miner carrying his own lamp. It is specially intended to light the roads of the mines, the lamps being placed about fifteen yards apart.

A new weekly electrical journal is to be published next month at one penny. The name of the new journal will be *Electricity*. It will be edited by Dr. Maier.

Mr. St. George Lane-Fox is trying to enforce his claim to "the employment of secondary batteries as reservoirs of electricity in combination with a mode or system of distribution such as is hereinbefore explained." This is the claim to his patent specification No. 3988 * * of 1878, and everybody using secondary batteries in combination with dynamos and lamps in parallel is threatened with legal proceedings, unless the user is prepared to pay him a royalty. The English technical press is taking the matter up, and it is believed that the claims put forward on behalf of Mr. Lane-Fox will be shown to be absurd. After all it was nothing but a method of connecting up existing apparatus which anybody would naturally try, and I scarcely think that this will be held as patentable. Anyway there seems every probability of lively times for the legal profession.

Mr. W. B. Esson, the newly appointed president of the Old Students Association of the City & Guilds of London Institute, and who is one of the greatest authorities on this side on dynamo electric machinery, will deliver a most elaborate address next week on "Industrialism." It is expected it will command great attention.

H. S.

LONDON, Oct. 29th, 1890.

AN ELECTRICAL CHAIR FOR INVALIDS.

An electrically propelled chair for invalids has been designed by J. V. Sherrin. The chair is of wicker work, weighs 200 pounds and is mounted on wheels of the tricycle type. The primary cells, eighteen in number, weighing 80 pounds, are suspended from the rear wheels. The motor, a modified two-pole Gramme machine, with laminated field magnets, has a uniform output of ¼ horse power. Properly charged, the battery is capable of propelling the chair over an ordinary road for nine hours at the rate of about six miles per hour. It is easily steered and stopped, and can be charged each time for about ten cents.

CORRESPONDENCE.

ST. LOUIS.

The Power Plant of the Union Depot Railroad.—The Mound City Electric Railway.—Removal of Electric Wires From the Streets.

THE 1000 h. p. addition to the power house of the Union Depot Railroad is rapidly approaching completion. One of the 500 h. p. Hamilton-Corliss engines is set up and in use, and the other one is being set up. The 14 additional 80 h. p. generators are on hand and being placed in position. Three of them are finished and in use. In the boiler house two additional Heine patent safety boilers, each of 250 h. p. capacity, have been set up, and a new brick smoke-stack, 162 feet in height, has been erected. Everything is expected to be finished and in readiness for supplying current to the Mound City Railroad by the middle of November.

A large machine shop for repairs and manufacture of everything pertaining to maintenance and operation of the road is being erected. The loop to Union Market via Broadway to Lucas avenue and returning on Sixth street to Pine street was finished and put into operation this week.

The Mound City Railway will have their overhead electrical equipment finished by the middle of November; 25 motor cars are being built for them by the St. Louis Car Co., a part of which are now finished and in use temporarily on the Union Depot road. The Mound City road will be supplied with current from the power house of the Union Depot Railroad, which is located over a mile away from their line, a separate system of feed wires being used for the purpose.

At a meeting of the Board of Public Improvements, last Tuesday, the committee on city lighting was instructed to prepare and report a plan for the removal of electric wires from the streets in the business district. This action of the Board was brought about by a complaint from the Chief of the Fire Department, that at a recent fire the working of the firemen was seriously interfered with by the breaking and crossing of a number of telephone and telegraph wires with electric light and power circuit wires of the street railways.

The Lindell Railway Co. have introduced a bill before the Municipal Assembly authorizing them to construct a branch line on Mississippi avenue, Park avenue and Vandeventer avenue to Tower Grove Park.

The Western Union Telegraph Co. have let contracts for the alteration and fitting up of the Lucas building for their new quarters.

ST. LOUIS, October 29th, 1890.

PITTSBURGH.

A Fitting Reward for Folly.—Electric Railway Work.

ROBERT WASHINGTON, a colored man, was instantly killed by a shock from an arc light circuit at the Edgar Thomson Steel Works, in Braddock, Pa., on the night of October 30th. The accident was the result of a foolish piece of bravado. Washington was known among the men at Carnegie's blast furnaces as a venturesome and foolhardy young man. He took a special delight in catching hold of electric wires, when the current was off, and he would laugh when somebody warned him that he might one day find himself holding on to a charged wire. That night, while standing in the Carnegie blast furnaces, young Washington said he was not afraid of electrocution, and reaching high over his head, he grasped the arc lamp above him. He fell instantly to the floor, and when he was picked up by the men who only a few minutes before had been laughing at his attempted joke, Washington was found dead. Across the palm of his right hand was a scar, burned deep in the flesh. It was the exact shape of that part of the lamp he had caught hold of and was blackened to a crisp.

The Wheeling Electric Railway Co. has purchased the electric poles, wires and the power generators of the Wheeling Electric Co. which were formerly only rented by the street railway people. It is also stated that these two concerns are now negotiating for a consolidation of interests.

The corner stone for the new power-house of the Pittsburgh, Allegheny and Manchester Electric Street Railway Co. has been laid. According to the contract of the company, the foundation is to be ready for the placing of the engines and motor generators by Feb. 15, 1891.

There have been a good many delays in the construction of the electric railway line of the Birmingham Traction Co., which have hitherto greatly handicapped the company from getting the road started. Among other things, the company had to build an addition to the Smithfield street bridge, in order to make that structure suitable for the traversing of the electric cars. However, all the difficulties seem to have been overcome now. The wires are about all strung and it is the company's intention to have the cars running the first week of December. While the power-house

and the machinery are not in shape yet, the company will use the power, for the operation of its cars from the Allegheny County Light Company.

An electric street railway company is now being organized by a number of capitalists from Braddock, McKeesport and Wilmerding, for the purpose of constructing an electric street railway between McKeesport and Wilmerding.

PITTSBURGH, Oct. 31, 1890.

BOSTON.

Britishers Visiting the Lynn Factories.—Arguing for the Elevated Road.

ANOTHER delegation of visitors, representing the Iron and Steel Institution of Great Britain, visited Boston and Lynn this week, and were the guests of the Thomson-Houston Electric Company, and the Thomson Electric Welding Company. The party, who came from Canada, were met at Lowell by Messrs. C. H. Richardson and Mr. F. R. Royce, and on their arrival in this city were taken under the protection of a reception committee, consisting of James M. Meech, H. N. Sweet, H. C. Spaulding, P. L. Saltonstall and C. B. Davis. After lunch, which was served at Young's hotel, the visitors were taken to Lynn, where they spent the afternoon in inspecting the factories of the Welding Company and the Electric Company, the greatest possible interest being taken in the various processes of electric welding.

The hearing on the extension of Harrison avenue for the elevated railroad was continued on Saturday last before the street commissioners. The Hon. William G. Russell presented the case for the West End Street Railway Company, and ably met all the arguments of the remonstrants. He clearly proved the necessity of an elevated railroad, discussed the merits of the route proposed, and warmly defended the plans of the West End Company.

CHICAGO.

The South Side Elevated Road.—Congressman Allan C. Durburrow.—Hyde Park Lighting.

THE Chicago and South Side Rapid Transit Co., who are building the alley elevated road, are pushing the work on their main line rapidly along and those at the head of the enterprise expect to have trains in operation by next spring. The stations now being built differ materially in their construction from those in use in New York. As the road runs in an alley instead of a street the stations will be on the ground instead of on a level with the elevated structure. The passengers after purchasing tickets will ascend by means of stairways to platforms beside the tracks. Sheltersheds of light construction will be erected over these platforms. The stations are of an attractive design and will be built of pressed brick, trimmed with granite and terra-cotta, and cost about $15,000 each. Tickets will not be taken on the train, as the passenger will be required to give up his ticket before ascending the stairs to the train. According to the company's plans trains can be run with safety one minute and a half apart, when for any reason traffic is unusually heavy. It is not unlikely that electricity will be used as the motive power and it is certainly to be hoped that this will be the case, as any additions to the present smoke nuisance would be unbearable, and this point is but one of the great advantages of electricity over steam for railway work.

Mr. Allan C. Durburrow, the well-known business manager of our contemporary, *The Western Electrician*, has been elected to Congress in the Third district, as a Democrat, by a majority of 2,593 votes. I heartily congratulate him upon his success and expect to see him win many further honors in the field of politics.

The Hyde Park Thomson-Houston Electric Light Co. are now very busy supplying incandescent lights in private residences. They are charging moderate prices, and this class of their lighting business is growing very rapidly. It is encouraging to note the way the electric incandescent lamp is forcing its rival gas even from private residences.

CHICAGO, Nov. 6th, 1890.

BROOKLYN INSTITUTE—BATTERY EXHIBITION BY THE ELECTRICAL DEPARTMENT.

The electrical department of the Brooklyn Institute, gave a very interesting exhibition of batteries Oct. 31. Every form, from the gravity, Grenet and the different types of Leclanché and dry cells to the Edison-Lalande accumulators, was represented.

Among those most attractive were the Electrical Accumulator Company's four small accumulators driving a fan with one of the Electro-Dynamic Company's small motors, and illuminating seven small incandescent lamps; and two cells of Law battery working an elaborate outfit of medical coils.

The New Haven Clock Company presented their exhibit of dry and carbon batteries, electric bells and telegraph sounders to the department.

REPORTS OF COMPANIES.

THE EDISON TOY MFG. CO.

The annual meeting of the Edison Toy Manufacturing Company was held at Portland, Me., on Oct. 30, 1890. Mr. Edison was represented by his secretary, Mr. Tate. This was the treasurer's exhibit Sept. 30:

LIABILITIES.

Capital stock	$1,000,000.00
Working capital	62,871.87
Total	$1,062,871.87

ASSETS.

Treasury stock	$160,000.00
Licenses and patents	846,894.84
Cash	2,978.08
Cost of dolls' parts and merchandise	35,384.23
Edgar S. Allen, general manager	69,025.00
European expense account	5,699.84
Thomas A. Edison	1,000.00
Office furniture	1,289.18
Total	$1,062,871.87

These officers were elected:—Directors, Benjamin F. Stevens, Daniel Weld, John W. Mackintosh, Winfield S. Hutchinson, Thomas A. Edison, George Borgfeldt, Oscar E. Madden; clerk, Clarence Hale; treasurer and secretary, Daniel Weld.

Mr. Edison is the only creditor of the company—for about $50,000 to $57,000. The company is capitalized for $600,000, in 60,000 $10 shares. It has 16,000 shares in the treasury, and has received about $600,000 in money for the remaining 84,000 shares.

ERIE TELEPHONE CO.

The Erie Telephone Company will pay a dividend of one per cent., November 17, to stockholders of record Nov. 8. The combined report of the Cleveland Telephone Company, the Northwestern Telephone Exchange and the Southwestern Telegraph and Telephone Company for the quarter ended Sept. 30, and the first half of the current fiscal year, is as follows:

QUARTER ENDED SEPT. 30.

	1890.	1889.		
Gross	$195,903	$178,526	Inc.	$17,377
*Expenses	140,082	119,911	Inc.	20,171
Net	$55,821	$58,615	Dec.	$2,794
Dividends	48,000	48,000	Inc.	....
Surplus	$7,821	$10,615	Dec.	$2,794

FIRST HALF FISCAL YEAR, APRIL 1, TO SEPT. 30.

	1890.	1889.		
Gross	$385,296	$355,614	Inc.	$29,682
*Expenses	271,632	238,583	Inc.	33,049
Net	$113,664	$117,031	Dec.	$3,367
Dividends	96,000	96,000		......
Surplus	$17,664	$21,031	Dec.	$3,367

*Includes construction and dividend on the Bell company's stock.

SUBSCRIBERS ADDED.

	1890.	1889.		
Quarter ended Sept. 30	276	138	Inc.	138
Total connected Oct. 1	12,938	11,702	Inc.	1,236

The Erie Company received $4,290 surplus from its sub-companies after paying its dividend, making the total surplus for the quarter $12,111.

GROWTH OF A MINNESOTA ELECTRIC PLANT.

The Superior Water, Light & Power Co., of Duluth, Minn., which has a capital stock of $1,000,000, has been obliged again to increase its capacity. It controls the gas plant, electric light and power plant, and the water works. Mr. John Mather, the general manager, writes us:—"On Nov. 1, 1889, our electric plant consisted of one 35 light Western Electric arc machine, and 4 Daft dynamos of 50 h. p. for incandescent lighting. We have to-day four 50 light Thomson-Houston arc machines, besides the above, and one 1500 light Westinghouse alternator, as well as two 80 h. p. Thomson-Houston generators with which we furnish current to the street railway, and 50 h. p. of stationary motors. Notwithstanding the great increase in our machinery, we have now again almost reached our full capacity, and have placed orders for another 1500 light alternator and another 80 h. p. generator, both of the Thomson-Houston make." The company has about 50 miles of circuit, of which about two-thirds is underwriter, the remainder being K. K. and Candee. The plant is run by a 400 h. p. compound condensing Buckeye engine, and two 125 h. p. Buckeyes, with Babcock & Wilcox boilers of corresponding capacity. The company, which is certainly to be congratulated upon its remarkable growth, has A. H. Wilder, as president; V. M. Watkins, vice-president; F. A. Ross, secretary, and J. Mather, general manager.

FINANCIAL MARKET.

QUOTATIONS ON ELECTRICAL STOCKS.

F. Z. Maguire & Co., Electrical Securities, of 18 Wall street, this city, report the following quotations of November 8th, from New York, Boston and Washington:

NEW YORK.

LEGAL NOTES.

CARLIN vs. WEST END RAILWAY, BOSTON.—INJURY TO PASSENGER.

An important suit was decided in the Superior Court, Judge Thompson, last month, in which one Carlin sought to recover $10,000 from the West End Street Railway Company, of Boston, for injuries received while attempting to board an electric car in Cambridge. The plaintiff testified that he signaled the car to stop at a point between the stations where it regularly stopped; that the car slowed up, but started ahead with a jerk just as he was about getting on board. At the conclusion of the plaintiff's testimony, Judge Thompson ordered the jury to find a verdict for the defendant. The ground taken by the court was that no one had a right to get on a car except when it had stopped at its regular stations, and that between stations the car was liable to start ahead with a jerk at any moment, the driver being justified in thinking that no one was getting off or on.

ELECTRICAL EXECUTION IN THE U. S. SUPREME COURT.

The Supreme Court of the United States has granted the motion to advance the case of Suibuga Jugigo, who is under sentence of death by means of electricity in New York State, and assigned the case for argument on the third Monday in November, after the cases already set down for hearing on that day.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

At a meeting of the Executive Committee held at the Electric Club, New York City, Nov. 7, the following business was transacted:—

The date for holding the Thirteenth Convention was fixed for February 17, 18, and 19, 1891.

Eugene F. Phillips, of Providence, was appointed chairman of a committee of five, on Reception and Arrangements, he to appoint the other members of the committee.

Gen. C. H. Barney, of New York, was appointed chairman of a committee of three on Electrical Exhibits and Transportation, he to appoint the other members of the committee.

The committee on Papers reported the following as promised, and stated that the prospects of securing two or three more important papers are most excellent. Announcements of these will be made later. The committee has not only secured the promise of these papers, but has gone a step further, and named a person to open the discussion on each paper. This must inevitably tend to bring out the best points of the topic and to greatly add to the interest in, and value of, the proceedings.

(*a*) How Can the National Electric Light Association Best Serve Central Station Interests? by C. R. Huntley. Discussion by A. M. Young.

(*b*) Distribution of Steam from a Central Station, by F. H. Prentiss. Discussion by George H. Babcock.

(*c*) Distribution and Care of Alternating Currents, by T. Carpenter Smith. Discussion by G. H. Blaxter.

(*d*) Municipal Control of Electric Railroads, by M. W. Mead. Discussion by M. J. Francisco.

(*e*) The Ferranti System, by C. B. Haskins. Discussion by C. L. Edgar.

The resignation of Mr. James English as a member of the Executive Committee was accepted, and Mr. Edward A. Leslie, manager of the Manhattan Electric Light Company, of New York City, was elected to fill the vacancy.

INVENTORS' RECORD.

Patents issued October 28, 1890.

Alarms and Signals:—*Railway-Truck Electrical Annunciator*, J. W. Lattig, 439,409. *Fire-Alarm or Fire and Heat Indicator*, C. W. Summerskill, 439,441. *Burglar-Alarm*, J. J. Griffith, 439,503.

Distrubution:—*Electric Lighting System*, T. A. Edison, 439,389. *Electric Lighting System*, T. A. Edison, 439,390. *Junction-Box for Electric Wires*, T. A. Edison, 439,391. *Electric Lighting System*, T. A. Edison, 439,392. *Automatic Regulator for Electric Currents*, W. Morrison, 439,417.

Dynamos and Motors:—*Electric Motor*, C. S. Bradley, 439,102. *Synchronous Alternating-Current Electric Motor*, C. Zipernowsky, M. Déri, and O. T. Bláthy, 430,459.

Electro Medical Apparatus:—*Electro Dental Heater*, L. A. Faught, 439,238.

Galvanic and Thermo-Electric Batteries:—*Dry Battery*, W. L. F. Hellesen, 439,151. *Porous Cup for Galvanic Batteries*, C. A. Hussey, 439,516.

Lamps and Appurtenances:—*Repairing Incandescent Electric Lamps*, C. Pauthonier, 439,178. *Electric-Lamp Socket*, J. O. Phillips, 439,304. *Electric-Lamp*, A. Swan, 439,363. *Incandescent Lamp Socket*, A. Swan, 439,364. *Incandescent Lamp Socket*, A. Swan, 439,365. *Incandescent Electric-Lamp Socket*, A. Swan, 439,366. *Incandescent Electric-Lamp Socket*, A. Swan, 439,367. *Adjustable Lamp-Standard*, O. Luetke, 439,411.

Measurement:—*Electric Meter*, W. H. Bristol, 439,381.

Miscellaneous:—*Electro-Magnetic Clutch*, C. H. Veeder, 439,213. *Electric Elevator*, F. B. Perkins, 439,180.

Railways and Appliances:—*Trolley-Arm Guide*, A. F. Bardwell, 439,092. *Power-Gearing for Cars in Train*, A. R. Cavner, 439,108. *Trolley-Pole*, L. Pfingst, 439,182. *Trolley-Pole for Electric Cars*, B. C. Rowell, F. E. Galloupe, 439,192. *Apparatus for Transferring Electric-Car Batteries*, F. G. Corning, 439,237. *Electric Railway*, L. Westerland, 439,262. *Automatic Wire-Finder for Trolley-Heads*, G. S. Slocum, 439,308. *Electric Locomotive*, F. W. Dean, 439,345. *Mechanism for Operating Street Car Switches*, W. A. Lee, 439,354. *Electric Railway*, C. Richter, 439,428. *Electric Motion-Transmitter*, M. W. Dewey, 439,577. *Electric Railway Motor Car*, E. Wagemann, 439,584. *Electric Railway Conduit*, R. M. Hunter, 439,597.

Storage Batteries:—*Method of and Apparatus for preparing Electrodes for Secondary Batteries*, C. D. P. Gibson, 439,240. *Secondary Electric Battery*, J. F. Mehren, 439,301. *Secondary Battery*, E. J. Mason, 439,334. *Making Storage Battery Plates*, W. Morrison and L. Schmidt, 439,416. *Secondary Battery*, W. B. Hollingshead, 439,594.

Telegraphs:—*Perforater for Automatic Telegraphing*, F. D. Mack, 439,164.

Telephones and Apparatus:—*Mechanical Telephone*, H. M. Chamblin, 439,475.

Patents issued Nov. 4, 1890.

Alarms and Signals:—*Street or Station Indicator*, L. Goldstone, 439,941. *Electrical Indicator*, L. O. Chatfield, 440,013. *Electrical Burglar-Alarm*, F. Pierce, 440,115.

Clocks:—*Electric Actuating Device for Pendulum Clocks*, J. H. Dyson, 439,838.

Conductors, Conduits and Insulators:—*Guide for Machines for Covering Wires*, J. McCahey, 439,675. *Insulating Composition*, T. D. Bottome, 439,796. *Insulator for Electric Conductors*, W. Kessler, 440,042.

Distribution:—*Methods of and Apparatus for Connecting Dynamos*, C. T. Childs, 439,979.

Dynamos and Motors:—*Electric Motor and Generator*, A. Gartner, 439,775. *Electrical Generator*, F. L. McGahan, 439,974. *Automatic Regulator for Dynamos and Motors*, F. J. Cleaver and G. Fassold, 440,016.

Galvanic and Thermo-Electric Batteries:—*Standard Galvanic Cell*, E. Weston, 439,737.

Lamps and Appurtenances:—*Electric-Arc Lamp*, H. C. Shubert, 439,904.

Miscellaneous:—*Electric Heater*, C. W. Drew and E. R. Francis, 439,724. *Electric Log*, W. P. Granville, 439,840. *Rheostat*, E. R. Gilbert, 439,939. *Magnetic Separator for Grain*, E. von Syo, 440,070. *Electric Heater*, C. H. Talmage, 440,071.

Railways and Appliances:—R. M. Hunter, 439,662. *Trolley-Line Switch for Overhead Electric Conductors*, W. L. R. Emmet, 439,746. *Electric Railway*, M. W. Dewey, 439,867. *Adjustable Trolley and Guard for Electric Wires*, L. S. Hoyt, 440,106.

Secondary Batteries:—*Secondary Battery Plate*, A. E. Woolf, 439,850. *Electrode for Secondary-Batteries*, J. B. Entz and W. A. Phillips, 440,023. *Method of Making Electrodes for Secondary Batteries*, J. B. Entz and W. A. Phillips, 440,024.

Telegraphs:—*Telegraph-Key*, W. A. J. Kohrn, 439,959.

Telephones and Apparatus:—*Holder for Telephone Receivers*, F. T. Tinning and W. K. S. Tinning, 440,091. *Telephone*, S. Bergmann, 440,096. *Automatic Toll System for Telephone Pay Stations*, H. C. Root, 440,118.

TRADE NOTES AND NOVELTIES

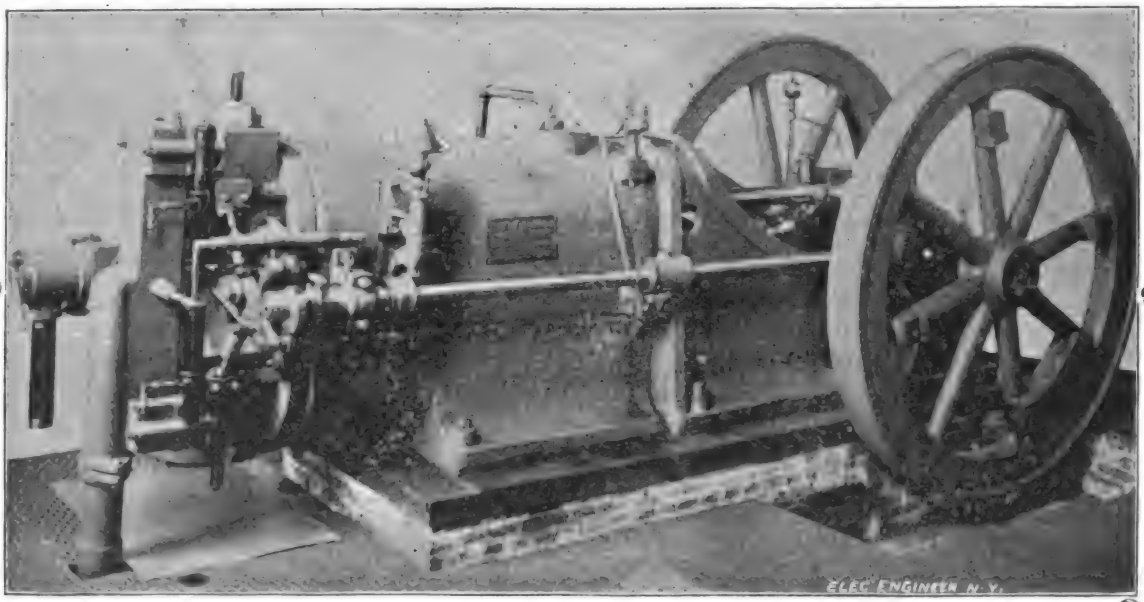
AND MECHANICAL DEPARTMENT

OTTO GAS ENGINES IN ELECTRIC LIGHTING.

It has long since been acknowledged, and proven over and over again by theoretical calculations, that no method of power production can reach as high an economy in the utilization of the heat units combined in the fuel as is obtained in the gas engine. This fact has spurred on the makers of gas engines to build larger sizes of engines every year and while the high prices for gas charged to the public restricts the size of engines used by it to those of less than 20 h. p., the gas companies themselves, consuming the gas as it is made on their own premises without charging it with the expenses of distribution, have had occasion to try practically the theories advanced for gas power; and as many of them operate electric light stations, it is in these that the gas engines were placed, varying in size from 50 to 100 h. p.

As it is the economy of the power in electric stations that makes the dividends, this departure with the gas companies, who are familiar with gas matters and would incline to the use of gas power more naturally than any other power users, was not only a happy one as far as they themselves were concerned, but it led others to make use of simple methods of gas production and utilize them in connection with gas engines.

At the Otto Gas Engine Works, in Philadelphia, we saw recently three engines of 100 h. p. each—for one order and intended to be used in conjunction with a producer gas system, which is to bring the coal consumption down to less than 1¼ pounds per horse-power per hour. This result has perhaps never before been arrived at, even by the best and most modern compound steam-engines. We understand that the English makers of gas engines have supplied gas producers in conjunction with engines to produce as high as 500 h. p., and that numerous power users requiring as low down as 30 h. p. find it economical to avail themselves of gas producers.



New 100 Horse Power Otto Gas Engine.

At the Philadelphia Otto Gas Engine Works a producer plant for 750 h. p. is now in course of erection for their own use as well as for experimental purposes and it will interest our readers to know that this method, as far as its use in this country is concerned, is used for electric light stations only.

Among the gas companies using gas power, we may mention the following:—Racine, Wis., Gas Light Co., 90 h. p., running 80 arc lights; Woonsocket, R. I., Gas Light Co., 100 h. p. arc and alternating incandescent; Oshkosh, Wis., Gas Co., 100 h. p., in course of erection; besides companies in Rockville, Conn., Grand Forks, N. D., Sioux City, Iowa, Atlantic City, N. J., Hamilton, O., and numerous other places. Quite a number of engines have been installed in isolated plants such as that of Potter Palmer, Chicago, C. F. Brush, Cleveland, Ed. Weston, Newark, N. J., the Electric Car Co., of America, Philadelphia, etc.

The Rockville Gas Co. has recently added to its 80 h. p., another engine, indicating a maximum of 120 h. p., which is illustrated in the accompanying engraving and which is the largest built up to the present time by any manufacturer, here or abroad. It is arranged with two cylinders, placed one above the other, and a gear shaft running near a centre line between the two gives motion to the various devices for admission of gas and air, ignition of same and exhausting of burnt gases. The ignition is effected by incandescent tubes, instead of by slides and flames.

At Rockville, the gas made is that known as water gas, made from anthracite coal and some oil is added to give illuminating power. Reducing the value of the oil to pounds of coal, taking into account their relative cost, and comparing the yield of gas of these materials with the cubic feet consumed by the engines it is found that less than two pounds of coal are consumed in Rockville for each horse-power hour.

RECENT WESTINGHOUSE WORK.

The month of December promises to bring such a great amount of new business to the Westinghouse Electric Company, that it will probably receive the credit of being the "Red Letter Month" of the year. A large number of the older alternating current central station plants have made contracts with the company for an increase in their capacities and among the new plants is one to be established at Kirkville, Mo., and another at Taylor, Tex. Each of these plants will have a capacity of 750 A. C. 16 c. p. incandescent lamps to start with, but it is expected that this will have to be increased very shortly.

Including these two new stations, the Westinghouse alternating current system is now operated in more than 350 central station plants. The total capacity of these stations aggregates 700,000 lamps. This is understood to be the greatest record of any electric manufacturing company in the world.

The street railway business of the Westinghouse Electric and Manufacturing Company is increasing in the manner which manifested itself from the very first day the company commenced to take orders for the equipment of electric street cars. The department is occupied day and night to its full capacity and the motors are now expected to be turned out as rapidly as they are demanded. Springfield, Ill., is the latest road in operation with the Westinghouse electric motor system and everything started off with the greatest success.

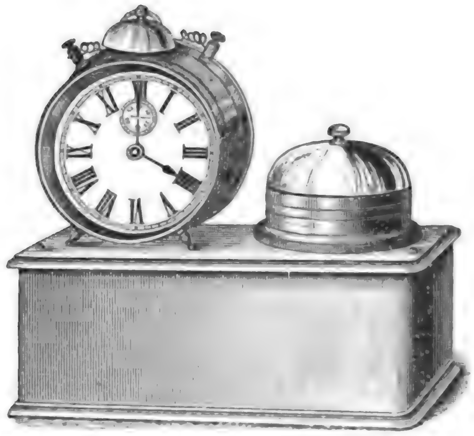
INSTALLATIONS OF THE EVANS FRICTION CONE SYSTEM.

The Evans Friction Cone Co., of 85 Water street, Boston, have received contracts for their friction system for the following plants: Lebanon (N. H.) Electric Light and Power Co., one 650 light alternator; W. S. Griffith & Co., Philadelphia, Pa., two 200 light Mather dynamos; Washington (Pa.) Electric Light Co., one 500 light alternator; Hopedale (Mass.) Electric Car Co., two 30 h. p. generators; National Transit Co., Oil City, Pa., one 140 light dynamo; Rhodes M'f'g Co., Philadelphia, Pa., two 80 light dynamos; A. M. Church & Co., Troy, N. Y., one 20 arc light and one 50 light incandescent; Clinton (Mass.) Gas Light Co., two 45 arc light, two 650 light alternators and one 30 h. p. generator; Worcester (Mass.) Polytechnic Institute, one 500 light alternator and one 250 light incandescent; Edison General Electric Co., Broad street, New York, one 180 light dynamo; Belfast (Me.) Electric Light Co., one 500 light alternator and one 300 light alternator; P. H. Glatfelter, Spring Forge, Pa., one 400 light incandescent and one 20 full arc; Seamless Rubber Co., New Haven, one 100 light dynamo; making a total up to date of 4,000 h. p. equipped.

THE "MANHATTAN" ALARM CLOCK.

The uses to which electricity can be applied in the home are becoming more and more manifold each day.

Clocks with attachments for bringing an electric circuit into action are not new, but their application has been in connection with more or less elaborate apparatus, chiefly burglar alarm work, where they are used to connect and disconnect the battery at cer-



THE MANHATTAN ALARM CLOCK.

tain hours. The accompanying cut shows an ingenious combination of a clock with circuit-closing mechanism, battery and bell. It is intended to take the place of the old-fashioned mechanical alarm clock which, with its few seconds ring, is the best that has been done up to this time. The great difficulty with this old clock is the short duration of the alarm, and here is where electricity steps in. The "Manhattan" clock is set in the usual manner to ring at a certain hour, and the movement of the clock throws into circuit a vibrating bell which will ring for about two hours, unless switched off. The cut shows binding posts on the top of the clock; but the legs of the clock may also serve as this feature, which allows the clock to be detached and used as an ordinary timepiece. Small receptacles are placed on the top of the box, to which are connected the wires to the bell and battery, and when the legs of the clock are set into these receptacles they serve as binding posts, being insulated from the metal body. The whole arrangement is handsomely mounted, the box containing the battery being made of hard wood, polished. The Manhattan Electric Supply Co., 36 Cortlandt street, this city, are the manufacturers of this useful novelty.

F. SARGENT, M. E. AND E. E.

Mr. F. Sargent has recently established himself at 215 Dearborn street, Chicago, as a consulting electrical engineer, having long recognized the fact that there existed a field for experienced engineers well posted in modern appliances and approved methods of construction, who were in a position to give unbiased advice to the investor. Mr. Sargent entered in 1875 the service of John Elder & Co., the famous Clyde engineers, who by the way, were the first to introduce both the compound and the triple expansion engines. He spent seven years in their shops and drawing offices, and took an active part in the designing and constructing of compound engines ranging from 500 to 15,000 h. p. indicated; as well as heavy gearing and mill work. The next four years were spent with prominent American firms designing steam, mill and mining machinery. He then became connected with the Edison Company, spending five years down to date, as chief engineer of the Western Edison Co.; superintendent, Chicago Edison Co.; chief engineer, Edison United Mfg. Co., and assistant engineer-in-chief, Edison General Electric Co.

Mr. Sargent does not intend going into construction work, but simply furnishes the necessary data and supervision for the complete installation of plants.

EUREKA TEMPERED COPPER ON ENGINES.

The following communication was recently addressed to the Eureka Tempered Copper Co., of North East, Pa., by the Pittsburgh Traction Co., E. W. Davis, superintendent:—"I have great pleasure in being able to testify to the excellent quality of your tempered copper. We have been using a guide shoe made of it on a 500 horse-power Corliss engine for the past six months; it looks as well to-day as when we put it on. We are also using your metal for connecting rod boxes on a 35 horse-power Ball engine, making 300 revolutions per minute. We find it takes much less oil than any other metal we have used, and runs much cooler. We intend equipping all our engines with your tempered copper."

THOMSON-HOUSTON PLANTS.

The Western Isolated Lighting Department of the Thomson-Houston Electric Company have closed contracts with the East St. Louis Packing and Provision Company, East St. Louis, Ill., for 800 incandescent lights;

Montgomery, Ward & Co., 111 Michigan avenue, Chicago, for 400 incandescent lights;

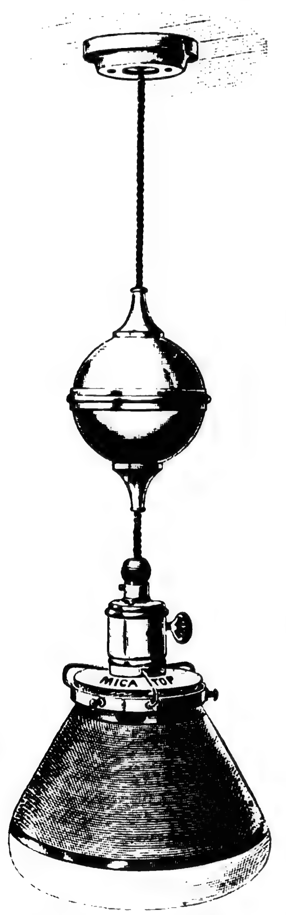
The Missouri Car and Foundry Co., of St. Louis, Mo., have bought of the Thomson-Houston Electric Co. through their St. Louis agent, the arc light dynamo exhibited during the recent exposition.

PASS & SEYMOUR'S CHINA SPECIALTIES.

Pass & Seymour, manufacturers of china for electrical purposes, at Syracuse, N. Y., have succeeded in making a china for electrical purposes that, they believe, far exceeds in strength any china heretofore made for the trade. Some of their customers are riveting brass work directly to their china pieces, and volunteer the statement that there is less than 1 per cent. loss of the china pieces in so doing.

THE BRADNER ADJUSTABLE HANGER FOR INCANDESCENT LAMPS.

WE illustrate herewith an excellent novelty, the Bradner adjustable hanger for incandescent lamps, which has just been put on the market in the East by the McCreary Electrical Specialty Co., of 18 and 20 Cortlandt street, and in the West by the Electrical Supply Co., of Chicago. This device consists of a suspended differential pulley enclosed in a neat brass shell. The flexible cord is wound several times around the large drum, passed through an opening and around the small drum; the lamp and shade being perfectly balanced by the weight of the pulley, the lamp will remain in any position between ceiling and floor. Should the lamp and fixture be heavier than the pulley alone there are small weights provided with each pulley, that fit a recess in the large end of the pulley, and by inserting one or more of these weights the balance can easily be made perfect.



Size A is especially adapted for all single light pendants in offices, stores, libraries, etc. Size B is for engravers, printers, factory and mill lights, the pulley being held in a stout wire cage. Size C is extra heavy for chandeliers, umbrella and cluster lights of all kinds.

Mr. C. C. Foster, the secretary of the company, has just returned from a six weeks' trip through the West. He reports business as excellent and has received larger orders than ever before.

THE WAY TO SPELL ALUMINUM.

We are pleased to note that that admirable electrical journal, THE ELECTRICAL ENGINEER, has joined the great majority of American technical journals and technical men in styling the latest addition to the list of cheap and useful metals alumin*um*, and not alumin*ium*, which latter designation it had previously been using, and which latter is still, we regret to say, the more common form in England. That a change will come soon there also, we cannot doubt. Reason, analogy, euphony, the history of the metal, the practice of all the large manufacturers, the genius of the language, which strongly leans toward the shortest form for all words in common use, all favor the shorter term. Unfortunately, chemists, naturalists and such like folk have rather a leaning the other way, toward using the longer form of any name when there is a choice, as seeming the more scientific and abstruse. While the metal was a mere chemist's curiosity, they had their way unchecked, and so managed to interpolate another syllable into a word used only by themselves. Now that it is coming into common use, it is becoming already clear that this unwarranted interpolation will not "stay put."—*Engineering News.*

THE BECKER VERTICAL MILLING MACHINE.

THE development of the electrical arts has created a demand for a machine which should be adapted for use on medium light work, and this has been successfully met by the machine illustrated in the accompanying engraving. In this machine, known as the No. 2 Becker Vertical Miller, there is employed an entirely new principle of the application of motion to the cutter spindle, by which means the friction of all belt strain, common to all ordinary milling machines, is done away with, utilizing the power thus gained, on the cut. With the cutter spindle and bearing entirely relieved from the usual strain of the belt, the spindle can be successfully run 10,000 revolutions per minute without any heating of bearings, or danger to cutter. This machine at 8,000 rev. per minute will carry a cutter ⅛" in dia., ¼" deep in brass or composition ten running inches per minute. For large cutters the speeds range from 240 to 1,400 rev. per minute; smaller mills from 2,400 to 10,000 rev. The counter-shaft has two sets of driving pulleys for two ranges of speeds. For surface milling with a 2" end mill it is on a large variety of small work superior to the planer both in speed and quality of work.

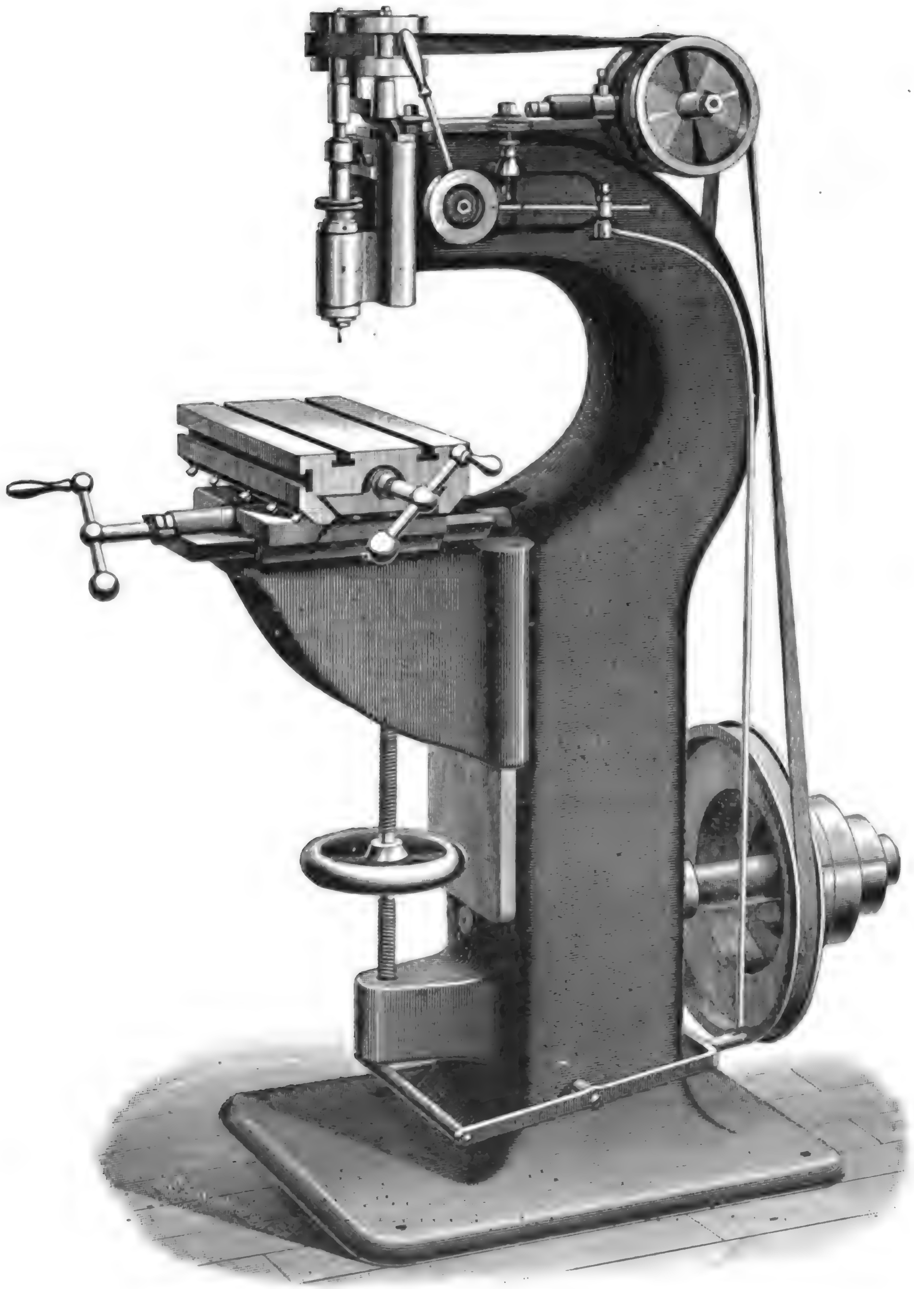
The No. 2 is specially recommended for use in machine shops where experimental electrical work is made a specialty. It is also specially adapted for metal engraving, as it will carry delicate cutters at the rate of over 10,000 revolutions per minute.

The hollow spindle is made of tool steel hardened and ground inside and out, running in aluminum bronze bearings.

The No. 1 machine is intended for the most delicate kind of metal engraving, being like No. 2 in all respects, except in size and weight.

The No. 3 miller is designed for heavy milling. It has hollow spindle with taper socket for Browne and Sharpe end mills, power feed, and rotary chuck with power feed for milling arcs, segments, etc.

These machines are built by the John Becker M'f'g Co., of 157 Pearl street, Boston, Mass.



THE BECKER VERTICAL MILLER.

A GLASS TELEPHONE SWITCHBOARD.

A plan to effect a saving of labor has recently been discussed in the New York telephone office. It is the project of a Chicago man, who proposes to make switchboards entirely of glass plates or sections, each containing 100 plug sockets. The board will be arranged horizontally. Each hole will be partially filled with mercury, which will afford a dust-proof contact. By this arrangement it is claimed that 24,000 metallic circuits may be handled on a section measuring 3 by 5 feet. The lines will be disposed in banks of 100 each, and a set of 100 line terminals will be contained in one glass plate 3 by 3 inches, including a space for numbers. No annunciators are to be used, and the orders will be taken directly by the operator without any preliminary signal. In other words, her ear will be always on the telephone line.

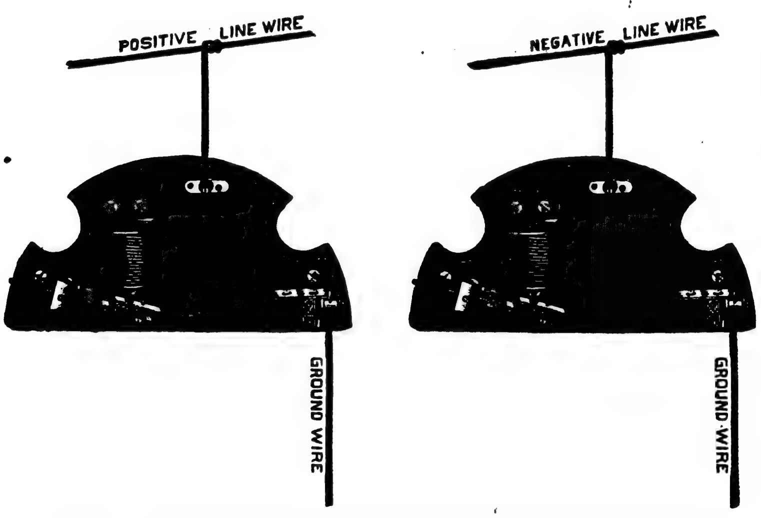
STANLEY AND HALL.

This well known and enterprising firm of electrical manufacturers, 32 and 34 Frankfort street, have recently brought out a number of novelties, one of which is their new combination armature rod and hammer to be used in connection with their popular dust proof bell, to which it forms a neat and effective complement, meeting the objections to the old style of rod in general use.

Stanley & Hall have lately prepared and distributed among their friends and customers a very handy and pretty nickel plated screw driver, all metal from handle butt to business end. They have also got out, in the same philanthropic spirit, a useful little 6 inch pocket rule of celluloid ivory, made to fold, and divided off in eighths of an inch.

THE SPERRY CO'S. NEW LIGHTNING ARRESTER.

We illustrate on this page the new lightning arrester recently brought out by the Sperry Electric Co., of Chicago. The cuts, Figs. 1 and 2, show the method of operation clearly. The appliance is shipped by the company, with all their plants, and is very effective, owing to the fact that while it clears the lines thoroughly of invasive static charges it is free from liability to short circuit the dynamo on itself. It is said that through its automatic action and instantaneous recovery it answers its purpose to admiration, having been known to dispose of more than a



Figs. 1 and 2.—The Sperry Co.'s New Lightning Arrester.

dozen lightning discharges in a single storm. The arrester is carefully mounted on a neat wooden base as shown, and the exposed metallic portions are nickel plated. The company invite correspondence as to this meritorious device.

PHILADELPHIA TRADE NOTES.

Warren Webster & Co.—The "Vacuum" Exhaust Steam Economizers manufactured by the above named company, are enjoying a brisk demand and are day by day becoming more appreciated by central station men who are anxious to save on the coal end of the line (and most of them are). The recommendation we print below is a fair sample of many letters received by Mr. Webster containing spontaneous expressions of enthusiastic gratification with the performance of the "economizer." We omit the name of the heater whose performance was not so satisfactory as the Webster's:

American Tube and Iron Co.,
Middletown, Pa., Oct. 10, 1890.

Messrs. Warren Webster & Co., Philadelphia, Pa.

Gentlemen: After having made a trial during the past two months of your 500 horse power "Vacuum" Exhaust Steam Economizer at our Youngstown mills, we found it to give an average of 10 degrees higher temperature of feed water than the temperature gotten from the 500 horse power ———. The conditions during the tests were the same; and we accept it, as it fulfilled your guarantee.

Please hurry delivery of the one we ordered for the machine shop boilers, and oblige. Yours truly, etc.

The new catalogue of Warren Webster & Co. will be found interesting to central station men, and will be promptly mailed upon application.

WESTERN TRADE NOTES.

The Fort Wayne Electric Co. have recently made an increase of 500 lights to the Litchfield mine plant. Mr. W. J. Buckley has just closed contracts for 120 Wood arc lights and 650 incandescents of the Slattery induction system with Armour & Co., Kansas City, Mo. Mr. J. E. Keelyn has sold Montgomery Ward & Co. 50 Wood arc lights and 400 incandescent lights. This company have just put upon the market a new dynamo of 80 2,000 c. p. lamps capacity. The machine is of the well-known Wood pattern, and, it is said, the largest size of arc dynamo that has ever been made commercially practicable. Among other recent sales are two plants sold to Philadelphia, one of 360 arc lights, Wood system, and the other comprising five 1,000 and one 650 Slattery alternating incandescent machines. The Fort Wayne Electric Co. are making arrangements for equipping the West End line at Ft. Wayne, Ind., with the Slattery system of storage battery cars. The Municipal Electric Light and Power Co., of St. Louis, Mo., have ordered an addition of 300 arc lights of 2,000 c. p. from the Ft. Wayne Electric Co., making a total of 3,675 2,000 c. p. arc lamps sold by the Ft. Wayne Co. to St. Louis and now burning on the streets there.

The Matchless Metal Polish Co., No. 88 Market street. Chicago, recently received through the Department of State at Washington the bronze medal and certificate of award for the best metal polish exhibited at the Centennial International Exhibition held at Melbourne in 1888. On the obverse is a likeness of Queen Victoria, and on the reverse side is a wreath composed of the British oak and the Australian wattle. The two ends of the wreath are bound together at the stem by a true lovers' knot. In the centre is the motto, "Artibus Dignis Honor Insignis," and the five stars of the Southern cross. The distinction was won in competition with metal polishes from France, Germany, England and other countries.

Mr. J. R. Markle, of the Markle Engineering Co., of Detroit, Mich., accompanied by Mr. Thomas P. Whittier, was a caller at this office last week. They are busily engaged in working out a number of new and valuable specialties for electrical work.

Mr. W. S. Love, secretary of the Pond Engineering Co., of St. Louis, has been in town for some days visiting their Chicago office. Mr. Albert Blanchard, the well-known Chicago representative of the company, has been so loaded down with filling orders and looking after construction work that Mr. Love's assistance has been very welcome to him.

The Thwing Electric Co. are busily engaged in fitting up their new factory at the corner of Lake and Peoria streets. This company will manufacture incandescent lamps and various other electrical specialties.

The Nubian Iron Enamel Co., W. Jackson street, Chicago, are doing a very large business in their iron enamel paint and other specialties. Their enamel is especially suited to electrical work, such as coating arc lamps, dynamos, etc.

NEW ENGLAND TRADE NOTES.

The Standard Electric Company, of Vermont, have sold a 500 light standard dynamo to the Overman Wheel Company, at Chicopee Falls, Mass.

Mr. D. C. Spruance, of the Star Electrix Company, of Philadelphia, was in Boston this week looking up business in the interests of his company. Mr. Spruance has had a wide and thorough experience in electrical work in various fields and different capacities, and knows well what to offer to the electrical trade in the way of interesting novelties. They are at present pushing the Star switch and electric attachments for gas brackets, which are having a large sale. Mr. Spruance is associated in his new enterprise with Mr. Norman Marshall, who is well known in New England, and who has also had a wide training in electric light business. With such a combination and good goods to offer, success is assured.

The Economic Electric and Manufacturing Company, at Brockton, threw their factory open to the inspection of the Brockton Commercial Club this week, and showed the members the mysteries of the manufacture of incandescent lamps. Business has been steadily growing with this company, and they now have a brisk demand for their goods. At present they are stretching every nerve to increase their plant, and are daily adding to their capacity, installing pumps as fast as they can be built. The lamps have now been well tested, and have given remarkable results, both for efficiency and lasting qualities.

ST. LOUIS TRADE NOTES.

The Southwestern Electrical Engineering Co. have taken quarters with the St. Louis Electrical Supply Co., at No. 403 N. Eighth street, where they will continue their usual line of work in electrical engineering and construction work.

Van Nort Bros. have taken quarters at 515 Walnut street and will carry on a general business of electrical engineering and construction work.

THE
Electrical Engineer.

VOL. X. NOVEMBER 19, 1890. No. 133.

A PRACTICAL GUIDE TO THE TESTING OF INSULATED WIRES AND CABLES.—I.

[*Copyright, The Electrical Engineer.*]

BY HERBERT LAWS WEBB.

THE use of high-class insulated wires, both in the form of underground and overhead cables, and, indeed, for all classes of electrical work, has of late years increased to such an extent in this country that the necessity for careful and systematic testing has grown proportionately, and an opinion exists, shared both by the editors of THE ELECTRICAL ENGINEER and the writer, that a simple and practical description of the methods and apparatus employed in making tests for insulation resistance, inductive capacity and conductor resistance, would probably be welcome to those who find it necessary to include such work in the catalogue of their daily duties.

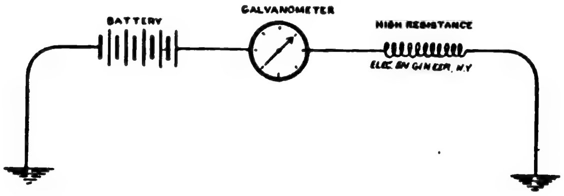


FIG. 1.

It is not a difficult matter for anyone who exercises a little ordinary care to make the usual tests referred to if the instruments are properly set up for him and nothing goes wrong; but it is not unusual to find a man take very kindly to working in this way and yet not have more than a very vague idea of what he is actually doing, and why certain manipulations of the battery and keys give certain results and certain other manipulations give quite distinct results. For this and other reasons, in preparing these articles I have decided to confine myself strictly to the most simple methods (which, be it stated, are those most generally used), and to describe them very fully, avoiding mathematics as far as possible. If after following me through these first courses in the science of electrical testing, any budding expert has acquired an appetite for stronger meat and more of it (as I sincerely hope he will) let him turn to Kempe, where he will find it in abundance.

A wire or cable to be used for telegraphic or telephonic purposes is submitted to three distinct tests, in order to determine its insulation or dielectric resistance, inductive or electrostatic capacity, and conductor resistance. The conditions of the wire are generally referred to as insulation, capacity and resistance, and the greatest of these three is insulation.

When we test a wire for insulation or dielectric resistance, we simply measure the resistance offered by the insulating covering to the passage of a current of electricity from the conductor to the ground. This is done by charging the wire from a powerful battery, the distant end of the wire being free, or disconnected, and the current being allowed to pass through a delicate galvanometer before entering the wire or cable. Now, it is clear that as the far end of the wire is not connected to anything, the only escape for the current is across the insulation to ground. A certain amount of current escapes in this way, causing a deflection of the galvanometer needle. By comparing this deflection with that obtained by allowing the current to flow to ground through a known resistance we arrive at the resistance of the insulation.

It stands to reason that the first operation is to obtain this standard deflection with which the deflection given by the cable is to be compared; this is called "taking the constant of the galvanometer," and the deflection obtained is generally termed the *constant.*

Fig. 1 shows diagrammatically the arrangement of instruments for getting the constant. One pole of the battery is connected to earth, and the other to one terminal of the galvanometer, the second terminal of which is joined to one side of the high resistance, the other side of the high resistance going to earth.

Here we have a complete circuit through the galvanometer coils and high resistance, and the galvanometer needle is deflected over a certain number of divisions of the scale, and remains steady at that point, as long as no variation takes place either in the strength of the battery or in the amount of resistance in circuit. In this way we know how much the galvanometer needle will be deflected when a certain resistance is offered to the current from the battery. The deflection is noted and constitutes the galvanometer constant. By comparing the deflection obtained from the cable with this deflection, the insulation resistance of the cable, in terms of the resistance used in taking the constant, is arrived at. In practice, as we shall see further on, the galvanometer is always shunted when taking the constant, so that only a fractional part of the current shall pass through the galvanometer coils, but for the sake of clearness the shunt is not shown in the diagram.

In Fig. 2 the cable is substituted for the high resistance shown in Fig. 1. The cable is charged up from one end

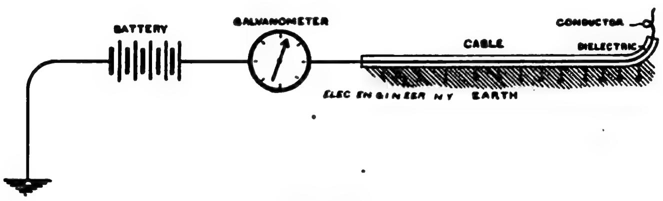

FIG. 2.

by the battery, the far end being free, and the current passes to earth across the dielectric, much in the same way as it would through the coils of the high resistance. A slight leakage of current takes place along the whole length of the cable, and the longer the cable the more leakage there will be. The passage of the current through the insulation to ground will be more readily understood if the dielectric be considered, as it really is, merely a conductor of very high resistance, one side being in close contact with the earth and the other side connected by the cable conductor, which, of course, makes perfect contact with the dielectric along its whole length. In this case the dielectric merely takes the place of the high resistance, the conductor of the cable being the connecting wire. It is plain, therefore, that the leakage will vary directly as the length of the cable, which constitutes the cross-section of the conductor whose resistance we are measuring; the longer the cable, the greater the cross-

section of the conductor and the lower its resistance; while, if the cable is short, the cross-section of this high resistance conductor will be correspondingly decreased, causing a proportionate increase of resistance. The length, of course, is always the same, being merely the thickness of the dielectric.

The simplest method of measuring the electrostatic

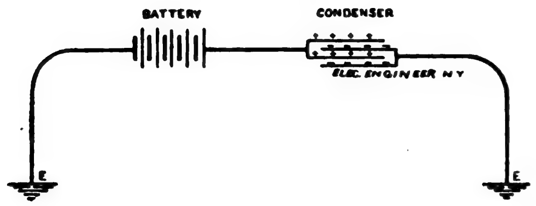

FIG. 3.

capacity of an insulated wire or cable is by comparing the charge of electricity which it is capable of receiving, with the charge of a standard condenser of known capacity. A condenser is practically a Leyden jar in a small space, and consists of a number of plates of tinfoil alternated with plates of mica or paraffined paper. On connecting one pole of a battery to one set of the tinfoil sheets, the other pole of the battery and the other set of tinfoil sheets being connected to earth, the condenser is charged to its full capacity, the charge on one set of plates inducing another of opposite sign on the other set of plates. This arrangement is shown diagrammatically in Fig. 3.

If now we connect the terminal of the condenser, which

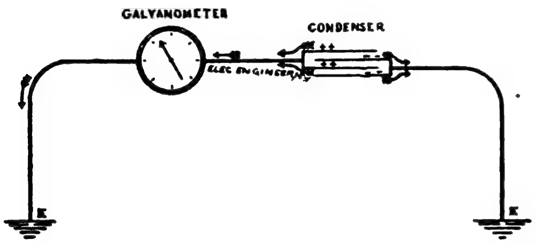

FIG. 4.

was first connected to the battery, to earth through a galvanometer, as in Fig. 4, the charge is released, and a discharge to earth takes place, producing a sudden throw of the galvanometer needle. This deflection is noted. The discharge from the cable can now be obtained in the same manner. The cable itself is practically a condenser, the conducting wire being one plate, the outer sheathing the other, and the dielectric the separating medium. If, as in Fig .5, we connect the battery to one end of the conductor, the far end being left free, the cable will be charged up in the same way as the condenser. After charging for a few seconds the battery is disconnected and the cable is allowed to discharge to earth through a galvanometer, as shown in

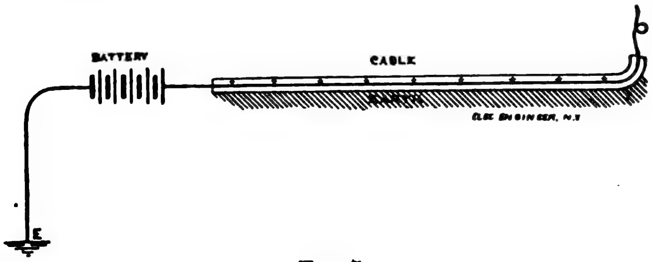

FIG. 5.

Fig. 6. The deflection produced is noted, and dividing it by the deflection obtained at the discharge of the standard condenser, we arrive at the capacity of the cable in terms of the capacity of the standard condenser.

In Fig. 7 is shown diagrammatically the method of measuring the resistance of a conductor, by means of the Wheatstone bridge. One pole of the battery is connected to the centre of the bridge at A, the other pole being put to earth. The conductor is connected to one end of the bridge at C; and to the other end, at B, is connected an adjustable resistance; both the conductor and the adjustable resistance being also connected to earth. Between B and C is placed the galvanometer. The current from the battery divides at A and goes to earth partly by way of A C and the cable, and partly by way of A B and the adjustable resistance. It is obvious that if the branches between A and the earth are not of equal resistance, there will be a difference of potential between B and C, and, there being a connecting path between them by way of the galvanometer, a certain amount of current will pass from one point to the other, producing a deflection on the galvanometer.

By consulting the diagram, the aptness of the term, bridge or balance, is easily noticeable. Assuming the

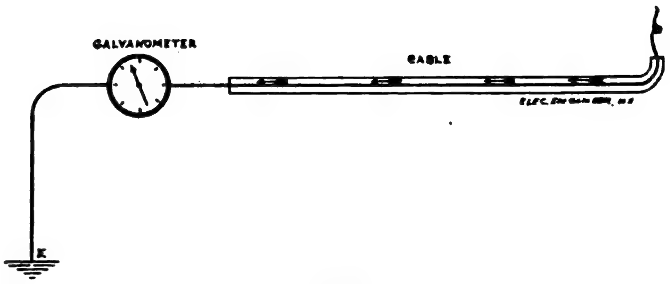

FIG. 6.

arm B A C to be the beam of a balance, and the galvanometer to be the pointer, it is obvious that the pointer will only be at zero, when the objects attached to B and C are exactly equal, assuming the two arms to be of equal value. If a deflection is produced on the galvanometer it is a sign that there is a difference of potential between B and C, and that consequently the resistance connected to B is not equal to that connected to C. As the latter is the fixed resistance to be measured, the adjustable resistance must be altered until there is no deflection on the galvanometer. This shows that the battery current dividing at A flows in equal proportions towards B and C, producing equal poten-

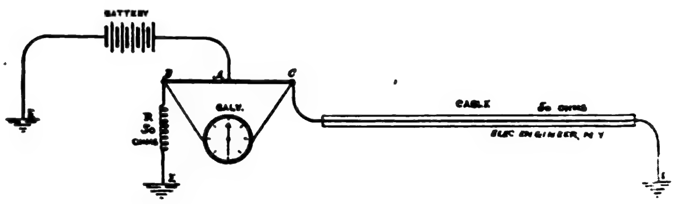

FIG. 7.

tials at those points; consequently, the resistances attached to B and C are now equal, and the resistance of the cable is ascertained by observing the amount of resistance in the adjustable coils.

CHICAGO AND THE BRAGG FIRE ALARM HITCHING PATENT.

"The Indianapolis electricians are doomed to be disappointed if they expect to get $100,000 royalty on the Bragg patent from Chicago," says Electrician Barrett.

In an Indianapolis dispatch it is claimed that under a recent decision of the Supreme court in favor of the owners of the Bragg patent for releasing the horses and dropping the harness upon them simultaneously with the sounding of the fire alarm royalty to the extent of $100,000 can be collected from Chicago, St. Louis, and other cities now using this system in their fire departments. "Chicago," says Mr. Barrett, "has not used the system since it was patented. Three years before the patent was secured we used the plan, but discarded it because it was not suited to our purposes. We now use our own system."

THE LA ROCHE SYSTEM AT DEVON, PA.

The incandescent light, which had until within recently been confined mainly to the larger cities, is rapidly making headway in the smaller towns, and even to-day we see the installation of incandescent plants in towns where it would have been considered absurd to enter upon the commercial distribution of electric light but a short while ago. As an instance of this we note the recent starting at Devon, Chester Co., Pa., of a station operated by the Devon Electric Light and Power Co.

The entire electrical plant was built and equipped by the La Roche Electric Works, of Philadelphia, and for that purpose there were installed two 400 light La Roche dynamos (of the type familiar in a large number of isolated plants), one 80 h. p., Beck high speed engine, and a 100 h. p. boiler. The system of line construction adopted embodies quite a number of novel methods and a potential of 110 volts is carried on the entire system.

La Roche Central Station Plant, Devon, Pa.

Great care has been taken to maintain the potential equal in every part of the circuit, and at no point does the drop exceed 2 per cent. The success already obtained with the plant is such that it will be increased to double its capacity during the coming winter. The accompanying engraving, made from a photograph, is the first ever made of a La Roche central station plant, and shows the plant installed, which has worked without interruption since its inauguration.

A LABORATORY ON WHEELS.

One of the electric lighting companies in Paris has introduced a traveling testing-room or ambulance laboratory for use when repairing cables. The van is fitted with a battery and testing instruments, including a photometer, and is large enough to hold two persons. The plant has been in use since April last, and is found to work well.

THE GEYER-BRISTOL INTEGRATING METER FOR CONTINUOUS OR ALTERNATING CURRENTS.

As originally designed and described before the American Institute of Electrical Engineers,[1] the Geyer-Bristol meter was a self-registering instrument, which made a continuous record in ink on a uniformly moving chart. For commercial use, however, an integrating type of meter is most desirable, and it was with a view of meeting this need that the form described below has been designed. The Geyer-Bristol differential expansion-bar is used, which consists of two elements of the same metal, bound together, but insulated from each other except at one end. The elements are of such relative cross section that one is heated to a greater degree by the passage of the current, than the other. The resulting deflection due to the difference in expansion of the elements gives an indication of the amount of current. In the application of the bar for a self-registering meter a pen is attached directly to the free end of the bar and records the amount of deflection on a uniformly revolving dial.

In the integrating form of the meter the differential expansion-bar is combined with a drum provided with tappets which are adapted to engage with an arm or extension carrier at the free end of the bar itself. The vibrations of the arm are directly transmitted to a register or counter by means of a ratchet wheel. Figs. 1 and 2 (page 556) represent respectively a side and an end view of the present device. At the lower free end of the expansion-bar an arm or extension is attached by a spring-plate *a*, the arm or extension being in the plane of motion of the bar, and in virtue of its spring connection with the bar it is capable of being moved or vibrated at right angles to the plane of deflection of the bar without appreciably moving the bar from the position it would naturally take, due to the current. The drum E, is uniformly rotated in the direction of arrow 2, Fig. 2, by a motor or clock movement. The surface of the drum and

1. The Electrical Engineer, December, 1888.

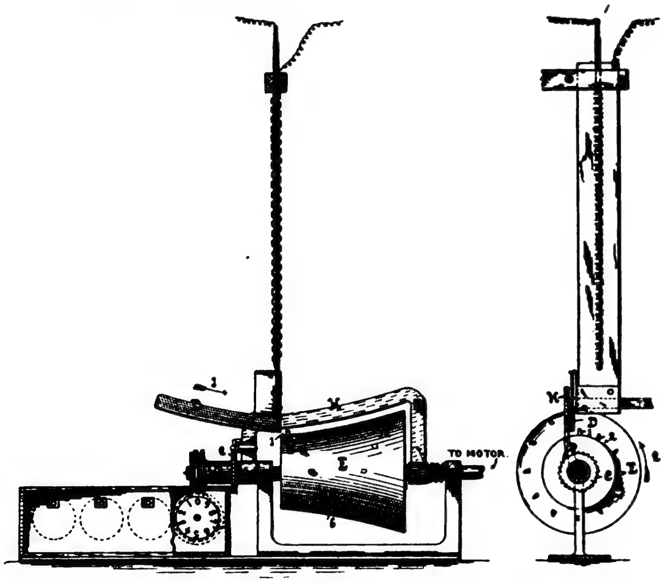
the lower edge of the extension D are of such form that the motion of the extension arm across the drum will be approximately parallel to the surface of the drum.

The tappets shown on the surface of the drum are arranged to engage with the arm or extension D and to vibrate or deflect the same. No two of the pins or tappets lie in the same longitudinal element of the drum; consequently the greater the deflection of the bar the more frequently the arm or extension is deflected or vibrated. At the rear of the extension D and parallel to it is located a frame having bearings in line with the axis of the drum. The lower edge of the frame is above the lower edge of the extension D, so that it is above the path of the pins or tappets on the drum.

It will be evident that when the extension D is vibrated by the tappets it impinges upon the swinging frame and imparts its motion to the frame. Upon the release of the extension arm, both the arm and the frame return to their normal positions. The swinging frame carries a pawl which engages with the ratchet wheel *e*, turning the wheel through one tooth at each vibration. The ratchet wheel could itself be one of a train of counters, or its motion may be transmitted to a system of counters by means of a worm-wheel, as shown.

The action of the instrument will now be readily understood. When no current is passing, the expansion-bar stands in the position shown in Fig. 1, and the tappets on the uniformly revolving drum pass successively under the swinging frame without touching it, and consequently without operating the counter. Under the influence of a current passing through the bar, it will deflect in the direction indicated by the arrow 1 and assume a position corresponding to the strength of the current. The extension arm D will thus be brought into the path of the tappets and will be vibrated more or less according to the deflection of the bar.

The tappets are situated along the length of the drum so that the spaces between them correspond to the amount of deflection per ampere of current; from which it will be seen that the reading of the counter will be the summation of the current in amperes.



FIGS. 1 AND 2.—THE GEYER-BRISTOL INTEGRATING METER.

Where it is desired to increase the range of the instrument, a compound meter is used, both bars of which ultimately actuate the same counter. Suitable devices are also provided to automatically cause the current to pass through one bar or the other, according to the strength at the time. Fig. 3 shows a diagram of the two bars, the circuits, the connections and devices used for automatically causing the current to pass through one bar or the other. In this diagram A B represents the more sensitive bar or galvanometer, and A′ B′ the less sensitive bar. I is the dynamo or other source of current which is to be measured. J is an electro-magnet, K its swinging armature, and L a device for placing the armature under tension and for regulating the tension. The current from the dynamo, when the parts are in the position shown in Fig. 3, is as follows: From the dynamo through the wire 12, the coils of electro-magnet J, elements

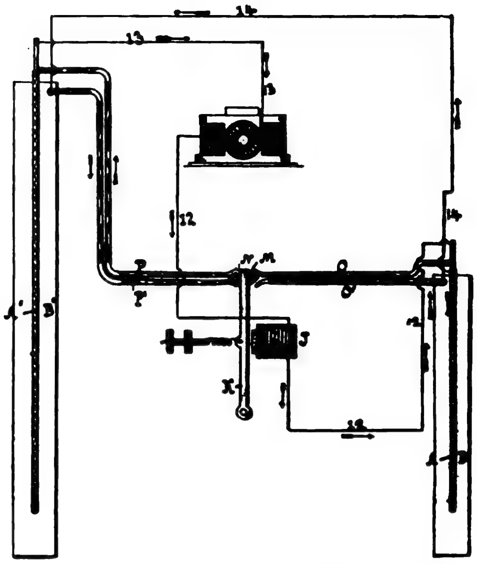


FIG. 3.—THE GEYER-BRISTOL INTEGRATING METER.

A and B of bar AB over wire 14 to element B′ of bar A′ B′ through the conductors P P′ and contact N, and over wire 13 to the dynamo; thus producing a deflection in the bar AB. The resistance offered by the elements A′ B′ to the current when compared with that of the conductors PP′ is so great that no appreciable current flows through that bar. Consequently it is not deflected, and the bar AB alone operates the integrating device as long as the current is maintained within the range that the bar has been designed for.

If now the strength of the current becomes such as to exceed the range of the bar AB, the armature K is attracted by the electro-magnet J. The circuit is broken at N through conductor PP′, and closed at M through conductors OO′. The current will then flow through the bar A′ B′, while the bar AB is not appreciably affected.

It will be noticed that the circuit is never broken, consequently sparking at the contacts M and N will not occur, so that the danger of burning the same is averted.

ELECTRICAL OSCILLATIONS.[1]

BY PROF. J. TROWBRIDGE.

THE author has photographed the oscillatory discharge of air condensers by means of a revolving mirror making 3000 revolutions per minute; and he also placed a Leyden jar within a coil charged by a Gramme machine to observe whether a powerful magnetic field affected the electric waves. The latter has not been found, but will be further investigated. As regards the first experiment, he concludes that the effective capacity of an air condenser depends upon the rapidity of its vibrations, *i. e.*, that its dielectric coefficient is not a constant. This Dr. Lodge—who has made similar experiments, as have also Boys and Bottomley—questions, as the capacity of the leads had been able to produce something like the observed anomaly, or hysteresis.

1. Abstract of a paper presented at the British Association Meeting, Leeds.

TABULATED CONSTANTS FOR DETERMINING THE HORSE-POWER OF TRACTION.

BY W. F. D. CRANE, M. E.

The table of constants forming a part of this article will be found especially convenient by those who have much to do with traction calculations, as by its use the operation of finding the horse-power by the ordinary formulas may be much abbreviated.

The usual formula

$$\frac{W \times S \times K}{33000} \quad \frac{W \times 2000 \times S \times \sin\theta}{33000} = \text{h. p.}$$

wherein W is the weight to be moved in tons; S, the speed in feet per minute; K, the coefficient of resistance to be overcome in pounds per ton; and θ, the angle of the grade. The formula consists of two parts: The first, involving K, relates to levels exclusively, and the second to the additional power required to raise W through the vertical distance represented by the sine of the angle of the grade to be ascended; the sum of the two, therefore, gives the total power required to move the weight W up an inclined plane. The double sign of plus and minus is introduced, for, in climbing a grade, the power required on a level is augmented by the work required to raise the weight through sin θ; while in descending the grade the potential energy of the weight may be in excess of the track and other resistances included in K, and the vehicle will descend of its own accord.

For these reasons the table of constants given herewith naturally divides itself into two parts, each part being computed from its respective part in the modified formula

$$\frac{Wn}{375}(K \pm 2000 \sin\theta) = \text{h. p.};$$

or,

$$Wn \times .002666\,(K \pm 2000 \sin\theta) = \text{h. p.},$$

in which the speed n has been converted into miles per hour from feet per minute. It is convenient to remember that a speed of 88 feet per minute is equivalent to a speed of one mile per hour. For instance, if a car travels 500 feet in 50 seconds, it will have traveled 600 feet in one minute, which, divided by 88, gives a speed of 6.8 miles per hour.

W, n, K, and sin θ (the latter conveniently represented in per cent., or so many feet rise per hundred) are therefore variable. Taking $K = 10$, for the sake of brevity, and substituting the miles per hour and per cents. of grade given in the table, we find therein the constants of power required to move one ton.

Let H represent the constants of power given in the table required to move one ton on a level at the speeds given with $K = 10$. Then

TABULATED CONSTANTS FOR DETERMINING THE HORSE POWER OF TRACTION.

COMPUTED BY W. F. D. CRANE, M. E.

H. P. $= \frac{Wn}{375}(K \pm 2000 \sin\theta)$. W = Load in tons. n = Speed in miles per hour.

$= Wn \times .0026\frac{2}{3}\,(K \pm 2000 \sin\theta)$. K = Resistance in pounds per ton. $K' = \frac{K}{10}$.

H = Constants of power required to move ONE TON on LEVEL at speeds in table, with $K = 10$.
H' = Constants of ADDITIONAL POWER required to raise ONE TON on GRADES and at speeds given.
$H \times WK'$ = H. P. required on LEVELS alone for speeds given.
$H' \times W$ = H. P. additional on GRADES alone for speeds and % given.
$W(K'H \pm H')$ = total H. P. required.

Miles per Hour.	H on Levels $K = 10$.	H′ on Grades—To be Added to Horse Power on Levels.

$H \times WK' =$ h. p. required on levels alone.

$$K' = \frac{K}{10}$$

$$H' \times W = \text{h. p.}$$

will be the additional horse-power required on grades, the same to be added to, or subtracted from, the horse-power on the level to give the total horse-power required to drive the vehicle when moved up-hill and down-hill, respectively.

These two parts of the formula used singly in determining the horse-power required for each, and afterwards algebraically added to find the total power required, will usually be found to be the more useful and instructive form in which to use the general formula, which in this case reduces to

$$W(K' H \pm H') = \text{h. p. total.}$$

K has been found to vary in value from 12½ to 20 lbs. on clean raised rails, and from 20 to 56 lbs. on sunken rails. Perhaps 30 lbs. is a fair working average for tramways with the rails in good condition or wet. The influence which dirty tracks have upon the increased value of K and consequently upon the increased power necessary to move a self-propelled car has been frequently underestimated, and the safety of the motors imperilled in consequence of the over-duty required of them, and the success of a system insufficiently supplied with power has been delayed by inadequate allowances in the original calculations for increased traction and other resistances. However, much of the insufficiency of power in motor systems can be traced more directly to underestimated losses in the motors and power transmitting mechanism. But a sandy or dirty track covered with gravel or frozen mud is alike dreaded by the power station manager and storage battery enthusiast.

A few illustrations will show the application of the constants given in the table.

1. Assume an electric motor car weighing, with load, 8 tons, to pull a tow car weighing, with load, 6 tons, to travel on level at a speed of 15 miles per hour; $K = 40$. What is the theoretical horse-power required?

The total load to be moved is 14 tons. H, for 15 miles per hour, is .400. Then $H \times WK' = .4 \times 14 \times \frac{40}{10} = 22.4$, the theoretical horse-power required.

2. Given a motor car, total weight 9 tons, to ascend a 7 per cent. grade at a speed of 6 miles per hour. What is the estimated horse-power required, with $K = 30$ lbs.?.

H for 6 miles per hour is .16, which, multiplied by $9 \times \frac{30}{10} = 4.32$ h. p., in overcoming the track resistances alone.

$H' = 2.240$, which, multiplied by $9 = 20.16$ h. p.; or nearly 4.7 times as much power is required to alone lift this weight at the rate of 7 feet in a hundred, than is required to move the car on a level at a speed of 528 feet per minute. This comparison incidentally shows the vast influence which grades on a railroad exert in increasing the power required to move the cars, and the importance and economy of selecting routes containing the least number of grades, and of ascending the same at the lowest practicable speed. The sum of the two will give the total theoretical, *i. e.*, 24.48 h. p. required. Allowing 50 per cent. as the combined efficiency of motors and gearing, to operate this car would require a draft of 48.96 h. p. upon the generating station.

3. A storage battery car, weighing complete, with load of passengers, 12 tons is required to ascend a 5 per cent. grade at a speed of 4 miles per hour; $K = 30$.

What will be the current required, assuming that the batteries give 180 volts at that time and that the combined efficiency of motors and gearing is 50 per cent?

$$H \times WK' = .1066 \times 12 \times \frac{30}{10} = 3.84 \text{ h. p.}$$

$$H' \times W = 1.066 \times 12 = 12.8 \text{ h. p., plus } 3.84 = 16.64 \text{ h. p.}$$

Assuming electrical and mechanical losses to amount to 50 per cent., we have 33.28 h. p. as the actual horse-power required. This, multiplied by 746, equals 24,826 watts, which divided by 180 gives 137.9 amperes.

Some constants for speeds of miles and fractions of miles per hour other than those given in the table may be obtained by interpolating and manipulating the constants for the various speeds and fractions given, by simple addition and subtraction. Thus the constant for a speed of 9¾ miles per hour will be the sum of the constants for 9 miles + ¾ miles; that is, $.020 + .240 = .260 = H$. Various constants for the grades may be obtained by a similar process.

In order that calculations for the horse-power of traction shall be of practical value some knowledge must exist of the correct value to be given K under various conditions, of the allowances to be made for the temporary increase of power required to start the car quickly, and of the wind resistances when running, of the increased power consumed in overcoming curves, switches and obstructions, of the efficiency of the motors and of mechanical losses, predeterminations of some of which are difficult, if not impracticable, to arrive at by simple calculation. Suitable provision for these and the exigencies arising in public traffic come within the experience of the traction engineer, a thorough knowledge of which, to be successful, must constitute a prominent feature of his education.

ON KINETIC STABILITY WITH MAGNETIC FORCES.[1]

BY PROF. G. F. FITZGERALD.

If a perfect conductor move near a magnet there are currents induced in it which tend to stop the motion. If the conductor be perfect, the kinetic energy of motion will ultimately, if small enough, be all changed into electro-kinetic energy, and the conductor will begin to move in the opposite direction, and when in its former position its electro-kinetic energy will have been reconverted into kinetic energy. For instance, if a perfectly conducting shell were placed near three magnetic poles it would be in a state of kinetic equilibrium if the energy given to it by a small disturbance were not great enough to drive it to infinity, or into contact with the magnet. It is to be remarked that I have assumed the perfect conductor to have been brought within a finite distance of the magnet pole without having had currents induced in it, *i. e.*, I have assumed that the body can be brought up as an imperfect conductor, and then changed into a perfect conductor, *in situ*. As the effect of a magnetic pole is to induce in a perfect conducting plane sheet currents which can be magnetically represented by a pole at the reflection of the first pole in the sheet, it follows that with a perfect conducting sheet there would be no action such as, in Arago's experiment, prevents motion of the sheet parallel to itself. There would, no doubt, be a gradual radiation of the energy due to the varying magnetic field. This would have a damping effect on the vibrations much the same as would result from resistance in the conductors.

The system is interesting as an illustration on a large scale of how meteoric swarms have their energy gradually frittered away into electro-magnetic radiations.

ELECTRICAL ENGINEERING IN SIAM.

Mr. A. J. Lawson, the well-known electrical engineer, who was formerly Canadian agent of the Edison Co., and lately represented the Brush Electric Co. in the Dominion, has received the appointment of superintending electrical engineer to the Siam Electric Light Co., of Bangkok, Siam. This company has bought a Mordey alternating current plant of 10,000 lights in England, and Mr. Lawson will have charge of its construction and operation.

1. Abstract of a Paper read before the British Association in Section A, Leeds, September, 1890.

ELECTRICAL ENGINEERS.

EMILE BERLINER.

For so young a man, Mr. Emile Berliner has certainly had a most varied experience, and to hear the story of his life from his own lips is not one of the least pleasures of acquaintance with him. The old German city of Hanover gave him birth in 1851, and after receiving an ordinary education he went into a dry goods store to learn the business. Possibly the goods around him set his fancy to work, for it was in this employ that he constructed a small model of a new type of weaving machine. Like many another young genius he was disgusted to find that he had been anticipated.

In May, 1870, he emigrated to the United States, and took a position as clerk in a fancy goods house in Washington, where he stayed nearly four years. In 1874, he ventured on to New York to see life—and saw it. Facile, courageous, inquiring, he was not disheartened by the buffets of fortune, but when work failed him in one line, turned readily to another. He took up anything that offered a chance to make a living. He clerked, kept books, taught German, painted backgrounds on enlarged tin-type portraits, and sold glue. Occasionally he practiced abstinence involuntarily by getting along on three dinners a week, but combined high thinking with plain living by spending nearly all his leisure hours in the library of Cooper Institute. After a brief Western experience as a drummer up and down the Mississippi, he drifted back in 1875 to New York, and secured employment as assistant bottle-washer in Fahlberg's laboratory for sugar analysis, at $6 per week. The occupation was a dreary one, but learning thereby the Scheibler method of analyzing raw sugar, he constructed a calculating machine for rapidly resolving the percentages of water, crystals and syrup. Fahlberg, it will be remembered, afterwards discovered saccharine. He had three big balloon blue-stone cells, the first galvanic batteries Berliner had ever seen, and was greatly enraged when he caught his inquisitive bottle-washer examining them critically one day.

Finding he could obtain no advance of salary in this position, Berliner went into a feed store on South street as bookkeeper and assistant salesman, and to this day is knowing in oats, meal, hay, corn and the eccentricities of Gotham's wagon drivers. In 1876 he chanced to meet his old Washington employer, who did not have much difficulty in persuading him to go back and assume charge of the retail department.

It happened that in 1874, a friendly German apothecary in New York had presented him with an old edition of Müller's "Physik" (1856), and from that he learned the rudiments of science, becoming particularly fascinated by sound and electricity. Soon after he stumbled across Paul La Cour's researches in phonic wheels, and this drew his attention to the possibility of transmitting speech by telegraph wire. The idea possessed him day and night. His first notion was to connect two vessels filled with mercury, by a wire, and pass a current through. Talking to one mercury surface, he reasoned, should vibrate the current and emit the sound at the other vessel. Lippman's capillary telephone nearly realized this conception. Returning to Washington, in 1876, with the fever of research upon him, he began electrical experiments, and, for the purpose of learning something of practical work, paid frequent visits to the Fire Alarm headquarters, where the operators, as is their wont in every office, were kind and ready to answer all questions.

Mr. Berliner had just begun making diaphragms and contacts, and had looked up Bell's patent of 1876, when one day, Mr. Richards, an operator, showed him, at his request, how to manipulate a telegraph key à la Catlin. "You have to press down harder," said Richards, "otherwise it may happen that the sounder at the other end will not respond well." The remark had probably been made a few million times before, but it had not been made to a Berliner; and the young dry goods clerk immediately wanted a thorough explanation of the phenomenon. "It flashed on me," he says, "that if pressure made a difference in an electrical contact, and modified the current passing the contact, a vibratory contact would transmit speech by means of undulatory currents. In this manner, the telephone transmitter, now known as the microphone, was invented." He set to work at once to study the principle just enunciated and tried to transmit speech, using for receiver an apparatus as shown in the Bell patent of 1876. For a transmitter he used metallic diaphragms, touching screws tipped with either platina, steel or broken lead pencil points. One day in April, 1877, he had adjusted the transmitter—a soap box and a black sheet-iron diaphragm against a steel ball—to the utmost nicety, *i. e.*, an extremely loose contact, and, closing the two wire ends leading to the battery he suddenly heard a scraping sound coming from the transmitter. He had discovered, in fact, that a microphonic contact could be vibrated by a current, and that such a transmitter would act as a receiver of sound as well.

How he followed up these interesting results, we will let Mr. Berliner himself tell. "This analogy with the Bell telephone," he says, "struck me very forcibly, and immediately making a duplicate transmitter, two days afterwards I actually transmitted speech and music with these two simple contrivances, almost as simple as a lover's telegraph. This work was mostly done before, or after, business hours, or on Sundays. I now tried all sizes of instruments, and various metals as diaphragms, and finding that distance would weaken the effect very considerably, hit upon the idea of placing the transmitter in the primary of an

induction coil, thereby transforming the undulations into high tension currents, passing these over the line wire, and re-transforming them again into low tension currents at the other end, to actuate the microphone receiver. No Bell telephones were used in these tests, but each instrument was used both for transmitter and receiver. My patent for this was issued Jan. 15, 1878, and was later re-issued. Without this, practical telephone work would be impossible. When, soon afterwards, I was introduced by a prominent Washingtonian, Mr. A. S. Solomons, to Prof. Henry, this great scientist was particularly pleased with the use to which I put the induction coil. I mentioned to him at the time that telephone circuits were found to be affected by parallel wires on which Morse signals were sent. He then related to me that he himself had traced signals on long lines between two wires which were a mile apart.

"I made some attempts to interest practical electrical men in the transmitter principle, and in Jan., 1878, visited the New York local branch of the Bell Telephone Co., but they refused to pay a very modest sum for the invention, which was then not yet perfected. It was not until during the summer of the same year that, by request of Mr. Anthony Pollock, the attorney of the Bell Co., Mr. Thos. A. Watson, general superintendent of the Bell Co., visited Washington and examined the transmitter, when he immediately declared that his company would want it. As one of my conditions, I asked to become a member of their electrical staff, and a contract was closed in Sept., 1878, in New York. Returning to Washington, a few nights later, to prepare for leaving, I sank into a severe nervous prostration, which lasted seven weeks, and from the effects of which I suffered many years afterwards. Leaving the hospital, I went to New York to enter upon my new duties."

Mr. Blake had just invented his transmitter, but it was not yet possible to control its functions in such a way that a number of instruments could be made of like quality, for when they were adjusted in the evening, they would be out of working order the next morning. Mr. Blake was taken ill similarly as Mr. Berliner had been, and the task of getting the instrument into a reliable construction was placed in Mr. Berliner's hands. After several months of labor, the conditions and gauges of the transmitter were so modified, and the rules were so laid down, that thereafter 200 transmitters were turned out per day, working alike in quality, and keeping the adjustment to perfection. One of the improvements consisted in re-baking the carbon buttons in a hydrocarbon gas retort, which made them very hard and susceptible of a fine and lasting polish. During the next few years Mr. Berliner's time was occupied with experimenting for the Bell Co., and in watching the manufacture of their instruments in Boston.

In 1881 he paid a visit to Europe, and laid the foundation for a telephone factory in Hanover (now J. Berliner's), which has since introduced one of the modifications he invented—the so-called "Universal Transmitter," which can be used under all conditions with like superiority, and is exclusively used by the Austro-Hungarian government, and in other countries. The line Buda-Pest—Vienna—Prague, 800 kilometres long, is fitted up with 50 of these instruments.

Returning to the United States, Mr. Berliner married Miss Cora Adler, of Washington, a lady whose bright and cheerful temperament has done much to help him in the cares and burdens to which the sensitive inventor is always heir. They moved to Cambridge, Mass., where he made the first studies which led on later to the gramophone, and where he conceived also the principle of his pyromagnetic generator, for which he filed a patent application as far back as 1885. Leaving Cambridge for Washington, he established a small laboratory on his return to the latter city, and devoted himself to a number of problems, foremost among which were those connected with the gramophone. This invention, the details of which are now familiar, Mr. Berliner considers his most important published invention to date. Not only does he expect to found a new art on it, but he believes that there will be an agreement of scientific men on the superiority of the principle of the gramophone, over that of the phonograph, in the perfect preservation of the voice and of sounds generally.

In 1889, he paid another visit to Europe, and has since formed a company for introducing a small sized gramophone. This company has orders for many thousands of such gramophones, which can be sold retail at $10 apiece, and orders for over 70,000 copies of 5-inch discs. These copies are made by making an electrotype matrix of the original sound etchings, and this matrix is impressed in celluloid, a material excellently adapted for gramophone discs. Laboratories have been established in Berlin, Leipsic, Frankfort and Hamburg, and soon each city will have a gramophone office where voices can be taken in solid metal, and copies furnished in the same manner as photographs are now made.

As soon as Mr. Berliner has got out an American programme, a public exhibition will be given before the American Institute of Electrical Engineers, to show the results with the latest improvements.

It deserves mention that while Mr. Berliner was last in Berlin, Prof. Helmholtz called on him with eighteen assistants of the Imperial Physical Laboratory of Charlottenburg, to inspect the gramophone and invited him to visit Charlottenburg as soon as the further developments in the invention were made.

Like other thinking electrical engineers, Mr. Berliner has made a favorite study of the problem of turning the energy stored up in carbon into electricity without the intervention of a steam engine. He believes the problem to be entirely solvable, but only by continuous original research and by leaving the beaten, dusty path of investigation on the subject.

Touching the theory of the microphonic action of loose contacts, he long ago held that it is the layer of air or gas between loose contacts which, acting as a variable resistance on increasing or decreasing thickness, produces the undulations; and that carbon is such an excellent material for a transmitter because it has the property of condensing a cushion of air upon its surface.

Among Mr. Berliner's other inventions of interest to electricians are his molecularium and his secondary battery. The former is an instrument of very simple principle, to illustrate the effect of the electric current by means of a single mechanical movement, that, namely, of the rotatory vibration of molecules. In his storage battery, 5 per cent. of alcohol is added to a Planté type of cell, with the result that fresh lead plates form in a few minutes. This, he thinks, is due to the formation of ozone in such a cell. Mr. Berliner has also brought out a superior spongy carbon, obtained by heating ordinary battery carbon to redness for several minutes in an open fire. This burns out the lighter hydrocarbons, leaving a spongy or capillary structure which increases the power to depolarize and decreases the resistance. In such a spongy carbon, the gases will themselves give cause to currents if a piece of unburned carbon be used as the other electrode.

LONDON ELECTRIC SUPPLY COMPANY.

The machinery at the Deptford station is working in a highly satisfactory manner. The current that is now being daily generated is greater than any that has yet been supplied. Both the 1,500 horse-power engines and dynamos are working without any hitch, and have been supplying current continuously to about 40,000 lamps every night for about a month through the Ferranti mains. The disturbing effect on the telegraph lines has now been reduced to an insignificant and hardly appreciable magnitude. For reasons which are not yet thoroughly understood there is a rise of pressure of nearly 50 per cent. at the ends of the mains.

THE CUSHING ELECTRIC SWITCH-BOARD FOR THEATRES.

THOUGH eminently adapted to harmonize with interiors of whatever style of decoration, the electric light has probably found no better field of application to show the full value of its light-giving, healthful and safe character than in the illumination of theatres. As a result of this it may be safely stated that every theatre of prominence now uses electricity, at least in part, as an illuminant.

The introduction of the electric light in theatres has, of course, made it necessary to provide arrangements for the manipulation of the lights in order to obtain the effects which had heretofore been obtained by means of gas. It therefore became necessary to provide means for working the various circuits in a variety of ways involving quite a large number of combinations of circuits, while at the same time requiring the independence of each particular circuit when the effect desired made it necessary. To fulfill these conditions successfully is evidently no small task, when we consider the large number of circuits with which a theatre is provided, and, above all, the fact that the entire manipulation of the lights must be done by one man.

This particular branch of theatre lighting has been the subject of much study and indeed may well claim the attention of electric light engineers both from the electrical and the mechanical standpoint. As an example of this class of work which deserves attention from the thoroughness with which all the details have been worked out, we desire to bring to the attention of our readers the new switch-board which has just been placed in Herrman's Theatre, in this city, and which was built by Messrs. John P. Cushing & Co., of Boston, after designs by Mr. Wm. J. Kelly.

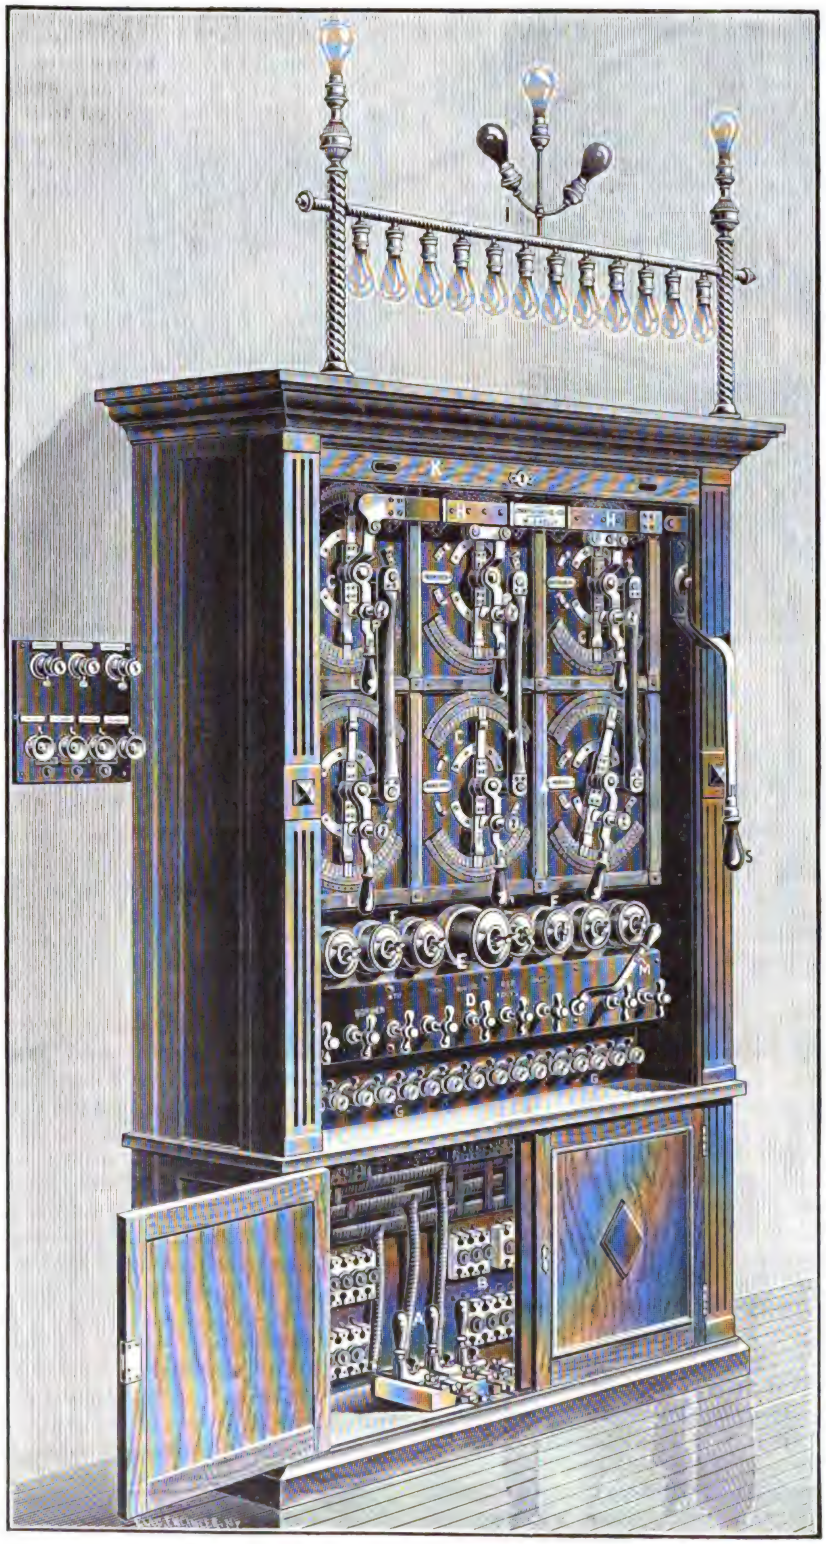

FIG. 1.—CUSHING'S ELECTRIC SWITCHBOARD, HERRMANN'S THEATRE, NEW YORK CITY.

The board which is illustrated in the accompanying engraving has been constructed with special reference to insulating and fireproof qualities and for that purpose the entire switching apparatus is mounted on plates of molded mica. Every possible care was taken in these details. The wiring has been arranged for the three wire circuits entering the building from the Edison street mains on Broadway, and the main circuits are led directly to the base of the board which forms a cabinet containing the feeder plugs and cut-outs. The former, shown as A, when unplugged, cut off the entire current from the switch-board, so that no current can reach any part of the house unless specially fed by an independent wire, for accommodation light. By this means all danger from fire is eliminated.

The fusible cut-outs B contained in the cabinet are included in the different circuits controlled by the switch-board. The safety fuse, being properly marked with its ampere carrying capacity, can at once be replaced in case of its being blown.

After passing through the safety cut-outs the wires pass to the main house and circuit switches E and F, which are arranged in one row. These switches are of sufficient capacity to supply any current necessary for the auditorium. From the main house switch E the smaller switches at the sides are branched, which control the parquet, balcony, gallery, private boxes, bulls-eyes, etc.

Immediately below these switches are those controlling the lights on the stage and shown at D. Among them is a gang-switch M, which, by a single movement, switches in or out, one, or all the lights or combinations of lights on the stage, an effect which has not heretofore been accomplished.

Before proceeding to explain the full effects which can be obtained by this switch, it will be necessary to describe the regulators C, which are in connection with the resis-

tance coils. These regulators are designed to produce any change from full light to darkness without switching the current entirely off. For this purpose the resistances which are in series in the circuits have both positive and negative ends connected to the regulators, the switch arm, pivoted at the centre, passing over a series of contact segments at each end.

Each of the regulator handles L is provided with a spring pin P, which, when withdrawn, allows the switch to be worked independently so that its operation effects only the lamps connected to it. These switches, it will be noted, regulate both the stage and the house lights.

It is frequently desirable, however, to regulate all the lights in unison, or, on the other hand, to bring lights on two or more circuits to a certain brilliancy without affecting those in any other circuit. To accomplish this with certainty, the board is provided with a very simple movement, consisting of a lever, S, which, operating through the horizon-

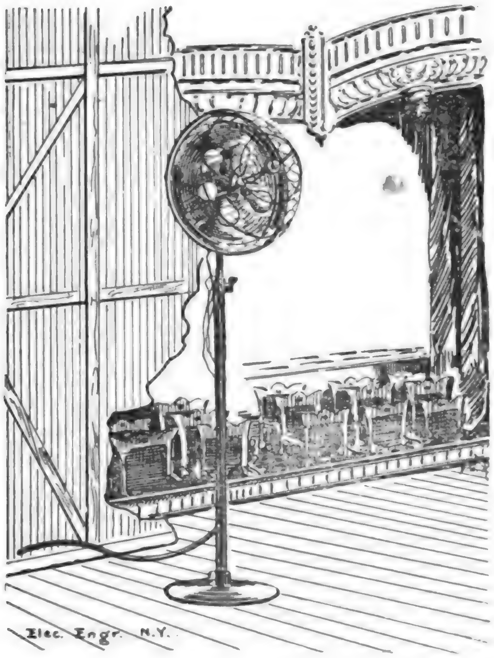

FIG. 2.—COMBINATION BUNCH LIGHT.

tal and vertical connecting rods, H and M, allows of the movement of all, or any combination of, the regulator switches which may be required.

As has been remarked above, the spring pins P, when withdrawn, allow of independent movement of the switches, But when released, they engage with the movement connected with the lever S and are moved accordingly. Thus. if all the pins are released, which is done by a turn of the milled head, the lever S operates all the regulators to bring the lamps on those circuits to uniform brilliancy; but the withdrawal of any pin, such as that belonging to the bunch lights in the lower left-hand corner, leaves the lights on that circuit unchanged.

In order that the attendant at the switchboard may know the exact condition of the illumination in every part of the house, each circuit is provided with a pilot light. These, as shown, are placed at the top of the case at I, and give an exact representation of the brilliancy of the lamps in each particular circuit, and show at the same time whether the circuits are in working order. At the same time, however, each pilot lamp can be controlled independently and extinguished, if desired, by the horizontal row of switches shown at G.

Just what effects can be produced by the arrangements we have explained will now be understood. Thus, if white foot lights and borders representing daylight are in use at the rise of curtain, and red is required for sunset, the stage lights are drawn into the resistances, the white foot lights are snapped out and red thrown in. This is done by one movement of the lever S. The border lights are gradually worked up to the height required for sunset, the foot light regulator disengaged and the foot lights worked up slowly, producing sunset effects. For moonlight effects, all lights are worked down again, the reds drawn out and, by the same movement, the blues thrown in and the foot light regulator worked up until the proper effect is produced.

The gang switch, D, operates all the other snap switches when a little pin on each switch, is inserted; and any switch which is not desired to be operated is kept free by pulling out the little pin, precisely in the same way as described in connection with the resistance switch.

With the stage gang switch D, any and all stage lights can be thrown in or out, together or alternately, as for instance first and fifth border, red, white, or blue foot lights; second, third and fourth borders, bunches and sides; thus making it possible to make any changes in lighting that may be desired, all being done by and under the control of one man.

The board which we have just described is enclosed in a polished hard-wood case and when not in use a roll front is drawn down, thus enclosing the whole and preventing the entrance and accumulation of dust.

The theatre is also provided with combination bunch lights of an improved form, designed by Mr. Kelly. These, as shown in the engraving, Fig. 2, consist of a cluster of six incandescent lamps placed in front of a polished reflector and protected by a wire netting.

Centered on the same point as the incandescent lamps, are a bunch of gas burners. The latter are fed by a rubber hose, while flexible cords serve to carry the current to the lamps. The latter, with the reflector, are mounted upon a rod which telescopes into the standard so that the bunch can be fixed at any height and at any angle.

Another device introduced consists of a series of lamps mounted in front of a curved reflecting surface and provided with glass fronts having different colors; these can be readily manipulated both as to position and color and thus afford a good substitute for the lime or arc light.

Besides the board installed in Herrmann's Theatre, a similar one has been placed in the Tremont Theatre, in Boston, and another in a Brooklyn theatre and the managers of all express their utmost satisfaction at their operation.

THE PARIS TELEPHONE SYSTEM.

Beginning with Nov. 3, any subscriber to a telephone, and any person entering the telephone offices, will be allowed to speak to any of these offices a message to be transcribed and conveyed to a person living in the district. The charge will be 50 centimes for five minutes, and the message will be limited to 100 words. The work of altering and enlarging some of the main sewers, with a view of facilitating the connecting of the new central telephone exchange in the Rue Gutenberg with the various subsidiary exchanges, is now being vigorously pushed on. In some instances the sewers will be entirely transformed. Thus in the Rue Faubourg-Montmartre the tunnels will be about 13 ft. broad by 10½ ft. high, with a sewer course 4ft. deep in the middle. On either side of this channel there will be a platform 2ft. wide, one of which will be used by the Municipal Sewers Department, while the other will be given over to the telephone service. The roof of the tunnel will rest on cast-iron pillars, and on brackets fixed to these will be run Patterson 50-wire telephone cables. The cost of this work will be shared between the Municipality and the Postal Telegraph Department.

TAKING TEMPER OUT OF PENS.

"Young man, you must take more pains with your writing." The youth looked up and replied: "'Tain't my fault; it's the pen." "Then get a new pen," replied the teacher sharply. "That won't do any good," the boy made answer, "for the electricity in the street cars throws all the temper out of the pen." "It would be a good thing if it had a similar effect on the children," said the teacher *sotto voce*.—*Albany Journal.*

ELECTRIC LIGHTING IN THE CHAMBER OF COMMERCE BUILDING, CHICAGO.

BY CHARLES WIRT, E. E.

ONE of the most striking features of the modern tendency towards centralization is to be found in the erection of immense office buildings in which the merchant or professional man is now provided not only with room to transact his business but is afforded all the comforts and conveniences which are so conspicuously absent in the older

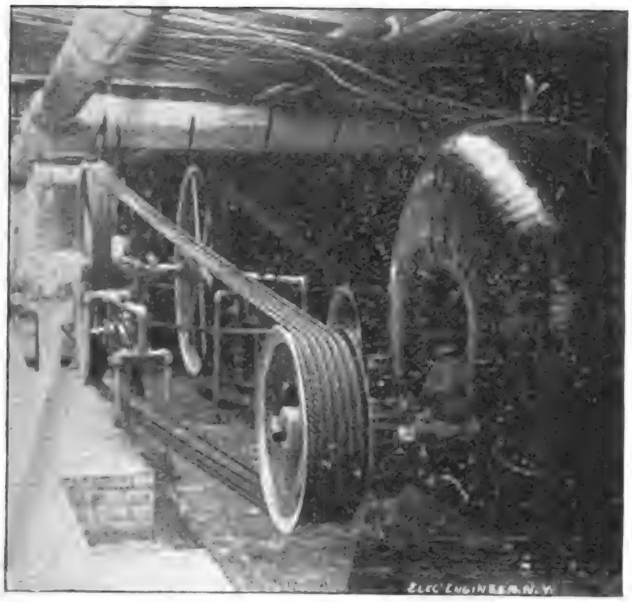

FIG. 1.—MATHER GENERATING PLANT, CHICAGO.

buildings devoted to business purposes. Among these features of advantage probably none stands out more prominently than the electric light, and it is safe to say that at present no modern office building is erected without provision being made for its installation; indeed, not a few are in existence in which this is the only form of illumination provided, such has been the confidence developed by the experience of but a comparatively short time.

The city of Chicago, already famous for its enormous office palaces, has now added another to the long list in the completion of the Chamber of Commerce Building, which, with its thirteen stories, is the highest commercial structure in the city, and, with one exception, the largest. To light this enormous building an incandescent plant of the Mather system was installed by Mr. Bow, Western manager of the Mather Electric Co., consisting of four 00-light Mather incandescent dynamos. These are driven by two 150 h. p. Corliss engines, built by Messrs. Weisel and Vilter, of Milwaukee, Wis.

The limited space available for the placing of the machinery made its arrangement a matter of no little skill, the engine room being 11 ft. 6 in. wide by 113 ft. long. An interesting feature of the construction is the rope driving which is illustrated in the accompanying engravings and which is used both for the main belt of the engine and for the dynamo belts, Figs. 1 and 2. The engines run 88 revolutions per minute, have driving wheels 9 ft. 6 in. in diameter, weighing 24,000 lbs. each, and are grooved for ten one-inch raw hide ropes. The dynamos are driven from the counter-shaft by five ¾ inch raw hide ropes, the slack of which is taken up by an improved single track tension carriage. This arrangement of driving ropes, which was installed by the Link Belt Machinery Co., of Chicago, is found to run very smoothly and quietly. The sheaves that drive the dynamos are each provided with disc friction clutches, so that either or both machines can be run at will.

The number of lights in the building is 3,400, and the lighting of the interior court, which is 13 stories high, is by clusters of 7 lamps placed 16 feet apart, all the way around the court on each floor.

The building is a fine example of modern fire-proof construction, showing what can be done in a limited ground space with the methods of modern constructive engineering.

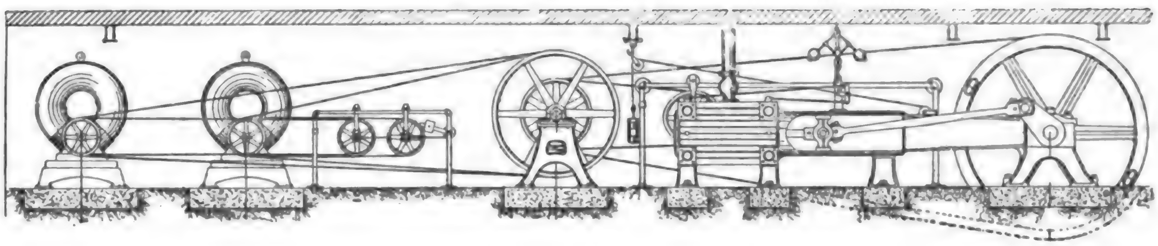

FIG. 2.—ELECTRIC GENERATING PLANT, CHAMBER OF COMMERCE BUILDING, CHICAGO.

CATAPHORIC MEDICATION.

THE question of the absorption into the skin of solutions by means of electric currents has been, according to Dr. S. Ehrmann, of Vienna, the subject of many experiments with him since Prof. Wagner first started the discussion by his researches on the cataphoresis of cocaine; and he has at last hit on a very simple experiment. Take two similar glass vessels, with zinc electrodes at the bottom, and filled with a very weak solution of methyl-blue; and if an individual places one of his hands in each vessel, then when a constant current of from 10 to 20 milliamperes is allowed to pass for five or ten minutes the hand in the anode vessel becomes covered with blue spots, whilst the other is not marked. The spots appear most on the back of the hand, where the hair and fatty glands are situated. In the palm and around the nails they do not occur.

ELECTROSTATIC FORCES BETWEEN CONDUCTORS CARRYING CURRENTS.[1]

BY DR. O. J. LODGE.

BOYS had in vain attempted to measure the mechanical effect and also the thermal effect first observed by Gregory, who thinks the forces too small to be observed. Dr. Lodge pointed to some curious conclusions. He thinks that a small electric oscillator radiates to a moderate distance with greater intensity than terrestrial sunlight; but it must be remembered that if steady sunshine were as intense as the intermittent artificial radiation, metals would not only get heated by Foucault currents, but would send out torrents of sparks to contiguous pieces, especially when some period of solar vibration happened to agree with their own. The energy of solar radiation, however, is spread over a considerable range of wave length, the greatest portion of it being embodied in extremely short waves somewhat below the red end of the spectrum; whilst the energy of an artificial radiator is embodied in very much larger waves, mostly all of the same size.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, *150 Broadway, New York city.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them, are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. X. NEW YORK, NOVEMBER 19, 1890. No. 133

In a thousand years from now, or even sooner, the people who exist then may have minds that can see and understand easily phenomena which are now a mystery to us. We may be looked upon as an ignorant race, and what we have done considered nothing.—Thos. A. Edison.

THE VALUE OF THE STEAM JACKET IN ELECTRICITY.

IN one of his addresses Sir William Thomson has remarked that the electrical engineer ought to be nine-tenths a mechanical engineer, thereby indicating his observation of the fact that much of the work of the electrical engineer is mechanical in its nature. This statement need not be taken in its exact, literal phrasing; the truth and value are to be found also in its application. It certainly is true that the electrical engineer of to-day in designing and laying out work, involving lighting, power, electro-deposition or the like, is constantly called upon to devise the best plans and arrangements involving the use of steam; and hence in order to carry out his work intelligently, a thorough knowledge of steam engineering ought to be a part of his professional equipment. Ever since electric lighting became an established industry, for example, a discussion has been carried on as to the best type of engine to be employed for driving dynamos. The two factions which have been most prominent in this are, of course, those favoring respectively the high speed and the slow speed engine. While the discussion on this basis may be said to have left the question still unsettled, more recent controversies have somewhat shifted the field of battle so that now it may be considered to be one involving units of power, and leaving the question of the particular type of engine a little in the background.

The points now coming up are of the first interest to electrical engineers. The experience of the past has shown that the coal economy which can be derived from either type of engine *per se* can be made alike, practically, provided each is run *at its maximum capacity*, and hence when units of power are adopted and the arrangement is such that each is operated at its best load, the question of the type of engine is under these conditions no longer a matter of paramount consideration, so far as coal consumption is concerned. The relative cost of engines and floor space occupied by the two types for the same power is another matter, which, though entering into the calculations, does not bear upon the main point. But there are still some other points in steam engineering practice in which the electrical engineer is deeply interested, and one of these is the value of the steam jacket as an economizer of fuel. The father of the modern steam engine, Watt, was the first to recognize the value of maintaining the cylinder at as high a temperature as that of the steam entering it, and for that purpose first applied the steam jacket. Since that time the practice has been followed to a very large extent, yet strange to say, after one-hundred years, authorities still differ on the relative value of this adjunct to the steam engine.

In the paper just read by Prof. R. H. Thurston, at the Richmond meeting of the American Society of Mechanical Engineers, the author presents a magnificent résumé of facts and current opinions, as well as of authorities, on the steam jacket. After reciting the experiments of Watt, he traces the results obtained by a large number of steam engineers, who quite generally concede the value of the jacket, but who agree that the exact economy obtainable varies considerably with the nature of the engine and the conditions under which it is worked, depending upon the ratio of expansion, and whether the steam is worked in one or more cylinders, etc. The fact is also brought out that besides the steam jacket, the super-heating of steam prior to its introduction into the cylinder is another efficient means, and, under some circumstances, a more efficient one for preventing loss and condensation in the cylinder. Attention is also drawn to a fact which deserves more consideration than has been given to it in the past, namely, the application of hot gases from the chimney as a means of maintaining the temperature of the cylinder at its proper value.

With some of the best authorities agreed on the fact that steam jacketing involves a gain of from 15 to 20 per cent., the statement is also made by Prof. Thurston, and should be brought out prominently, viz., that a large proportion of the steam jackets in use are steam jackets in name only. Owing to the accumulation of water, or of air, or both of them, arising from the careless manner in which they have been made, or laziness on the part of the attendant, the ends for which the jackets are designed may not only be entirely frustrated, but they may even become a source of additional waste. Thus, instances are cited in which the jackets have been actually shut off and allowed to fill with water by the attendants in order to keep the engine room cooler! The pernicious effect of such carelessness is too obvious to require further comment.

It is curious to note, however, the more modern opinions on this subject, especially those of some of the designers of modern high speed engines. Thus the experiments of the Westinghouse Co. on their "Duplex No. 1," an engine

having both cylinders partly jacketed, showed no appreciable effect of the jacket, the saving of steam in the cylinder being fully equalled by the condensation in the jacket. Mr. F. H. Ball's experience indicates a measurable saving, but not enough to be considered important; his compound engines are, therefore, not in this respect improved by the addition of the jacket. It would, therefore, seem, and has also been expressed by some of the authorities, among them the well known engineer, Mr. John W. Hill, that the jacket is of unquestionable benefit when used under proper conditions and may be expected to improve the economy ten per cent. and perhaps more in some cases; but that the jacket is better adapted to low-speed high-expansion engines than with the higher speed modern engines of to-day, and that with the modern high pressures and initial temperatures, the value of the jacket becomes of comparatively little importance. Much also depends, as above stated, on the ratio of cut-off, the shorter the latter, the greater the gain of the use of the jacket.

We have deemed it well to devote this space to a brief résumé of Prof. Thurston's admirable paper and we hope that our readers who may have had experience in the application of the jacket will take up the matter and that it may lead to a discussion which will help throw more light on this important subject.

THE DIVIDED-EXCHANGE MULTIPLE SWITCH-BOARD SYSTEM.

In our issue of September 10, we published a description of the divided-exchange multiple switch-board system, invented by Mr. Milo G. Kellogg, of Chicago. Our description was founded upon one of Mr. Kellogg's United States patents, issued March 25, 1890, the application for which was filed December 8, 1887. A synopsis of the patent with drawings, claims and date of application, appeared in the *Official Gazette* of the Patent Office for March 25, 1890. We notice that substantially the same system is described by Mr. E. Bouchard in the issue for May and June, 1890, of *Annales Télégraphiques*, Paris. In view of the date of Mr. Kellogg's application for a patent, Mr. Bouchard's work on the same lines would seem to be subsequent to that of Mr. Kellogg.

This system of operating telephone exchanges promises to be of much value in the larger and growing "centrals," and seems likely to do for such exchanges what the multiple switch-board has already done for exchanges that have hitherto been deemed large, in the saving of apparatus and labor. The multiple switch-board system becomes useful when an exchange has reached about five hundred lines, and avoids the necessity of trunk-line service between the several boards until about ten thousand lines are reached. The divided-exchange multiple system would become of utility in exchanges, say, of about three thousand lines, and would, apparently, avoid the necessity for trunk-line service between the several boards in exchanges of any size likely to be constructed; that is to say, for as many lines as can ever be brought into one exchange. In the multiple switch-board system, now so largely employed, there is one switch-board for about every two-hundred lines, and each line requires a switch on each board of the exchange. In the divided-exchange system the switch-boards are divided into several divisions (two or more according to the number of lines); the lines are divided into the same number of divisions. Each line has a switch on each board of its own division, and on one board only of each of the other divisions. Thus, with a two-division system, as compared with the ordinary multiple system, there would be only one-half as many switches plus one for each line, and practically twice as many lines can be operated with the same quantity of apparatus. With a four-division system there would be only one-fourth as many switches plus three for each line as are required in the ordinary multiple system, and nearly four times as many lines can be operated. It is obvious that further sub-division can be made as exchanges grow larger, with a similarly increasing rate of gain in apparatus and labor.

Mr. Kellogg has, we understand, worked out the divided system in its details for any number of divisions and for any system of exchange operation, whether for ground circuits, metallic circuits, or mixed lines. Telephone engineers will, we think, look with interest upon Mr. Kellogg's system and its practical operation in a large exchange.

LONG-DISTANCE BUSINESS COMMUNICATIONS.

The recent excitement in Wall street, and the sympathetic agitation in business circles, has, of course, been the means of keeping the wires very busy. The tickers have had all they could carry, and we understand that the Atlantic cables have also been subject to the strain of an enormous volume of traffic. The land telegraph lines are tolerably equal to the burden put on them, provided a little delay does not matter to the sender and receiver, but at such times as the recent ones the long-distance telephone service, abolishing delay, preventing ambiguity and bringing interested persons directly together, even if hundreds of miles apart, proves at once its value and superiority. Evidently wherever direct and swift communication is desired between parties widely apart nothing can possibly compete with the telephone, if available, but this is not as fully grasped by the financial and mercantile community as might be expected. A late experience of The Electrical Engineer has done more to inform us of the benefits of long-distance telephoning than any quantity of outside testimony could do in the way of conviction. The business manager of the journal being away in Philadelphia, he called up the New York office, whereupon a big batch of morning mail was read to him and replies were dictated to a stenographer in New York. So successful was the experiment, it has since been repeated more than once, and has become a practice on every such occasion. In this manner, continuity of work is kept up, no pressure or uncertainty is caused by absence, and both ends of the line are fully informed. We are not aware that the dictating of a heavy mail or scores of letters has been done before, but we can heartily recommend it as a new and successful feature of business economy and efficiency.

Lighting the New York Elevated Trains.

The statement recently made exclusively in The Electrical Engineer to the effect that the Manhattan Elevated Railway had been considering electric lighting for its cars, has been contradicted. The statement was and is, however, perfectly true. Col. Hain says that no plan has been formally accepted, and that $200,000 would be required. The fact that he names a sum at all is ample proof of our statements, which were to the effect that estimates had been made, even down to details.

ON THE BEST DIMENSIONS FOR STANDARD OPTICAL AMMETERS AND VOLTMETERS.—II.

BY A. E. KENNELLY.

Ammeters.—If the instrument is intended for an ammeter, it will be necessary to wind it with coarse wire up to the heat limit. The diameter which will attain this for a given maximum current, c amperes, is expressed by the equation

$$d^2 = \frac{a\,c}{\pi}\sqrt{\frac{8\,m\,\rho}{h\,q\,b}}, \tag{15}$$

where $b = a\sqrt{1 + \frac{4\,m}{\pi\,q}\left(\frac{D}{d}\right)^2}$, as before.

For example, suppose it were required to determine the most effective winding for an optical ammeter of 50 amperes maximum capacity, the length of tube being 80 cms., the winding diameter 1.3, and the weight of copper wire 8 pounds, the instrument to be kept permanently in circuit ($h = 0.01$).

Since the wire will be coarse, $\left(\frac{D}{d}\right)$ will be 1.02, say. Then $b =$

$$1.3\sqrt{1 + \frac{4 \times 8 \times 454 \times 1.02 \times 1.02}{3.14 \times 3.14 \times 1.3 \times 1.3 \times 80 \times 8.95}} = 1.956;$$

and $d^2 =$

$$\frac{1.3 \times 50}{3.14}\sqrt{\frac{8 \times 8 \times 454 \times 1.8 \times 10^{-6}}{0.01 \times 3.14 \times 1.3 \times 1.3 \times 80 \times 8.95 \times 1.956}} = 0.5489$$

$$d = 0.741, \text{ or } 0.292''.$$

The amplitude obtainable at full load in this case would be by (1), and (4),

$$\theta = 1.257 \times 50 \times 0.0420 \times 80 \times \left(\frac{1.956 - 1.3}{0.75 \times 0.75}\right) = 235', \text{or } 3°55'$$

subject to slight correction for polar influences, and for temperature.[1]

When the instrument is needed for an ammeter in a circuit containing resistance in such a degree that the heat limit cannot be reached, the above formulas no longer apply.

Let E be the E. M. F. of the circuit, and β its resistance.

Then $$c = \frac{E}{\beta + r};$$

whence $$\theta = \frac{4\,\varphi\,E}{10\,(b + a)}\sqrt{\frac{m}{\rho\,\sigma}} \times \frac{\sqrt{r}}{\beta + r}$$

Differentiating this with respect to r and equating to zero, we have for the maximum value of θ, $r = \beta$; or the resistance of the instrument should equal that of the rest of the circuit, and then

$$\theta = \frac{E\,\varphi}{5\sqrt{\beta}\,(b + a)}\sqrt{\frac{m}{\rho\,\sigma}}. \tag{16}$$

Substituting the values already stated for ρ, σ, and φ,

$$\theta = \frac{2.09\,E}{(b + a)}\sqrt{\frac{m}{\beta}} \text{ where } b \text{ is found by (8)} \tag{17}$$

To find d in this case, we have the relation

$$d^2 = \frac{4}{\pi}\sqrt{\frac{m\,\rho}{\beta\,\sigma}}; \tag{18}$$

or, $$d = 0.0239\sqrt[4]{\frac{m}{\beta}} \tag{19}$$

1. It may be remarked that in this case the calculated diameter of the wire (0.74 cm.) is too great for the coiling depth ($b - a = 1.956 - 1.3 = 0.656$) that eight pounds of wire spread over the whole length of tube will occupy. This discrepancy must occur whenever the weight of wire allowed is incompatible with the current strength to be measured, and the external radiating surface of the helix. The remedy in such cases is found in shortening the helix or increasing the weight of wire.

Thus, suppose the most effective winding to be found for an instrument to indicate the E. M. F. of one Leclanché cell of 1.5 volt, having a resistance of 1 ohm, using 10 pounds of wire and with the dimensions $l = 60$, $a = 1.2$ and $m = 4536$; $\left(\frac{D}{d}\right) = 1.18$.

Here $b =$

$$1.2\sqrt{1 + \frac{4 \times 4536 \times 1.18 \times 1.18}{3.14 \times 3.14 \times 1.2 \times 1.2 \times 60 \times 8.95}} = 2.49;$$

and $$\theta = \frac{2.09 \times 1.5}{2.49 + 1.2}\sqrt{\frac{4536}{1.0}} = 57' \pm;$$

while $d = 0.0239\sqrt[4]{\frac{4536}{1}} = 0.196$, or $0.077''$.

The above formulas enable the best size of wire to be found for all the conditions that are usually met with in practice. They have been proved practically reliable by experiment in the Edison Laboratory, the only constants about which there remains any uncertainty being the heat values 0.01, and 0.02, which are estimates fairly reliable.

The formula of correction for the polar influence of the helix upon its magneto-motive force, may be given in conclusion.

Let the accompanying diagram represent a longitudinal section through the axis of the tube and encircling helix. The tube is supposed to be set symmetrically in the helix, so that the distances d from the extremities to the terminal planes of winding are equal. While not essential, this adjustment is generally easy and abbreviates the correctional formula. Let l_1, l_2, l_4, l_6, be the distances, as shown, from one extremity of the axis in the tube, to the circumferences of the coil, while l_3 and l_5 are the corresponding distances to the mean circumference. Then equation (3) becomes more strictly

$$\theta = \varphi\left\{\frac{4\,\pi}{10}\,N\,c\left(\frac{l_5 - l_3}{l}\right)\right\}. \tag{20}$$

This formula corrects the length of the helix for the polar influence of a similar solenoid of like length and current turns, but of indefinite thinness fixed at the mean circumference. The amount of the correction is with long tubes so small, that this approximation is sufficient. When the correction needs to be made with more care, the formula is

$$\theta = \frac{2\,\pi\,c\,\varphi\,N}{10\,l\,(b - a)}\left\{b\,(l_6 - l_1) - a\,(l_4 - l_2) + D^2\log_e\left(\frac{l_6 + b}{l_4 + a}\right) - d^2\log_e\left(\frac{l_1 + b}{l_2 + a}\right)\right\} \tag{21}$$

where $D = l + d$.

This formula is often independently useful for the determination of magnetic differences of potential between points measured along the axis of a homogeneous coil, and equidistant oppositely from its mid-plane.

As an example, suppose the sodium line rotation to be required by computation from a uniform helix of 50,000 turns of length $l = 30$, and radii $a = 2$, $b = 4$, when carrying 0.1 ampere, over a tube 34 cms. long.

Formula (3) gives $\theta = \frac{4}{10} \times 3.142 \times 4.2 \times 10^{-3} \times 50,000 \times 0.1$
$= 263'.9 = 4°\,23'\,50''$.

By formula (20) $\theta = 4.2 \times 10^{-3} \times \frac{4}{10} \times 3.142 \times 50,000 \times$

$$0.1 \times \frac{(32.14 - 3.61)}{30} = 251'\,1 = 4°\,11'\,6''$$

By (21)

$$\theta = \frac{2 \times 3.14 \times 0.1 \times 4.2 \times 10^{-2} \times 50{,}000}{10 \times 30 \times (4-2)} \Big\{ 4\,(32.25 - 4.47) - 2\,(32.06 - 2.83) + 1024 \log_\varepsilon \left(\frac{32.25+4}{32.06+2}\right) - 4 \log_\varepsilon \left(\frac{4.47+4}{2.83+2}\right) \Big\} = 250'.5 = 4^\circ\ 10'\ 30''.$$

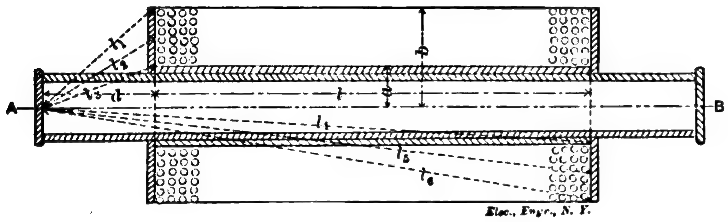
These equations of course enable the current to be determined in absolute measure when the amplitude of rotation is correctly observed, and the geometrical data of the winding are given.

The rotation obtained for a given current, really varies slightly with the temperature of the bisulphide of carbon liquid.

M. Bichat has given the following formula for reducing the rotation observed at one temperature, to that at another,

$$R_t = R_o\,(1 - 0.00104\ t - 0.000{,}104\ t^2),$$

where R_t is the rotation at t° c., R_o being the rotation at zero. From the standard value of $\varphi = 4.2 \times 10^{-2}$ and this formula, we have the following table of temperature values for the Verdet constant of carbon bisulphide:



Kennelly On Electro-Optical Measuring Instruments.

t° c	ϕ	t° c	ϕ	t° c	ϕ

RÉSUMÉ.

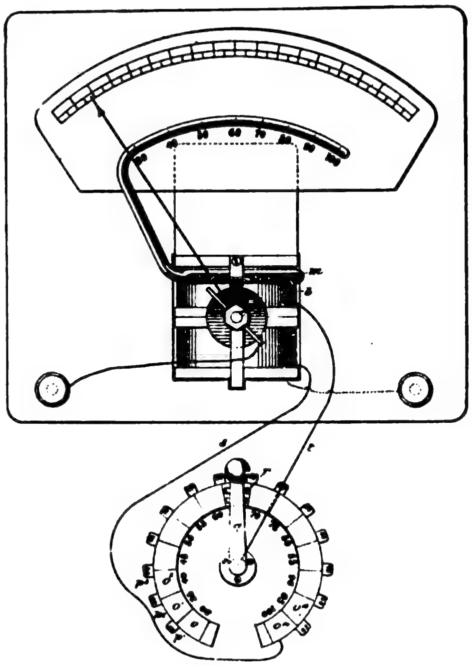
The amount of rotation obtainable from an optical ammeter or voltmeter, varies as the square root of the weight of copper used in the winding when used most effectively. It also varies as the square root of the ratio of length to internal diameter of helix, so that the length should be as great as possible, and the internal diameter as small as possible, consistent with good optical conditions. There exists a practical limit to which the rotation obtained from any such instrument is subject, owing to the heat developed in the coil by the current. This limit is about 25° according to the estimates here given for currents of short duration, and 18° for instruments permanently in circuit. No theoretical limits are however prescribed if the thermal effects can be obviated. The best sizes of wire to employ for different instruments when the dimensions of the tube and weight of wire have been decided upon, are given in formulæ with examples, together with corrections for virtual length, by which currents can be determined from good apparatus in absolute measure with an accuracy of at least one part in 750.

WESTON'S TEMPERATURE REGULATOR FOR MEASURING INSTRUMENTS.

Among the errors to which electric measuring instruments are subject, is that due to the heating of the coils by the passage of the current. This evidently increases their resistance and changes the value of the readings indicated. To avoid this as much as possible recourse is had to wire having as low a temperature coefficient as possible; but such wire of German silver or platinoid is very expensive when the finer sizes are employed, and hence it becomes desirable to retain copper wire if some means can be provided for correcting the error due to the change in resistance resulting from temperature variations.

Realizing this disadvantage, Mr Edward Weston has recently brought out an important addition to his well known and admirable instruments consisting in a temperature regulator, but which is, of course, applicable to instruments wound with whatever kind of wire.

In order that variations in temperature may be recognized, Mr. Weston provides a thermometer m, the mercury bulb of which is elongated, and is curved and fastened directly against the exterior of the coil. The thermom-



Weston's Instrument Temperature Regulator.

eter-tube is bent, as shown, and arranged upon the scale-plate and in a curve parallel to that of the scale-markings. By means of this thermometer the temperature of the coil is shown upon the same scale-plate as the regular indications of the instrument.

A series of contacts o to o^{14}, insulated from one another, are arranged in a circle, and between the successive contact-plates are included resistance-coils p^1, p^2, p^3, etc. Pivoted concentrically with the circle of contact-plates is a switch-arm q, having contact-springs bearing upon the surface of the contact-plates o.

This device is interposed in the circuit of the fixed coil, and is connected to it by the wires s t. The contact-plates o o', etc., are marked to correspond to the thermometer-scale. Thus the contact-plate o is marked "30" to correspond to the 30° mark of the thermometer, the contact-plate o' corresponds to the 35° mark of the thermometer, and so on, the contact-plate o^{14} corresponding to the 100° mark. When the arm q is placed on the contact-plate o, it will be evident that the current in the instrument then passes through all the resistances p, p^1, p^2, and p^3.

Suppose, for instance, that this is the starting point of

temperatures, and that the heat of the coil increases so that the thermometer shows a temperature of 65°. This means an increase of resistance in the coil due to the 65° difference of temperature. In order to compensate for this the switch-arm q is moved around until its contact-spring rests on the plate o^7, marked "65." Seven resistances p p' will thus be thrown out of the circuit, and as each resistance corresponds to the increase of resistance in the coil due to the elevation of 5° of temperature, it follows that by throwing out seven of these resistances we have exactly compensated for the increased resistance of the coil due to its increased heat.

In practical operation, therefore, it is simply necessary to note the indication of the thermometer and place the arm q on the contact-plate mark corresponding to that indication, in order to keep the resistance of the circuit in the instrument uniform.

THE WORK AND RESPONSIBILITIES OF THE "LOCAL ELECTRICIAN."

BY T. C. MARTIN.

TURNING over the pages of a well-known architectural journal the other day, my eye caught the remark: "Electric bells, in the architect's opinion, generally, are an unmitigated nuisance, because, possibly, their battery connections are so poorly wired, and in this case, as in others, his judgment is formed from results, not indications of what might be done if there were no *if* in sight." One can readily find food for reflection in such a cold-blooded criticism as that of ordinary electrical work; and it becomes impossible, in fact, not to recognize the truth that the "local electrician," by whom so much of the electrical bell-hanging is done, is a very important element in the electrical economy.

Uncertainty and anxiety with regard to the operation of such common appliances as electric bells, tnan which nothing should be more sure and regular in operation, or more easily maintained in efficiency, lead to distrustfulness respecting other apparatus of an electrical nature. It is not likely that a householder whose cheaply set up bells have given out on an average once a week will be very suddenly convinced of the reliability of the incandescent light. Reasoning from known to unknown, he is apt to think that one is as bad as the other. Nor is he likely to be very sympathetic and enthusiastic when invited to co-operate in the establishment of an electric railway. Evidently, the "local electrician" can make or mar other fortunes as well as his own.

The opportunities that present themselves to the local electrician are not to be despised. On the contrary, they have become such as should tempt anyone to make the most of them by winning first a reputation for good work, and then devoting his energies to getting in all the installations he can. The wonder is that more of the young men who leave our schools and colleges every year well grounded in electrical theory and practice do not take up the local supply business as a means of honorable livelihood. Every town or city of fair size offers chances of this kind, and large general supply houses are now so numerous, so well stocked and so handy that goods can be obtained in a day, unless special devices are required.

It is true that in many instances the local electrical business has been skillfully worked up, but, on the whole, it is the merest beginning of what it might be. I have been living in New York and Brooklyn for nearly fourteen years. During the whole of that time, although dwelling in populous neighborhoods, where trade could be easily drummed up, I have never once had the circular of a local electrician left at my house. In New York, where I now live, the avenues nearby show the signs of more than one "electrician, bell-hanger, and lockfitter," yet never have those worthies favored me with a polite request to be allowed to do a little electrical work for me. Some of them are excellent people, busy all the time on new residences and apartment houses. Others, when I have visited their stores, have handed me out sal ammoniac of the consistency of granite, or if asked for a bell showed one with binding posts gone.

The house I live in was wired in a very perfunctory manner, with the result that some of the circuits I have not yet been able to coax up to the working point. The batteries were installed on a small shelf in the cellar right under the floor beams and in the dark. The shelf is immediately in front of the winter furnace, so that the rate of evaporation of the electrolyte between October and May is about the highest that could be attained. Of course I have remedied this state of things to some extent, but no one cares to plunge heavily into rewiring a whole house that doesn't belong to him. A few "interior conduits" at the outset would have been a perfect boon, and the wonder is that any new house is built without them. I know that the state of affairs I describe is not exceptional, since, like most people reputed to be interested in electricity, I am now and then invited by neighborly folk to look in and tell them what is the matter with their bells.

The average resident in a city is too busy to bother with his bells, and often too pushed for time to go even half-a-dozen blocks out of his way for the local electrician. Hence, the bells, once out of order, often stay so for two or three days to the exasperation and confusion of every body concerned, whether occupants of the house or callers there. Now, could not the local electrician undertake for a small fixed sum, per month, or quarterly, to keep bells, batteries and circuits in order, calling to make necessary repairs and renewals? I believe such a service, diligently and honestly rendered, could be made to pay handsomely. There are many doctors, too, ready to pay a good round sum for having their medical batteries kept up to efficiency.

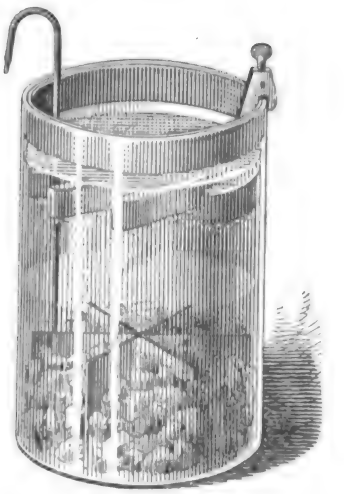
Every week sees the announcement of some ingenious electrical novelty for the house or office, and the big supply houses vie with each other in bringing out these goods attractively, at moderate cost. Yet, how few of them reach the would-be user and consumer of them! During the past summer, I often heard people ejaculate the wish that they could have in their houses the cooling little electric fans that mitigated the heat down town. All that was necessary was the canvassing of the residential districts, the installation on trial for a few days—and then the certain sale. In the case of primary batteries for current, there would at once be a market for renewals.

As with fans, so with motors for sewing machines, annunciators, floor and table pushes, burglar alarms, electric clocks, electric time and date stamps, small incandescent lamps for special decorative effects, and a dozen other appliances. If people do not know of these things, they do not call for them, though they may want them. If attention is directed to them, some will be sold at once, to serve in turn as an advertisement, creating a demand for more.

It is no exaggeration to say that if this local business were exploited to its fullest degree in each community, the stimulus to electrical industries would be as great as that from the development of electric lighting or electric railways. I look forward to the day when more will be made of such opportunities than is the case now. But the advance must evidently begin with better work, so that electric bells may cease to be an "unmitigated nuisance" to the architect, who is already showing himself so willing to employ electrical devices and appliances if trustworthy. Life is too short, anyway, for poor work, and if an electrician's prosperity depends, as it must largely, on the esteem in which his installations are held, it is the worst folly to use rotten material, scamp a job, and then ask a low price because it has been cheaply done. The public is ready to pay a fair price for electrical work when assured of honest material and skilled workmanship; and it will be the readier to believe in electrical engineering as a profession when its front door bell rings regularly.

THE DELANY BATTERY STRIP FOR PREVENTION OF "CREEPING."

One of the inconveniences which has attended the use of many forms of battery, especially those of the gravity and Leclanché type, is the creeping of the salts, and many devices have been applied to overcome the difficulty, but thus far with comparatively little effect. We are, therefore, glad to note the success of a very simple expedient for the prevention of this evil, due to the well known inventor, Mr. P. B. Delany, of South Orange, N. J. For this purpose Mr. Delany applies to the top of the cell, on the inside, a strip of rubber cloth, as shown in the accompanying engraving. The rubber offers a mechanical obstruction to the creeping salt, which accumulates underneath the strip,



Delany Battery Strip to Prevent Creeping.

and is re-dissolved in the battery fluid whenever water is added to make up for that lost by evaporation.

As creeping of salts is a fruitful source of local action and waste in batteries, the application of the strip affords a distinct gain. Besides, owing to the cleanliness obtained, batteries can be placed in wardrobes, closets or even on carpets, with perfect safety.

It is over a year ago that Mr. Delany first showed us this simple appliance, but he has thought it well to give it a thorough trial before offering it as a practical method. The results of a year's test have been such, that its value is now thoroughly established, and hence its commercial introduction.

RAWSON'S METHOD OF IMPREGNATING INSULATING PARTS.

In a patent recently issued to Mr. Frederick L. Rawson, of London, the inventor describes a new method of preparing a compound to be used for the bases of electrical instruments, casing or conduits for conductors, and generally those parts of electrical apparatus or machinery where insulation is required.

For this purpose there are first intimately mixed about six parts, by measure, of Portland cement with one part of plaster-of-plaster, and with sufficient water to convert the mixture into a paste suitable for molding under addition of a proportion of clean sand. This paste is molded to the form desired, coring in it such holes as may be necessary for bolts or other attachments, and molding in it such metal parts as may have to be permanently attached to it. After the material has set in the mold it is removed and dried slowly at a moderate temperature during ten days or more, the time depending on the mass that has to be dried and the degree of hardness required. The molded article may be further hardened by immersing it for a day or more in a solution consisting of equal parts of silicate of soda or potassium and water.

When the molded article is sufficiently dry and hard, it is heated to about 105° or 110° Centigrade and then submerged in a bath of molten ozokerite or paraffine-wax. When the molten material has cooled down to about 95° centigrade, the molded article is removed from the bath and cleared of the superfluous matter adhering to it.

In making boxes or tanks which cannot be conveniently immersed in a bath of the impregnating material, Mr. Rawson provides a closed metal vessel that can be put inside the molded article, leaving a space all around it to receive the impregnating material. This vessel is charged with steam at a temperature of 105° to 110° centigrade, so that the material is kept in a liquid condition as it soaks through the thickness of the box or tank. The article thus impregnated with the oily matter is hard, strong, tough, and incombustible and has high electrical resistance, so that it forms a good insulator, and being protected against access of moisture, it permanently retains its insulating properties.

JEANCON'S PROCESS OF ELECTRO-DEPOSITING ALUMINUM.

The valuable properties possessed by aluminum—coupled with the fact that it can now be obtained in a pure state at a greatly reduced cost—make it appear as probable that this metal may be largely employed as a protecting coating for others upon which it is deposited.

Considerable difficulty has, however, been experienced in the past in depositing aluminum electrolytically, and according to Mr. John A. Jeançon, of Newport, Ky., this is largely due to the readiness with which aluminum in a state of fine subdivision decomposes water, forming a hydrated oxide in the deposit and preventing the deposition of a sufficiently heavy layer for practical uses. This oxidation readily occurs even at a temperature of 100° Fahrenheit, and prevents further deposition of metal, either from the anode or from the electrolyte.

To avoid this action, Mr. Jeançon employs a saturated solution of persulphate of aluminum, that is to say, an acid sulphate of aluminum requiring a high temperature (about 180° to 200° Fahrenheit), to prevent crystallization. This high temperature is important not only in preserving the condition of supersaturation of the solution, but also in facilitating the dissolution of the molecules of the salt in the performance of the electrolytic work of the current, which in this case is of very low intensity, but of great quantity.

The anode is a plate composed of commercial aluminum having incorporated with it a separating substance affected neither by the current nor by the solution. This is prepared by melting the aluminum in a crucible and stirring in about thirty per cent. of carbon or some other substance inert in the sense above indicated. Mr. Jeançon finds carbon to be preferable, and the union, which is probably largely mechanical, is facilitated by the presence of a small quantity of hydro-carbon. The aluminum takes up an indeterminate quantity, and while agitated the mass is run out into flat molds and congealed.

The composition of the anode, according to Mr. Jeançon, modifies the action, probably, in several particulars: First, the uniform separation of the metallic molecules tends to distribute the current over the entire surface, thereby breaking up the electrolytic action into a vast number of lines of force of reduced intensity diffused throughout a wide area in relation to the cathode, while at the same time polarization is prevented; second, the separation of the metallic molecules of the anode increases by porosity the metal surface exposed to the dissolving action of the electrolyte without unduly enlarging the given field of conduction through the liquid to the cathode, thus facilitating the union of the freed oxygen with the anode molecules and in a manner protecting the deposited metal.

The process described is claimed to give a dense reguline deposit of aluminum.

THE WORKING OF AN ELECTROLYTIC COPPER REFINERY.[1]

BY DR. G. GORE, F. R. S.

THE entire economy of working depends essentially upon cheapness of motive power and minimum investment of capital, and nearly every attempt to improve the process, in the direction of such economy, involves a choice between two evils. For instance, if we try to save horse-power by enlarging the electrodes and adding to the number and size of vats in series, we rapidly increase the loss of interest upon capital expended in stock of copper, solution, plant, working space, etc. If we increase the density of current with the intention of working more rapidly with the same stock of copper, solution, etc., we increase the loss of energy by causing polarization, and run a risk of depositing impure copper. And if we attempt to diminish the resistance by placing the electrodes nearer together, or by quickly stirring the solution, we get dirt upon the cathodes, or short-circuiting occurs; and if we endeavor to decrease it by considerably heating the liquid, we rapidly increase the chemical corrosion of the deposited metal, and quickly alter the chemical composition of the liquid; or if we diminish resistance by large additions of acid, we promote chemical corrosion, polarization, and separation of gases.

Difference of potential required is a large element in the economical deposition of copper. Whilst the same number of amperes of current passing through the ordinary solution deposits the same amount of copper in all cases, the necessary degree of difference of potential to overcome resistance, etc., varies in different cases; and the greater this difference the larger the cost; double the potential requires double the motive power. It is desirable, therefore, to lower the difference of potential as much as possible by diminishing the resistance throughout the circuit, and by avoiding all polarization and counter electromotive force.

The degree of electromotive force required varies with every different kind of solution, and consequently of anode. It varies according as the anode is composed of pure copper, "black copper," or "copper matte," and whether the anode is clean, or covered with an adhesive badly-conducting coating; it is also much greater when gas is evolved at either electrode.

Influence of Impure Anodes upon the Liquid.—I will only speak of some of those substances which are more or less likely to be present in "black copper," "pimple copper," "Chili bars," "blister copper," containing from 89 to 98 per cent. of copper, and in cruder regulus of reduced pyrites of iron and copper. Those impurities include antimony, arsenic, bismuth, cadmium, carbon, cobalt, gold, iron, lead, manganese, platinum, silver, tin, zinc, suboxide of copper, sulphides of iron, copper, and silver in the particles of unreduced pyrites of those metals, alumina, lime, magnesia, silica, and alkalies in the enclosed portions of slag. Black copper has been found to contain "1.28 per cent. of arsenic, 1.0 of iron, .54 of sulphur, .4 silver, and .011 of gold." (*Engineering*, 1885, p. 306.)

In an acidulated solution of blue vitriol, the following of those substances, viz., cadmium, cobalt, iron, zinc, sulphide of iron, alumina, magnesia, and alkalies of the slag, dissolve readily; antimony, arsenic, bismuth, tin, and silica dissolve imperfectly, and partly fall to the bottom; carbon, gold, platinum and sulphur from the pyrites are insoluble, and precipitate entirely; lead is converted into sulphate, which almost wholly precipitates; silver is changed into chloride, provided a soluble chloride is present, which is usually the case, and is entirely thrown down; suboxide of copper, and the sulphides of copper and of silver, also precipitate. The lime is all changed into sulphate, a small quantity only of which enters into solution, whilst the remainder subsides.

One effect of using an impure metal or an alloy as an anode is, that its different constituents are corroded unequally, both by the ordinary chemical action of the liquid and by the influence of the current. By both these actions the most electro-positive metals are attacked first, and the others in succession, in accordance with the thermal law which governs such actions; and those which are not corroded at all, together with those which form insoluble compounds, either remain upon the surface as a coating, or fall to the bottom as mud.

In an anode containing copper, copper oxides and sulphides, the current goes most by the path of least resistance, *i. e.*, very largely by the metal, very little by the sulphides, and much less by the oxides. If, therefore, the anode contains very little sulphide or oxide, the whole of the current travels through the copper, and the oxide and sulphide fall to the bottom; but if it contains much sulphide, some of the current passes through it. At the same time, independently of the action of the current, the liquid is always acting chemically upon each of these substances, whether they form part of the anode or of the sediment.

It is evident that when the anode contains a large variety of impurities the chemical actions going on at its surface must be numerous and exceedingly complex, and modify each other, and make it very difficult to accurately describe them. One effect of those numerous impurities is to cause an almost infinite number of local electric currents all over the anode, attended by corrosion and solution of all the more positive substances without the aid of the external current, thus gradually neutralizing the free acid, and saturating the water with metallic salts.

Influence of the Impurities upon the Current.—Provided the anodes are wholly metallic, their lower degree of electric conductivity due to impurities has very little effect upon the total resistance of the circuit, because the resistance of the solution is so very much greater. Consequently, also, it has but little effect upon the kind of dynamo required.

Impurities in the anode, however, have in some cases a great effect upon the electromotive force and upon the strength of current, either by giving rise to polarization and counter electromotive force, or by the formation or accumulation of badly-conducting substances upon the anode. The greater the number of impurities also the greater the risk of waste of energy.

It is a fact that the electromotive force, and consequently also the strength of current, is increased when the anodes contain as impurities metals such as zinc, cadmium, manganese, or iron, which are more electro-positive than copper in the particular liquid, because they constitute with the copper cathode a voltaic couple sending a current in the same direction as the working one. But this assistance to the current, except with iron pyrites, is usually so very small that it is hardly observable, and the advantage of it is more than counterbalanced by disadvantages. The presence of iron in the anode aids the current to only a small extent, but that of zinc helps it more.

When the solution contains persalts of iron or manganese those salts are reduced to proto salts at the cathode, and a portion of the current is continually wasted in reducing them, instead of being wholly employed in separating copper, and the copper costs more to refine than when no iron or manganese is present. As long as there is sufficient persalt of iron in the liquid, no hydrogen is evolved at the cathode. With a copper-depositing solution containing much salt of iron, the difference of potential of plates of pure copper of a single vat has been found by experiment to be .22 volt, with an anode of black copper .25 volt, and with one of copper pyrites .5 volt, and when the solution was deficient in free acid, it was .35 volt with black copper, and .75 volt with copper pyrites. (Kiliani, *Engineering*, Vol. XL., 1885, p. 306.)

Effect of Impurities of the Liquid upon Purity of the Deposit.—The electrolyte is always less impure than the anode, because various of the impurities of the latter are either loosened by corrosion of the surrounding metal, and separate and fall to the bottom unchanged; or they are separated from their compounds by chemical or electro-chemical decomposition and subside; or they are converted by chemical action into insoluble compounds, which precipitate.

During the process of deposition the electrolyte continually becomes more impregnated with impurities, especially with iron, and, in much less degrees, also with zinc, manganese, cobalt, nickel, tin, arsenic, antimony, bismuth, aluminum, calcium (within small limits), magnesium, potassium, and sodium, and gradually poorer in free acid, and sooner or later, requires to be purified.

Influence of Impurities of the Liquid upon the Current.—The greater the number of impurities in the electrolyte the greater the risk of waste of electric energy. All ordinary sulphate of copper solution used in the electrolytic refining of copper contains, after a time, forms a greater or less proportion of dissolved ferrous sulphate, and this substance gradually combines with the oxygen of the air and becomes persalt. In such a mixture there is liable to occur a considerable waste of current and deficiency of deposited copper—1st, because much of the electric energy is wasted in deoxidizing the persalt at the cathode; and 2nd, because a solution of persalt of iron corrodes and dissolves copper; the free acid therefore decreases, and the liquid acquires greater specific gravity. The presence of green vitriol, however, prevents polarization at the anode, because it absorbs oxygen.

Purity of the Deposited Copper.—It is a mistake to suppose that electro-deposited copper must be pure; if it has been deposited rapidly from an impure solution it may be very impure.

Of all the various circumstances already described which tend to produce purity of the copper, the most important are:—1, Absence *in solution* of all the metals which are the most readily deposited with it: these are silver, bismuth, antimony, arsenic, and tin; 2, using a sufficiently moderate density of current at the cathode; 3, keeping the solution perfectly clear and well circulated; and 4, not allowing any of the mud from the anode to touch the cathodes. All other conditions being alike, the most slowly deposited metal is the most pure.

There is usually not much risk of depositing any other metal than copper (and silver or bismuth if in solution) under the ordinary conditions of working when the density of current does not exceed 5 amperes per square foot, or the rate of deposition is not more than 70.7 grains per square foot per hour, and the increase of thickness is not greater than 1.07 millimetres, or .04 of an inch per week of 156 hours. At Stolberg, with an impure solution, and a density of current of 1.482 ampere per square foot, the purity of the deposited copper is stated to be "99.92 and 99.95 per cent. in two analyses." One source of impurity is fine powder from the anodes diffused in the liquid.

1. Abstract from *The Electrician*.

Cost of Electrolytic Refining.—The cost of refining copper by electrolysis varies with the magnitude of the installation, and depends essentially upon the expense of motive-power, and of interest upon invested capital; also largely upon the degree of "commercial efficiency" of the dynamo, and upon the kind and amount of impurities in the crude metal, which are continually varying, because the composition of each batch of unrefined copper differs. The larger the proportion of foreign metals which are easily deposited with the copper, and the purer the refined copper required, the greater the cost of the process, because it must be conducted more slowly. The cost when anodes composed of the unreduced sulphides of copper and iron are employed instead of metallic copper, as in "Marchese's process," is considerably different.

Where motive-power or fuel is cheap, advantage is taken of the circumstance to economise the expenditure upon vats and copper, by using it more freely. At Casarza, where water-power is cheap, the proportion of copper deposited is 1.4 lb. per horse-power per hour; at Pembrey, where coal is cheap, it is 2.6 lb.; but at Hamburg, where motive-power and fuel are dear, it is 6.87 lb. The amount of electric energy and of horse-power consumed in depositing the same weight of copper differs in nearly every electrolytic refinery. Where coal is cheap, and the process is conducted on a large scale, with a good steam engine, at least 110 indicated horse-power is obtained during one week by the consumption of 50 tons of coal, and with good dynamos will deposit 20 tons of copper per week, at a cost of £20. The interest upon capital invested in plant, etc., during the same period will amount to about a similar sum. Or, if we reckon the cost of one mechanical horse-power at one penny per hour, the cost of such power for electrolytic refining of copper is about one farthing per pound of that metal refined. Difference of potential required to overcome resistance and polarization is also an element in calculating the cost of depositing a given amount of copper, because double the electromotive force expended costs quite double the money.

The chief elements of cost are:—1. Interest upon capital expended upon copper, electrolyte, vats, steam-engine, boiler, dynamo, and other plant. 2. Fuel, water, and oil for the engine. 3. Rent and taxes. 4. Labor. 5. Depreciation of steam-engine, boiler, dynamos, vats, etc. 6. Incidental expenses.

The total stock of copper required in order to refine a given amount of that metal per day or week varies in different works. In each refinery, besides the amount of copper in the vats, there is at least an equal quantity in the form of main conductors, raw copper for making anodes, new anodes ready for immersion, and residues of old anodes, also the stock of refined copper. The value of the stock of copper alone in one of the installations at Hamburg has been estimated at "£8,000." Practically, to refine 30 tons a week of ordinary "Chili bars," with a current density of 8 or 10 amperes per square foot, requires a total stock of about 400 tons of copper, which, at £50 a ton, costs £20,000, to which we must add about £10,000 for plant and premises.

A number of workmen are necessary, probably about twenty, working day and night, when depositing thirty tons of copper per week, to manipulate the electrodes, examine the vats, and attend to the steam-engine and dynamo, melt and cast anodes, wash dirty ones, etc. A chemical analyst is also employed to analyze the copper and the electrolyte. As stoppages in the process do not often occur, they are not a large element of expense; there is, however, the cost of occasionally emptying the vats, evaporating and purifying the solution, collecting and treating the mud, etc.

In consequence of the numerous circumstances which affect the cost, an approximately satisfactory estimate of the total amount of capital required to be invested in establishing an electrolytic refinery to deposit a given amount of copper daily, can only be arrived at by means of a knowledge of all the essential particulars in the given case.

Recapitulation.—In establishing an electrolytic copper refinery, the chief points usually require to be settled in the following order:—1st. The amount of copper to be deposited per week. 2nd. Amount of mechanical power required and the kind of motor. 3rd. Degree of purity of the solution and of the crude metal. 4th. Rate of deposition per square foot of cathode surface per week. 5th. Total amount of cathode surface necessary. 6th. Total number of vats in series. 7th. Magnitude of each vat. 8th. Electromotive force and strength of current necessary. 9th. Kind of dynamo. 10th. Magnitude of the main conductors. There are, of course, other important points to be first considered, such as the most suitable locality for cheap motive-power, cheap conveyance, etc., but those do not come within the intended scope of this article.

THE FORT WAYNE ELECTRIC CO. have just sold a 75 light arc machine to the Marion Electric Light Company, of Marion, Ind. Mr. W. J. Buckley, Western manager of the company, has recently sold a 1,200 light alternating current machine to the electric light company in Streator, Ill.

TESLA'S NEW ALTERNATING MOTORS.

REPLYING to the exceptions taken by Mr. N. Tesla[1] to the criticisms of *Industries* on some of his more recent designs of alternating motors that journal has the following in a recent issue:

The main difference of opinion, we think, lies in a nut-shell. Mr. Tesla holds that if an increasing excitation is applied to an iron core it affects the outside first, and the lines of induction, or lines of force, accumulate in the outside till the iron becomes more or less saturated, and then penetrate to the inside. The outside thus magnetically screens the inside. If the core is laminated, so that there are no Foucault currents, this cannot occur. The line integral of the magnetic force taken round any circuit interlinked with the magnetizing coils is $4 \pi n C$, where n is the number of turns and C the current in C. G. S. This interlinked circuit may be taken through the centre of the core or near the outside, and has the same value in each case. This value is independent of the time. If the iron is not laminated, Foucault currents will be generated in a direction opposed to the primary electromotive force, and these will introduce a time lag. At any instant the integral of magnetic force round a circuit passing along the outside of the core is still $4 \pi n C$, but along any circuit cutting the iron it is $4 \pi n C + 4 \pi n^1 C^1$, where C^1 is the surface integral of the Foucault current interlinked with the circuit in question, C and C^1 having positive or negative values according to their direction. As C^1 depends on the time rate of change of C there is thus a time lag. For instance, if a current is suddenly turned on a solid cored electromagnet, currents in the opposite direction circulate in the iron, so that at first they partly demagnetize the centre. They die away gradually, and the centre is then magnetized as fully as the outside. The lag is here produced entirely electrically, not by any sort of magnetic screening. Mr. Tesla develops his magnetic screening in this way. He wants to get a set of poles on a motor to lag behind another set. He therefore excites the leading poles with an alternating current in the usual way. The lagging poles have their cores wound with iron wire first. The iron wire is not wound parallel to the induction in the core, but at right angles to it, and is referred to as a closed magnetic circuit. Why is not clear, for it is not interlinked with any exciting circuit whatever. Outside this is wound the exciting coils proper. Mr. Tesla thinks this coil of iron wire screens magnetically. We think it acts as a secondary electric circuit. It gets slightly magnetized also, but the direction of magnetization is at right angles to the wire at every point, not round what Mr. Tesla calls a closed magnetic circuit.

Mr. Tesla also described a transformer. In this a ring of iron wire is taken as core, as usual. It is wound with secondary, also as usual. The secondary is then coated with iron wire. Apparently we were in error when, in our previous note, we said this shield was laminated in the wrong direction; the lamination in the wrong direction—that is, not parallel to the induction—is in the motor, and, from the description, one at least of the transformers has its "screen" laminated in the right direction. Over this "screen" is wound the primary. Mr. Tesla thinks this intermediate layer of iron acts as a magnetic screen. If it is laminated in the right direction, so as to have no Foucault currents, the induction at any instant in the inner core is $(4 \pi n C + 4 \pi n^1 C^1) \mu/l$, where n^1 and C^1 are the secondary turns and current, and l the length of the core circuit. The induction in the outer "screen" is $4 \pi n C \mu/l$, and there is no time lag. The effect of such an arrangement is that the primary coil is interlinked with more iron than the secondary, so the effect is just the same as putting a choking coil in series with the primary of on ordinary transformer. Mr. Tesla says triumphantly we are wrong, for it does screen; we say that he has misinterpreted his results.

COLLEGE NOTES.

EXPERIMENTAL APPARATUS FOR CORNELL UNIVERSITY.

In circular recently issued, Prof. R. H. Thurston, director of Sibley College, Cornell University, calls for plans and estimates for an "Experimental Steam Engine," such as is customarily made a part of the equipment of technical schools of the higher class, and used by them in researches in steam engineering. Cornell already has a number of engines adapted, in various ways, for this work; but it is desired that one should be here installed which shall present peculiar facilities for illustration, and for investigations in connection with the higher graduate courses of instruction, and in the schools of steam engineering, of marine engineering and naval architecture, now making preparation for their work, and in the school of railway mechanical engineering, which it is anticipated may be organized, should the former prove useful and successful.

The circular gives full specifications of the type and construction desired.

Proposals are also invited for a testing machine having a capacity of not less than 200,000 lbs., and intended for the Mechanical Laboratory.

1. THE ELEC. ENGR., Sept. 24, p. 344.

LITERATURE.

Electricity in Daily Life. A Popular Account of the Applications of Electricity to Every-day Use. By C. F. Brackett, F. L. Pope, Jos. Wetzler, H. Morton, C. L. Buckingham, H. L. Webb, W. S. Hughes, John Millis, A. E. Kennelly, and M. A. Starr. 125 illustrations. 288 pages. Cloth. New York: *Charles Scribner's Sons*, 1890. Price, $3.

ENCOURAGED by the great success attending their series of Railway articles, afterwards reprinted in book form, and constituting a most valuable work of reference, the managers of *Scribner's Magazine*, during the past eighteen months, have been publishing in that periodical a series of articles on electricity. In the present volume these electrical articles are gathered together, making a most interesting, valuable and handsome contribution to the literature of the subject.

A great peril—and more than one perhaps—awaits the writer of articles intended to convey to a public, of general culture, but uninitiated in the technicalities of any special science or industry, a clear, fair idea of what has been done and what the leaders in that field are aiming at. The peril is that of being so technical that half the information remains a dead letter, or else of falling into so juvenile a method of treatment that the reader's stomach is apt to revolt at the mess of sweet pap, as fit only for infants in knowledge. It is not given to everybody to act as a popular interpreter of the higher mysteries of science and art. The talents required for being in sympathy with the technical classes, and yet of fully understanding what the unscientific masses need, are rarer than the profusion of "popular science" efforts would indicate. In a series of this kind, under the skillful direction that one expects from a standard magazine, the slips to one side or the other of the happy mean should be few; and on the whole, one's expectations are gratified. Prof. Brackett's introductory article is probably that which makes most demands on the public, and seems at first too abstruse; yet, a second and third perusal renders it hard to say wherein it is not just what is wanted as a helpful exposition of the leading principles embraced in the science. A few similes and analogies might have helped it, but they are pitfalls for the unwary very often, and, besides, it is a magazine article of scant limits that we are discussing. It might also be objected to Prof. Morton's paper on electric lighting that the copious citation of patent references and dates is a mistake, since it leads nowhither so far as an untutored public could see. But, even allowing that there may be a little in it over the heads of the public, the book is sure to amuse, enlighten and instruct all who turn to its pages for information on what is unquestionably the most fascinating subject in physics to-day.

There are only two topics that we would particularly have cared to see added to the list treated of in this book, although many others might be suggested. The two are telephony and electro-metallurgy. In one sense the telephone is a telegraph, but since Mr. Buckingham's excellent article on telegraphy lets telephony alone, we do think some such expert as Mr. T. D. Lockwood or Prof. Cross should have been invited to describe that great department of work. So, too, in metallurgy, the range of electrical application is so enormous that it is hard to see why it should be unnoticed, while electricity in medicine, a specialty of less range, receives, at Dr. Starr's hands, a very creditable summarizing.

To a certain extent, the chapters group themselves. Thus Mr. F. L. Pope's and Mr. Joseph Wetzler's articles on electric motors and electric railways should be read together, and they will be found to sum up admirably the results and tendencies in the vast field of electric power. The statements made as to the development of electricity in electric traction are most stimulating, and the story of the evolution of the electric locomotive shows in many respects a close parallel to that of the steam locomotive. It is true that both gentlemen deal largely in forecasts and promises, but even since they wrote their "long distance" predictions, events have hastened to justify them. And then there is always more interest in the things men are going to do than in the humdrum things they do now as a mere matter of course. The present generation is a little bit tired of hearing its progenitors boast of being "the first to ride in the steam cars from Albany to Schenectady," and desires for itself the satisfaction of being the "first to ride in the electric cars from New York to Philadelphia." Yet even that, we note, will be a commonplace ten years hence.

Dr. Morton's paper on electric lighting serves as a link between these two and those which succeed, on the land telegraph and the submarine cable, just as the electric light itself linked the old electric dispensation of small currents and minute apparatus with the present time when the electrical engineer talks in units of 10,000 electrical h. p., and throws nightly into his circuits, in a single city, more electrical energy than would run the largest telephone office for a century. Due emphasis is laid by him on the fact that the improvement in arc and incandescent lamps came with the perfection of the dynamo; and these two elements together creating the modern central station reacted on the antiquated, primeval electric motor and perfected that.

As becomes an officer of the Western Union Co., Mr. Buckingham begins with a graceful tribute to Prof. Morse, but as an officer of that company, he should certainly have buried in deep obscurity, rather than have paraded it, that hideous, horrible tangle of wires shown as the underside of the big switchboard at "195." We have seen many messes of wire but none quite so bad as that, and, as it stands, the picture is a thorough and satisfactory explanation of the late great fire. We think there must be some mistake about that nightmare; it is so unlike the ideas of order and system necessary in a huge electrical establishment, and such as we know Mr. A. S. Brown to be an ardent advocate of. Perhaps if Mr. Brown had had his way, the tangle would have been wiped out of existence long before the fire saved the company the trouble.

A fitting adjunct to the telegraph paper is that on the making and laying of a submarine cable by Mr. Herbert Laws Webb, but it stands quite by itself in merit, as being the most genuine literary production of the lot. It is a really clever piece of work, for though one is simply made a *compagnon de voyage* in a cable expedition and not expected to assist, the feeling throughout is of actual, anxious participation in all the exciting incidents and vicissitudes, and of enthusiastic triumph when the work is done and De Sauty is once more vindicated.

Next come the papers on electricity in naval and land warfare by Lieuts. Hughes and Millis. It is clear to see that not only have we a new navy but that it is fought in a new way, much to the bewilderment and annoyance, we imagine, of the old school, which does not care to go into action with a telephone on its ear, its finger on a telegraph key and an electric range finder at its elbow. So, too, on land. Lieut. Millis makes it evident that electricity must play a big part in the next great war. Bismarck disliked the telegraph because it prevented diplomacy from being unctuous. As his diplomacy never ran much that way, we doubt the sincerity of this remark, but we do know that in the German military tactics of Von Moltke, as in every other advanced army studies, the determination to get rid of the unctuous and slow in warfare by pressing electricity to its very extreme of performance is more and more apparent. As an antidote to these two bellicose papers, the reader may, however, next take up Dr. Starr's and learn how powerful an agent electricity is for saving life and restoring health, as well as for malthusian ends.

Mr. Kennelly has a subject we should hardly have assigned to him, as he is a pastmaster of the laboratory and has not bothered greatly with push buttons and burglar alarms, but he acquits himself most excellently well, and his little diagram showing how the electric current tapped from the street main can be put to an endless variety of lighting, heating, driving and signaling purposes, is a revelation in itself. One wonders in looking at it how soon we may all be able to realize it, and thus escape from the dire misery and slavery to which European domestics now subject innocent American households. God speed the day! In the meantime it is to be hoped that the energy and enterprise of the electrical supply trade will do more than in the past to render these conveniences familiar in our homes and offices.

This book will not make any man an electrical engineer, but it is the best extant intended to inform the public soberly yet interestingly what there is in electricity and what may be expected of it. It deserves the widest circulation, especially among those who, while not electrical, have electrical interests. Directly and indirectly that includes pretty well every American citizen. The book is beautifully illustrated, clearly printed, and has a cover of special and characteristic design, appealing to every telegraphist who has watched the mirror or siphon, listened at the sounder or pounded holes into a Wheatstone tape.

LETTERS TO THE EDITOR.

THE NEW THOMSON DYNAMO.

[146].—I have recently noted with much interest the account in your paper of Elihu Thomson's new dynamo, but am somewhat astonished at the apparent implication made as to the newness of type, no reference being made as to machines of similar type already out several months.

I enclose you outlines of several machines already patented and which have been running several years in this laboratory. One of them, driven by a 4 h. p. Otto, is supplying 20 incandescents and 2 A. C. arcs (large Westinghouse) in the gymnasium of the University of Nebraska, at Lincoln. D. B. BRACE.

Boston, Mass.

[Our correspondent encloses copies of two patents issued to him, both entitled Dynamo Electric Machine, No. 421,479, Feb. 18, 1890, and No. 427,294, May 6, 1890. While both of these machines are of interest and may be considered to be of the same general type as that of Prof. Thomson, the latter has features quite distinct from those shown in the patents referred to.—EDS. ELECTRICAL ENGINEER.]

CORRESPONDENCE.

CHICAGO.

Lighting Street Cars.—Owens' Electric Musical Instrument.—A New Motor Company.—H. A. Douglass.—Charles Wilson's Ingenious "Busy Board."

THE West Side Street Railway Company are considering the question of placing electric lights in their cars.

Dr. Owens, of Chicago, has just devised a unique musical instrument which comprises a set of chimes to be rung by electricity, and is intended to be used for advertising purposes. The instrument, it is proposed, will be conveyed through the streets on an electric tricycle, and played during the trip like an ordinary piano. An electro-magnet is attached to each of the thirty bells hung above the keyboard. The keys make the circuit from a battery in the base to the electro-magnets at the bells.

A new company has been formed for the purpose of furnishing electric lighting to that portion of South Chicago known as the East Side.

The Northwestern Electric Motor Company has just been incorporated at Chicago to manufacture and use electric motors and sell and operate the same. The incorporators are Thomas B. Bryan, Frank Weeks and M. W. Towle.

Mr. H. A. Douglass, late superintendent of the messenger department of the Chicago Telephone Company, recently resigned his position to go into other business. His late employés called at his home last week and presented him with a handsome lamp.

The "busy-board" invented by Mr. Charles Wilson, superintendent of the Chicago Telephone Company, is now in successful operation at the central exchange. The arrangement of the instrument is such that when a subscriber calls for a number which is busy the desired wire is held at the "busy-board" and given to him as soon as disengaged. In this way a long list of subscribers who want the same number can be served in turn. The instrument is so constructed as to accommodate six operators and can take care of 6,000 wires. It supplies a long-felt want, as any one who ever used a telephone knows the tedious delays caused by "busy wire." Mr. Wilson's "busy-board" is the first solution of its kind of a problem which has always troubled the telephone companies, and it gets over the difficulty in the most simple and successful manner.

CHICAGO, Nov. 14th, 1890.

BOSTON.

Work in the City Council.—Snow Plows for the West End.—Boston Electric Club.

AT a meeting of the Board of Aldermen this week the street commissioners, replying to an order of the board, stated that it would cost $1,070,000 to extend Harrison avenue to Summer street and Hawley street to Water street and the widening of Water street, in accordance with the plan proposed by the West End railroad. The communication was placed on file.

The case of the Suburban Light & Power Co. vs. the Board of Aldermen of the city of Boston was argued before the full bench of the Supreme Court yesterday.

The action is brought by the Suburban Company to compel the Board of Aldermen to grant locations for electric light poles in certain streets of the city.

The West End Street Railway Company are preparing for the coming winter and have just completed four new snow plows for taking care of the heavy snows which are liable to interfere with their traffic. These are now being tested and as soon as approved they will manufacture more until they have 25 in all. In appearance it much resembles a small freight car. Its width on bottom is 6 feet, with a length of 14 feet. The cab is 8 feet long, 6 feet wide and 7½ feet high.

There are two 15 horse-power motors inside the car. These are of the ordinary railway type. Being inside the car body, they are protected from the rain, storm and wind. The rheostat is inside the car, and at the end of the route, for instance, will be used to throw off heat, so that the men operating the plow can warm up. The gears on the motors have been dismantled, and on the armature shaft has been placed a sprocket pinion, which gears down, by sprocket chain, to a counter shaft in the centre of the body, underneath the car frame. This makes one reduction and there is another from the counter shaft to the car axle sprocket wheel. The motors will furnish a speed of from 12 to 13 miles per hour, which will enable them during the winter months, when it is snowing, to keep out of the way of the regular passenger cars. The plows are all equipped with a powerful brake which requires no turning of spindle, but simply the pressure of a man's foot. The results are instantaneous and most effective. The interior of the plow is lighted by a bunch of three incandescent lamps. On each platform over the door, there are single lamps, which furnish sufficient light to men operating the plow. The customary headlight is carried on the dasher at night.

The first dinner of the season of the Boston Electric Club was held at Young's Hotel on Monday, President Cram in the chair, who was supported on the right by Prof. Elihu Thomson, and on the left by Capt. Eugene Griffin. The dinner was an excellent one, after which Prof. Thomson delighted the members with an impromptu lecture on the properties of alternating current, freely illustrated by experiments. The experiments have all been thoroughly described in these columns before, but many of the members had never witnessed them, and they were watched with the keenest interest. After the lecture Prof. Thomson was greeted to a hearty vote of thanks. The house and entertainment committee are arranging for a monthly series of these dinners and papers throughout the winter.

BOSTON, Nov. 14, 1890.

PITTSBURGH.

New Fire Alarm Office.—Braddock Electric Railway Troubles.—Allegheny City Lighting Superintendent.—Beaver Falls Electric Railway.

THE new fire alarm office of the city of Pittsburgh is now nearly completed. The handsome mahogany cabinets for the new switch board annunciator and other instruments are already in place and the rest of the furniture is expected to arrive in the city within a few days. The walls of the office are wainscoted in mahogany and the ceiling will be handsomely frescoed and decorated.

The next thing to be done will be to put up the instruments in position and to make the connections of the wires. Superintendent Morris Mead of the City Electrical Bureau stated a few days ago that, when the work is all completed, Pittsburgh will have the finest fire alarm office of any city in the country. The best offices now are equipped with instruments at least four years old and since then there have been so many improvements made, that are all being embodied in the work here, that from an electrical point of view there is not much doubt the Pittsburgh fire alarm office will be the finest in the country.

The switchboard alone costs $9,000.

The Braddock and Turtle Creek Electric Street Railway Company yesterday filed a bill in equity in the Pittsburgh courts against the borough of Braddock. The railway people claim that they obtained a right of way for their line through Main street, Braddock. They commenced work according to the terms of the ordinance, and among other things erected poles along the street. No objection was made to the putting up of the poles except three, which they were prevented from erecting. The objection to these, it is alleged, is only because of the complaint of the owners of the abutting property. The company asks that the defendants be restrained from interfering with them or removing the poles they may put up. The case will receive a hearing some time next week, and as it is the first time such a case has been brought before the courts of Western Pennsylvania the result, whatever it is, is very anxiously looked forward to.

The Allegheny City Council Committee on Gas and Lighting met last evening for the purpose of considering the advisability to abolish the office of Superintendent of Gas and creating that of Superintendent of Public Lighting. This change has been necessitated by the establishment of an alternating current arc and incandescent light plant, which the city authorities about a year ago contracted with the Westinghouse Electric and Manufacturing Company to be erected. That plant has been in operation since last July, and all the gas lamps have now been thrown out by the city.

Beaver Falls, in this vicinity, will have an electric street railway shortly. Yesterday a charter was issued at Harrisburg, Pa., to the Central Electric Street Railway Company, of Beaver Falls, capital stock $60,000.

PITTSBURGH, Nov. 7, 1890.

WESTERN THOMSON-HOUSTON PLANTS.

The Western Isolated Lighting Department of the Thomson-Houston Electric Co. has closed contract with the Atlantic Mining Co., of Houghton, Mich., for a nine light arc plant.

H. H. Shufeldt & Co. have for some years past been using electric lights at their distillery, 23 Larabee street, Chicago, having for the purpose a dynamo capable of supplying about 125 lights. Finding that additional lights could be used to good advantage, they recently asked for bids on a much larger plant, and after very severe competition, the order was placed with the Western Isolated Lighting Department of the Thomson-Houston Electric Co. for a 400 light incandescent plant. The dynamo previously used will be discarded and an entirely new plant will be installed.

SOCIETY AND CLUB NOTES.

NEW YORK ELECTRIC CLUB.

The regular monthly meeting of The Electric Club will be held at the Club House, 17 East Twenty-second street, Thursday evening, November 20th. The address of the evening will be delivered by Prof. E. L. Nichols, of Cornell University, beginning at 8 o'clock, on "The Artificial Light of the Future." His plan is to point out the nature of certain limitations which seem to preclude hope of any very marked improvement in the efficiency of our present methods of lighting; then to discuss the properties of certain sources of light, not made use of at present, with a view to the more or less remote possibility of their development as practical illuminants. The lecture will include the presentation of some original work not yet published, together with the collation of various researches, which have not attracted general attention, taken singly, but which seem to Prof. Nichols to be significant. The results will be presented by aid of lantern slides. Members intending to be present for dinner, should notify the clerk at the Club House in advance.

ELECTRICAL DEPARTMENT, BROOKLYN INSTITUTE.

The above department is steadily maintaining its high standard of excellence. President Hamblet soon followed up his inauguration by the delivery of an admirable exposition of the electric time service of the Western Union Telegraph Co., which is maintained under his supervision. The lecture was fully illustrated. This was followed up, last Friday evening, by a lecture from Mr. H. L. Webb, on "Submarine Telegraphy." Mr. Webb has had abundant experience in that department and was able to talk interestingly on all its details, not forgetting the ever fresh and romantic story of the first Atlantic cables. He made use of the lantern to illustrate the subject and showed specimens of early cables as well as of those that had been long submerged.

THE NATIONAL ELECTRIC LIGHT ASSOCIATION.

Mr. A. R. Foote, the secretary of the National Electric Light Association, has prepared and issued a prospectus of the Association for general circulation. It embraces the new constitution, lists of active and associate members, a statement as to the objects of the Association, and a review of the proceedings of the twelfth convention at Cape May. It is excellent campaign literature, and will, we trust, bring in many new local companies.

BOARD OF EDUCATION'S FREE LECTURES.

The Board of Education has organized a useful course of free lectures for the people to be delivered in Grammar schools Nos. 42, 83, 82, 51, 27 and 15. The lectures begin Nov. 17, and deal with practical subjects, telling people something about themselves, the work of their hands, and the world they live in. Among the speakers are Prof. C. A. Doremus, Prof. R. Grimshaw, Prof. H. A. Mott, Dr. C. S. Allen and other trustworthy specialists.

REPORTS OF COMPANIES.

WEST END STREET RAILWAY CO., BOSTON.

THE West End street railway annual report is interesting. President Whitney said the company had ordered 150 cars with 50 per cent. increased capacity, and some of them would be running in three months. From Oct. 1 to Nov. 10 travel increased 13.38 per cent. over last year; miles of road had increased 10 per cent. In three years the company would move from 30 per cent. to 50 per cent. more people, which means 175,000 to 200,000 passengers per day more than the company now carries. The plans for an elevated road already presented were the best for meeting this demand. New stock will issue for the L road $1,500,000 next year and $500,000 for the year following. Stockholders re-elected the old board and authorized elevated roads, only 872 shares voting "no." President Whitney stated, that in the new electric cars the noise from the gearing would be reduced to a minimum. He added: "Experience has shown that wherever the electric lines have been installed travel has enormously increased."

NEW ENGLAND TELEPHONE COMPANY.

The directors of the New England Telephone Company have declared a dividend of 75 cents per share, payable November 15, 1890, to stockholders of record at the close of business on October 30. The transfer book will be closed from November 1 to November 15, both days included. The report of operations for the quarter ended September 30 follows, and is noteworthy for the fact of increased expenses and construction charges:

Quarter Sept. 30.	1890.	1889.	Increase.
Receipts	$361,339	$326,181	$35,158
Expenses	261,482	225,790	35,692
Net	$99,857	$100,391	*$534
Construction	68,063	56,960	11,103
Balance	$31,794	$43,431	*$11,637
Since Jan. 1.			
Receipts	$1,042,788	$950,393	$92,395
Expenses	767,281	681,175	86,106
Net	$275,507	$269,218	$6,289
Construction	129,114	94,647	34,467
Balance	$146,393	$174,571	*$28,178

*Decrease.

ASBURY PARK, N. J.—The Asbury Park Electric Light Co. has declared a semi-annual dividend of 3 per cent.

NEWARK, N. J.—The Newark Electric Light and Power Co. has declared a quarterly dividend as usual of 1½ per cent.

ERIE TELEPHONE.—The Erie Telegraph and Telephone Co. has declared a quarterly dividend of 1 per cent.

EUROPEAN ELECTRIC WELDING CO.—The final payment of the purchase price of the European Electric Welding Company's patents for Great Britain has been postponed two months from Nov. 1, say to Jan. 1, 1891, when £40,000 is to be paid in cash, also the stock payment. The company has received £60,000 cash (not £70,000 as before stated) for the English patents, and £10,000 forfeit on the continental option. An incidental part of the new arrangement is that the English people shall pay for the machines sent over there to illustrate the principle, etc., about $16,000.

FINANCIAL MARKET.

QUOTATIONS ON ELECTRICAL STOCKS.

F. Z. Maguire & Co., Electrical Securities, of 18 Wall street, this city, report the following quotations of November 15th, from New York, Boston and Washington:

NEW YORK.

	BID.		BID.

Westinghouse Electric and Manufacturing Co	27⅛

AN "UNDERSTANDING" AMONG THE SWITCH MANUFACTURERS.

Various combinations and pools have been made from time to time among the manufacturers in certain lines of electrical goods, and some are in existence to-day. The switch manufacturers have now made up their minds to try this means of protection, and during the past week the "A. B. C. Exchange," 20 Cortlandt street, has been resorted to by them as a neutral meeting place. The good offices of Mr. Alexander were invoked to bring about harmonious action, whereby pendin suits were withdrawn, a price list was arranged and other business of great interest was transacted. The details are not yet ready for publication, but there is good ground for saying that as a result of the cessation of costly legal warfare, the switch buyer is likely to be benefited appreciably as well as the manufacturer.

INVENTORS' RECORD.

DIGEST OF ELECTRICAL PATENTS ISSUED NOV. 11, 1890.

Alarms and Signal :—

Combined System of Fire-Alarm and Police Patrol Telephone and Telegraph, G. C. Hale and A. Barret, 440,563. Filed Mar. 28, 1890.

Combined system of fire and police patrol telephone and telegraph, means for sending visual and audible signals to fire or police headquarters from any outlying subscribers' telephone, or from a street station, and to enable oral communication between headquarters and an outlying station; providing three distinct means of notifying headquarters of a fire or other disturbance.

Clocks :—

Electric Actuating Mechanism for Clocks, H. T. Schlegel, 440,241. Filed Sep. 6, 1889.

Automatic electro-magnetic motor driving clock train.

Electric Clock, F. Schwartz, 440,441. Filed Oct. 22, 1889.

Electro-magnets actuate pendulum directly, and indirectly actuate the train through the escapement-wheel.

Conductors, Conduits and Insulators :—

Insulating Composition, F. E. Blaisdell, 440,391. Filed May 3, 1890.

Asbestos, clay, and a flux, as feldspar and borax.

Method of Manufacturing Insulating Tubing for Electric Conducting-Wires, H. B. Cobb, 440,395. Filed April 29, 1890.

Molding upon the tubing, while soft, a continuous covering of metal, vulcanizing the soft tubing, and then stripping off the metal covering.

Distribution :—

Distribution of Electric Energy, S. Z. de Ferranti, 440,224. Filed Feb. 19, 1889.

Alternating currents and transformers; successive reductions of potential by intermediate transformers for long distances; concentric conductors.

System of Electrical Distribution, W. S. Richards, 440,326. Filed May 2, 1890.

A dynamo or other generator, two circuits and a current-director, both of which include the coils of the field magnets of the dynamo, one of said circuits also including translating devices.

Dynamo-Electric Machine, W. K. Freeman, 440,424. Filed Sept. 28, 1890.

Improved means for securing the coils upon the cores of the field magnets; specially applicable to alternating current machines.

Current-Collector for Dynamo-Electric Machines, W. K. Freeman, 440,425. Filed Sept. 20, 1890.

Applicable to alternating current machines. A metallic hub, consisting of a flanged sleeve, having a split portion or portion provided with clamping devices.

Dynamo-Electric Machine, W. K. Freeman, 440,557. Filed Sept. 20, 1890.

Design and construction to secure strength, compactness and ease of assemblage of parts; also intended to render the machine easily adjusted or shifted upon its base when mounted.

Electrical Governor, F. D. Hardy, 440,590. Filed Feb. 1, 1890.

The combination, with an electric motor, of a governor actuated by centrifugal force, a sleeve on the motor-shaft, a bell-crank lever connected thereto, and a pitman connecting the lever to the brush-holder of a dynamo.

Galvanic and Thermo-Electric Batteries :—

Battery-Zinc, Archibald J. Macdonald, 440,173. Filed Feb. 20, 1890.

Alloy of mercury ammonium and zinc added to melted zinc, finally adding magnesium.

Galvanic Battery, W. Cohlman, 440,420. Filed Jan. 20, 1890.

Design and construction for securing compactness and to permit the ready examination of any cell of a battery.

Lamps and Appurtenances :—

Arc Lamp, S. E. Nutting, 440,604. Filed March 10, 1890.

First claim as follows :—In an arc lamp, the combination of an electrode, a covering for the same of a material that disintegrates under the heat of the arc at a temperature lower than is necessary to consume the electrode, with its edge next to the arc at a distance therefrom to cause it to be disintegrated with the same degree of rapidity as the electrode is consumed, and a holder bearing against the edge of the covering next to the arc and holding the electrode from advancing until the edge of the covering is changed, consumed or destroyed.

Measurement :—

Dead-Beat Mechanism for Electrical Measuring-Instruments, E. Weston, 440,289. Filed May 12, 1890.

Retarding the movement o fan electrically-actuated body, by first establishing the actuating current and then diminishing a previously interposed frictional resistance.

Temperature-Regulator for Electrical Measuring-Instruments, E. Weston, 440,290. Filed June 25, 1890.

Means of indicating changes in temperature occurring in the instrument circuit, and, connected in said circuit a resistance and a means of varying the same comformably to the indications of the heat indicating apparatus; whereby the resistance of the whole circuit may be maintained constant.

Index-Controlling Device for Electrical Measuring-Instruments, E. Weston, 440,291. Filed June 25, 1890.

A pivoted body, means of indicating the extent of its rotary movement, and a second body moving about a centre in line with the centre of rotation of the first pivoted body, one of the bodies being provided with a projecting stop and the other having a recess in which the stop enters, thus limiting the movement of the stop.

Electric Meter, E. Mares, 440,431. Filed Feb. 26, 1890.

A balance-lever mounted to oscillate, an electro magnetic device to actuate the lever, a carriage on the lever, mechanism for reciprocating the carriage, and a registering device in the path of the carriage and separate and independent of carriage and lever.

Metal Working :—

Method of and Apparatus for Making Metallic Wheels by Electricity, W. P. Bettendorf, 440,584. Filed Sep. 11, 1890.

Adaptation of electrical welding to the joining of spokes to hubs and tires of metal wheels.

Miscellaneous :—

Electric Switch, A. R. Bush, 440,308. Filed June 9, 1890.

"Quick-acting" hand switch.

Combined Lighting-Arrester and Cut-Out, J. A. McManman, 440,361. Filed Feb. 7, 1890.

Fusible cut-out; formation of arc between terminals intercepted by ground bar.

Adjustable Resistance for Electrical Circuits, C. Wirt, 440,384. Filed Nov. 26, 1888.

Two relatively movable concentric cylinders, one having wires longitudinally upon it, the other carrying a contact piece bearing directly upon the wires.

Railways and Appliances :—

Electric Motor Truck and Gear, E. Peckham, 440,189. Filed May 29, 1890.

System of gearing whereby the motion of armature shaft of motor may be imparted simultaneously to both axles of the truck.

Station-Indicator for Railway Cars, G. N. Vanderhoff, 440,208. Filed Dec. 2, 1889.

Electro-magnetic mechanism controlling movement of parts.

Electric Switch, M. Wheless, 440,213. Filed Sept. 24, 1889.

For electrical railways with sectional conductors. An electric circuit separated at intervals and having at each side of the points of separation sockets pointing in opposite directions, in combination with magnets placed at such points of separation, the armatures of the magnets being bifurcated, and the forks being on opposite sides of the main circuit and having screws fitting the sockets.

Electric Railway, J. K. P. Nourse, 440,362. Filed March 18, 1890.

For storage battery cars, system of conductors leading from power station to one or more points on the track for charging batteries in transit.

Electric Railway Switch and Signal Mechanism, J. Ramsey, 440,502. Filed March 21, 1889.

An electric motor employed to move a railway switch; mechanism transmitting motion from the motor to the switch so constructed that the motor circuit will be automatically broken when the switch has been either opened or closed.

Electric Switch and Signal Mechanism, J. Ramsey, 440,503. Filed March 21, 1889.

Signal operated by an electric motor provided with mechanism for setting the signal in one direction only, an automatic circuit breaker for cutting out the motor after it has actuated the signal, mechanism for cutting in a magnet circuit for holding the signal.

Electric Train-Signal, F. Sargent, 440,508. Filed May 6, 1890.

The operating valve of locomotive whistle actuated by electro-magnet.

Shipper for Trolleys, H. H. Brooks, 440,584. Filed May 14, 1890.

Two diverging pivoted arms, one on either side of the trolley and extending outwards from either face, the arms projecting normally when the trolley is in contact with the wire and below any portions of the overhead construction adjacent thereto.

Electric Railway. R. M. Hunter, 440,595. Filed May 29, 1889.

Supporting the conductors over one or more parallel tracks by a line of poles, and supporting working and supply conductors by the same poles or means of support.

Electric Railway, R. M. Hunter, 440,596. Filed July 28, 1890.

In two crossing railways, the main conductor of each is severed at the point of crossing; a bridging switch is provided to span the gap made by the severing of the main conductor.

Contact Device for Electric Cars, R. M. Hunter, 440,597. Filed Aug. 11, 1890.

Conduit railway. First claim as follows :—In an electric railway, the combination of a conductor extending along the railway, a traveling vehicle, a frame jointed at one end to the vehicle and having its other end free, and a current-collecting device carried upon the free end of the frame and movable about a vertical axis.

Secondary Batteries :—

Secondary Battery, Friedrich Marx, 440,175. Filed April 18, 1890.

Metal or metalline electrode and a carbon electrode placed in an aqueous solution of a salt of a metal and an equivalent quantity of an acid.

Electrode for Secondary Batteries, E. B. Weed, 440,210. Filed Feb. 8, 1890.

Constructed to permit a large amount of active material to be placed in receptacles and to reduce the weight of metallic plates.

Metallic supporting plates with outwardly projecting receptacles for active material; receptacles wholly enclosing the masses of active material.

Secondary Battery Plate, A. E. Wolfe, 440,216. Filed Feb. 10, 1890.

A plurality of supports for active material, the supports being conductors of electricity, and a layer of mechanically applied active material between and in contact with the surfaces of adjoining supports, and continuous open passages for the liquid through the supports and through the active material.

Process of Producing Porous Crystalized Metal Plates, C. Payen, 440,267. Filed July 26, 1887.

Fusing two or more metallic salts together, pouring the mass into a mold, allowing it to crystalize, then reducing the structure to a metallic state and eliminating foreign matter.

Process of Producing Crystalized Metallic Lead Plates, C. Payen, 440,268. Filed Jan. 16, 1888.

Fusing the salts of lead, zinc and cadmium, casting the mass in a mold and allowing it to crystalize, then reducing to a metallic state.

Process of Producing Crystallized Lead Plates, C. Payen, 440,269. Filed Jan. 23, 1888.

Fusing a salt of lead and an ammonium salt, then treating as in 440,267.

Art of Producing Crystallized Metal Plates, C. Payen, 440,270. Filed Mar. 12, 1888.

Fusing the salt of a metal having the salt of another metal and a metal or a salt of that metal mixed or combined therewith, pouring the mass into a mold and allowing it to crystallize in columns, then treating as above.

Porous Crystallized Metal Plate, C. Payen, 440,271. Filed March 16, 1888.

Plate produced as above.

Method of Making Porous Crystallized Metal Plates, C. Payen, 440,272. Filed June 16, 1888.

Mixing and melting a fusible metallic salt or salts with a salt or salts not decomposed or fused below a red heat, then treating as above.

Process of Making Porous Crystallized Metal Plates, C. Payen, 440,273. Filed June 16, 1888.

Fusing a metallic salt or salts containing a mineral acid or acids with a salt of lead, then treating as above.

Process of Producing Porous Crystalliz'd Metal Plates, C. Payen, 440,274. Filed June 18, 1888.

Fusing with a salt of a metal and oxide of a metal and a non-oxidized salt or compound of the same or another metal, then treating as above.

Process of Producing Porous Crystallized Metal Plates, C. Payen, 440,275. Filed June 18, 1888.

Fusing two or more metallic salts and an oxide or oxides of a metal or metals, then treating as above.

Process of Producing Porous Crystallized Metal Plates, C. Payen, 440,276. Filed June 20, 1888.

Fusing an inorganic metallic salt or salts with an organic salt or salts; then treating as above.

Process of Producing Crystalized Metallic Lead Plates, C. Payen, 440,277. Filed Jan. 16, 1888.

Fusing the salts of lead and cadmium, then treating as above.

Process of Producing Crystallized Metal Plates, C. Payen, 440,575. Filed May 31, 1888.

Fusing a salt or salts of a metal or metals and pouring the mixture into a mold, allowing it to cool, with the crystals of the mixture uniting with each other to form columns or needles, and with these columns or needles meeting with each other at or beyond the median line of the plate.

Electrolyte for Secondary Batteries, B. Renault and M Desvernay, 440,505. Filed Jan. 11, 1890.

A depolarizing gelatinous silica, consisting of a mixture of water, bichromate of soda and silicate of soda. A neutral gelatinous silica enclosing negative e lectrodes, consisting of water, silicate of soda, hydrochloric acid, sulphate of mercury, chloride of zinc and manganate chloride.

Telegraphs :—

Telegraph-Circuit, David H. Keeley, 440,164. Filed Nov. 4, 1889.

Elimination of static retardation. Pole-changing transmitter at sending station and a rapidly and constantly acting current-reverser at receiving station, for either neutralizing or augmenting in pulses transmitted.

Multiplex Telegraphy, David H. Keeley, 440,165. Filed Nov. 4, 1889.

Adaptation of synchronous multiplex telegraphy to way stations.

Induced-Current Telegraph, A. M. Rosebrugh, 440,199. Filed Feb. 3, 1886.

Signaling by secondary electrical currents. Inductorium and circuit closing key in primary circuit; rheotome or equivalent in primary circuit; secondary circuit of inductorium in main line, and a shunt around inductorium.

LEGAL NOTES.

STORAGE BATTERY INFRINGEMENT.

BRUSH *vs.* ANGLO-AMERICAN.

Suit has been brought in the United States Circuit Court for the Southern District of New York by the Brush Electric Co. and the Consolidated Electric Storage Co., of New York, against the Anglo-American Electric Light Manufacturing Co. for alleged infringement of certain United States patents, known as the Brush Storage Battery Patents, owned by the former companies. A preliminary injuction has been asked for. The bill of complaint setting forth the grounds of the action was filed by Messrs. Witter & Kenyon, attorneys for the complainants.

STATE AND LOCAL TAXATION OF ELECTRIC LIGHT PLANTS IN PENNSYLVANIA.

A decision by Judge Archibald, of Lackawanna county, rendered in the case of the city of Scranton *vs.* the Scranton Electric Light and Power Company, holds that the property necessary to carry out the corporate purposes of a corporation engaged in business of a public interest is not liable to local taxation, where such property is included in the capital stock which pays a State tax. Only those corporations which owe a well-recognized duty to the public, and which hold their property and exercise their franchises in subjection to that duty, fall within this class. An electric light company, incorporated under the acts of April 29, 1874, and June 2, 1887, to supply light, heat and power to the public, belongs to this class ; and its lands, buildings and appurtenances, necessary to carry out its corporate purposes, are exempt from local taxation, where such property is included in the capital stock, which pays a State tax.

THE CENTRAL ELECTRIC CO. are the general Western agents for the new Brennan wire connector, which was described and illustrated in a recent issue of THE ELECTRICAL ENGINEER. Among other new things they are introducing a new wood box bell of superior merits in ringing qualities, and at prices within the reach of all. This new bell should be inspected by intending bell purchasers and appreciated, as it possesses many valuable and important features.

THE PROPOSED PACIFIC CABLE.

A special dispatch from Ottawa, of Nov. 4, says: The project of connecting Australia with Canada by a cable across the Pacific Ocean has now been before the public about ten years, having been first suggested by Mr. Sandford Fleming in the report submitted to the Dominion Parliament in 1880. As a practical question, however, the history of the scheme may be said to date from 1887, when a conference of delegates from various parts of the British empire was held in London. At this meeting the plan was fully explained by the delegates from Canada—Mr. Sandford Fleming and Sir Alexander Campbell—and aroused a great, and for the most part a friendly, interest. At the last meeting there was also revealed the fact that the project had a strong opponent in the Eastern and Eastern Extension which now control the telegraphic communication between Australia and Great Britain and enjoy a monopoly which would be destroyed if telegrams could be sent across the Atlantic, then through Canada, and then across the Pacific Ocean to Australasia. The conference adopted a resolution declaring "that the connection of Canada with Australasia by a direct submarine telegraph across the Pacific is a project of high importance to the empire, and every doubt as to its practicability should, without delay, be set at rest by a thorough and exhaustive survey." The favor with which the idea was received appears to have alarmed the existing companies, for last summer they endeavored to make an arrangement which would have given their monopoly a new lease of life. They offered to reduce their cable rates one-half, on condition that the governments interested would give a guarantee equivalent to about £54,000 a year. The Australian colonies were willing to enter into this arrangement, but Great Britain and New Zealand declined to share in the guarantee, and there the matter stands to-day. In the meantime, Mr. Sandford Fleming took the opportunity to explain the Pacific plan. It was contended by Mr. Fleming that the guarantee asked for in consideration of the reduction of the rates of the old company, namely, £54,000 a year, would be equal to the annual charge upon the capital required for the construction of a cable from Canada to Australia. The length of the cable necessary to stretch across the Pacific from Canada to New Zealand and Australia is estimated by competent authorities at 8,900 miles, and Mr. Fleming says that the outside cost of a cable of the very best sort would be £1,800,000. Three per cent. upon this sum would amount to £54,000 a year. It is further pointed out that the building of the Canadian line would reduce the cost of messages from England to Australia to one-fourth what they are now, while the proposal of the existing companies is to reduce them by only one-half. The length of the line is not so formidable an obstacle to the success of the project as may at first sight appear, for, owing to the presence of a number of stations in the Pacific, the longest stretch would be about 2,700 miles, the others ranging from 1,200 miles upward.

PERRET MOTORS AND DYNAMOS.

The Elektron Manufacturing Co., of 79 and 81 Washington street, Brooklyn, has now organized an excellent corps of selling agents for its motors and dynamos of isolated incandescent lighting. They are: C. M. Barclay, 205 Canal street, Chicago; W. W. Donaldson, 215 North Calvert street, Baltimore; J. U. Burkett & Co., 1,409 New York avenue, Washington; F. J. Renz, St. Paul, Minn.; G. Baquie, 140 Gravier street, New Orleans, and Cleverly Electrical Works, 1,018 Chestnut street, Philadelphia. Mr. C. M. Barclay, who is one of the latest acquisitions, and who has the agency for Chicago and several of the Western States, for several years managed the stationary motor department of the old Sprague company in the same territory.

ELECTRIC RAILROADING IN SIOUX CITY, IOWA.

The Riverside Park Railway of Sioux City, which is now being built, have adopted the Westinghouse electric system, and the line will be open for traffic on or about April 1st, 1891. This company also owns the Sioux City & Highland Park Railway, a broad gauge suburban steam railroad, which will also be equipped with the same electric system and both operated together. The experiment of using electricity as a motive power on this line will be watched with a great deal of interest, as it is a regular broad gauge railroad constructed with regulation railroad ties and 50 pound steel "T" rail, and it gives a chance to demonstrate the utility of electricity versus steam on short railroad lines.

The combined electric railway system, as above, will be about nine miles and will afford two avenues of travel to Riverside Park, Sioux City's Summer resort. The Westinghouse Company will furnish extra powerful motors, geared for a speed of twenty-five miles per hour, and capable of handling an enormous travel during the Summer months. C. W. Hornick is president; W. W. Byam, vice-president; J. F. Peavey, secretary, and C. M. Swan, treasurer.

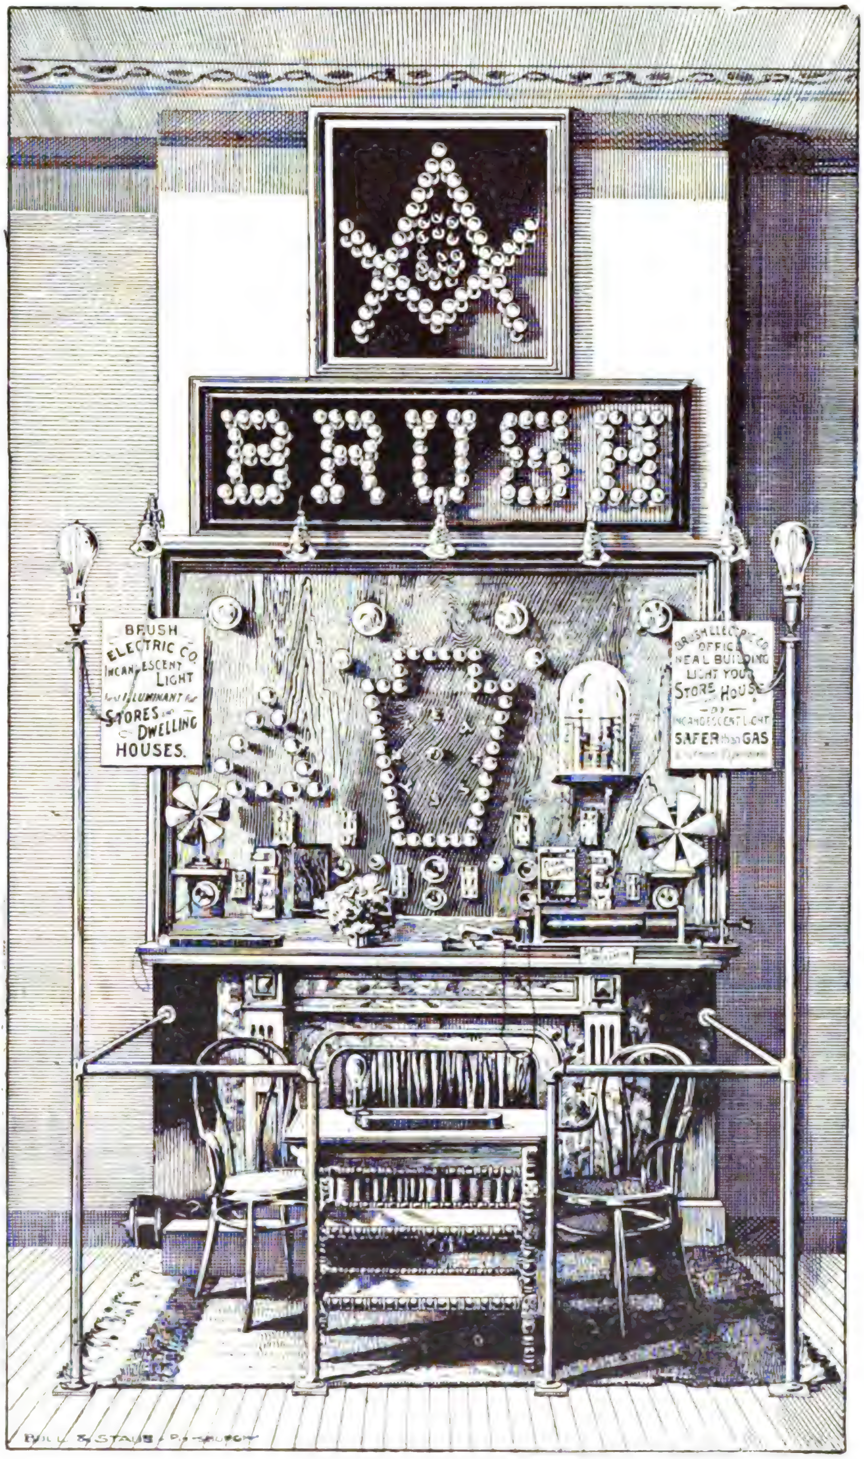
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT

WORK OF THE LOCAL BRUSH CO., BALTIMORE.

THE Masonic fraternity of Baltimore, Md., has just concluded a very succesful "Bazaar" in the Masonic Temple of that city. The object of this entertainment was to raise funds, which are to be used in the interests of the Baltimore Masons. The Temple had been very gaily decorated; a fine orchestra of musicians had been hired to entertain the guests during the evening, and, in addition, the management of the Brush Electric Company, of Baltimore, had been prevailed upon to make an electrical exhibition in the hall to attract the people.

The accompanying cut is a faithful illustration of the display, representing a number of those features which are characteristic of the Westinghouse alternating current system, under which the Baltimore Company operates. Besides the seventeen arc lights and about 200 incandescent lamps, which the Brush Company burned in the hall, the exhibit consisted of a stage regulator, the Shallenberger alternating current meter and its method of working, then the cigar lighter, which attracted special attention; on the table in the front two coils representing the converters and showing that the system is perfectly safe and harmless. The two lamps on the top of the rails are 250 c. p. lamps. Down in the corner there are several small batteries and an induction coil. From this the attendant at the exhibit gave the visitors who desired it shocks. The square and compass, the keystone and other Masonic emblems were represented by incandescent globes of various colors, and the whole exhibit was very beautiful. Over 50,000 people have been to see the electrical display, it having been the first of its kind ever seen in Baltimore.



ELECTRIC DISPLAY AT THE MASONIC FAIR, BALTIMORE, MD.

Since the reorganization of the Brush Company in Baltimore the management has instituted some great improvements in the plant, and a good many more are even now contemplated.

The power house has a boiler capacity of 2,800 h. p. There are 4 Buckeye engines of 300 h. p. each, 5 Buckeye engines of 150 h. p. each, 2 Ball engines of 75 h. p. each, 3 Buckeye engines of 75 h. p. each, and 2 Westinghouse compound engines of 250 h. p. each, and there are the foundations built for two more of the same type. The company has Brush machines of 1,400 lights capacity, all driving from shafting with patent safe feeding oil system. The company also operates 250 arc and 1,000 incandescent lights of the Waterhouse system; 280 arc and about 400 incandescent lights of the United States Electric Lighting Company. The company is, however, controlled by the Westinghouse Electric and Manufacturing Company, which company is now supplying the Baltimore company with a number of additional alternating current apparatus. This includes two 250 Westinghouse alternating current arc machines, and two No. 3 alternating current incandescent machines. When these machines have been installed, the central station will have a capacity of 20,000 incandescent lamps.

The company at present furnishes the illumination for the Johns Hopkins Hospital, all the Baltimore theatres, and also to the majority of the principal buildings in the city.

INCREASING THE CAPACITY OF THE SCHUYLER FACTORY.

OCTOBER 1, 1887, the Schuyler Electric Company removed from Hartford to this city, says the Middletown, Conn., *Sentinel*, after several changes in the management, and located in the old Victor Sewing Machine shop on Hamlin street. The shop has been greatly improved, and other improvements are shortly to be made. A lot has been purchased that will give the factory an outlet on William street, and sufficient room to erect a new modern brick structure with twenty-inch walls and heavily timbered, adapted to the heavy machinery used in the construction of electric goods. This new addition will be 207 feet long by 60 feet wide. It will be three stories high, and the first and second floors will be thirteen feet eight inches between joists, and the third floor will be twelve feet in the clear. Work on the new structure will commence at once, and the management are in hopes of having it finished by the first of January, 1891, ready for occupancy; but they have some doubts about getting into the new building by that time. October 1, 1887, when the company located here, but 35 hands were on the pay roll, independent of the officers of the company. To-day 272 employés are found working within the walls of the busy structure. The multiplicity of orders compelled them to increase their help little by little

until now it is the number stated, and upon the completion of the new addition the working force will be doubled, making a total of over 500 men. For some months the management have been inconvenienced by the overcrowded condition of the factory which has greatly retarded them in their efforts in trying to fill orders. The new addition will double the present output of the company. The new building will be equipped with an elevator and all new modern machinery known to the trade. The orders for a week in several different departments have been doubled, especially in the electric meter room, which is enjoying an unusually large boom at the present time. The company, after having the order doubled to 200 a week, placed new tools in the room soas to fill their orders. The tools used in this department are of a very expensive nature, and an ordinary assortment, covering the top of an average writing desk, costs in the neighborhood of $4,000. After the tools had been put in, the order was again increased to 400 a week, and this placed the company again behind on their orders in this particular department. The company are engaged in the manufacture of their own patent goods, the following: The Schuyler dynamo, the safety ventilated armature, the Schuyler regulator, arc lamps, lamp hoods, series incandescent lamps, with many minor appliances too numerous to mention. Besides the manufacture of their own individual patents, they have large contracts from the Thomson-Houston Electric Co. The Schuyler system of electric lighting is in vogue in various cities throughout the United States and Mexico.

THE NEW DECORATIVE INSULATING MATERIALS.

The need of decorative effects in electrical appliances is beyond question. What sufficed for the pioneers in the industry will hardly do for the present day—in fact, it is obsolete. Just as sure and rapid as has been the demand for better line construction, more symmetrical poles and cross-arms, superior insulation and safety appliances, so sure and rapid is now the demand for interior fittings, possessing besides the necessary quality of usefulness, the equally necessary quality in our day, of finished appearance to match with the surrounding furnishings.

This result could never be reached without the aid of color. All that we have had so far, in the materials used for safety appliances and electrical appliances, has been plain white, the color of porcelain, or plain black, the color of hard rubber. Of course, wood at one time was extensively used in this connection, but cannot be so used now, because of the restrictions of the fire underwriters.

Of the materials which will bring about this change of appearance in electrical fittings there are four, principally, classified as follows:

Plasticon, which is of special value in the manufacture of switch handles, push buttons, etc. It can be made in all colors, and combinations of color; imitations of marble and natural woods can be produced. Besides being perfectly water-proof, this material will withstand a high degree of heat. Its beautiful appearance will find for it many uses, which now can only be surmised at. If brass parts are necessary in connection with its use, they can be embedded into the material, an advantage which will be readily appreciated.

Fibrone is a material similar in appearance to Plasticon, but standing a much higher degree of heat. It can be tapped and drilled, worked on a lathe, and can be finished with a high polish, similar to that given hard wood. Its low cost should not be lost sight of, in comparison with other materials, besides the fact that it can be given any color. It can also be worked in sheets of any thickness, and is therefore well adapted for the insulating parts used in sockets.

Alexite is absolutely fire, water and acid proof. It can be made in any shape and any color. The uses for which it appears best adapted, at first glance, are cut-outs, switch bases, insulators, cleats, etc. Brass parts can be firmly embedded in the molds, thus adding strength to beauty.

Herculite is also fire, water and acid proof, having something of the nature of fibrone. Having great tensile strength, it is adapted for many special electrical purposes, and from the fact that it can be readily drilled and tapped, can be used to advantage where the making of a mould is not justified by the quantity required.

All these materials will be put upon the market together, at reasonable prices, and by so well known a house as that of Alexander, Barney & Chapin, of the Telephone building, 20 Cortlandt street, this city. This firm, for some little time, have been exhibiting their "Alexite," but owing to the difficulty of procuring suitable buildings and machinery, have been unable to make it in any large quantity. This difficulty has been removed, however, by their most recent combination, by which they obtain the exclusive agency, for the United States and Canada, of the manufactures of the Fibrone Manufacturing Company, besides arranging with them for the manufacture of "Alexite." The factory of the Fibrone Manufacturing Co., at 300, 302 Monroe street, this city, which is at present equipped with all necessary tools, etc., will have added to its present machinery sixteen new, large hydraulic presses. Additional floor space has also been taken, so that orders stand a good chance of being filled promptly. The development of this really new industry will be attentively watched, as showing the many branches which are necessary in conjunction with the discovery and utilization of the great unknown, electricity.

J. M. LENNON, ELECTRICAL MANUFACTURERS' AGENT.

Mr. J. M. Lennon, E. E., of 22 Loan and Trust Co.'s building, Minneapolis, has issued the following card, which has a refreshing vigor and buoyancy about it: "I beg leave to inform you that I have added to my business at the above address, an electrical agency. My object in this is to act as agent, or more properly drummer, for any electrical or other firms who manufacture first-class A 1 goods in any way of use in the electrical business. I have a large and rich clientage and am certain that I can increase your business in the West and Northwest fully 100 per cent. I handle goods solely on commission and by sample, sending all orders directly to you, accompanied by the prices quoted and standing of prospective purchaser. Selling samples must, in all cases, be sent, except in cases of very large or very fine apparatus. Net prices on all goods must be quoted (to me), yet I shall endeavor to get the highest possible price with fairness and honesty."

IDE AND IDEAL ENGINES.

W. R. Fleming & Co., of 174 Fulton street, selling agents for the Foundry and Machine Dept., Harrisburg, Pa., have just taken orders for the equipment of several large steam ships belonging to the Transatlantica Hispanola line, with their self-oiling "Ideal" engines for electric purposes. This steamship company ranks among the three largest in existence, and is the one to which belonged the "Viscaya," which was recently sunk by collision attended with such disastrous results in loss of life. The "Viscaya" was to have been equipped at once by W. R. Fleming & Co.

They also report the receipt of many large orders for engines, and their superior steel return tubular boilers from electric light and street railways. Their works are running day and night.

SCHIEREN BELTS IN THE TORONTO ELECTRIC RAILWAY PLANT.

On August 20th, 1890, Chas. A. Schieren & Co. furnished the Metropolitan Street Railway Company, of Toronto, Ont., with the following belting: 48 feet, 12" double electric perforated belt, and 85 feet 28 inch. In answer to their inquiry they received the following letter: "Toronto, Nov. 8th, '90. In regard to the belts, as far as we are able to judge they are giving every satisfaction. We have certainly realized that the power required for electric railway purposes is very exceptional, and the demand is very irregular. We are glad however to state that the belts seem to meet all requirements. We have not had, so far, the slightest trouble with slippage, and cannot but express ourselves as greatly pleased. If they will stand the test of time we do not see that we can desire any improvement. If any parties in this market require anything of the kind we shall be very pleased to have you refer them to us, and will show them our belts in operation. Yours truly, Metropolitan St. Ry. Co., of Toronto, Chas. D. Warren, Pres."

CHADBOURNE, HAZELTON & CO.

When Chadbourne, Hazelton & Co. took the agency for the United States for the Wenstrom Consolidated Dynamo and Motor Co., last June, it was the intention of that company to equip their old factory at Locust Point with new machinery. They determined however later to build a new factory, and purchased 100 acres of ground and commenced operations. The new factory has been somewhat delayed owing to the extremely rainy season, and there is such a demand for Wenstrom apparatus that they are entirely unable with their old facilities to fill their orders.

At a recent meeting of the directors, the situation was discussed, and as a result, in order to hasten matters, the Wenstrom Company have rented a large factory in Baltimore already equipped with boilers, engines and shafting. The new factory is 60 feet front, 260 feet deep and is three stories high, and will be in working order by the last of this month. They expect to be able to turn out enough machines here by working day and night to fill their most pressing orders, and in the meantime will push to completion their large new factory at Calverton, which will be ready for operation by the early Spring to meet the Spring trade and the demand for street railway apparatus, to which this new factory will be almost entirely devoted. This will give the Wenstrom Company as good facilities as any company in the country, and by the first of the year they will be able to fill all orders on time.

CUT-OUT SWITCH FOR ARC OR SERIES CIRCUITS.

We illustrate in the accompanying engraving a new switch which has been specially designed by Mr. W. S. Hill, of 133

Cut-Out Switch For Series Circuits.

Oliver street, Boston, for use on arc or series circuits, so that one lamp or a loop carrying any number of lamps, may be cut safely out of circuit, without disturbing the remainder of the circuit. The inside working of the switch is very similar to the usual Hill type, the contacts being made in the usual way. When operating, the one set of contacts is always thrown in before breaking the other, so that there is no sparking, the actual working of the switch being accomplished by two levers carrying the contact points on a common axis, lying in opposite directions, and so arranged that when the one lever is pressed down the other is free. The mechanism is mounted on a slate base, and is protected in the usual Hill fashion by a substantial weather-proof iron case, provided with a glass front, to show the words "off" and "on" to prevent any possibility of error, as to whether a loop may be in circuit or not.

A NOVEL TROLLEY LINE WIRE HOLDER.

To the street railway engineer the method of suspending the trolley wire has proved a problem of no little difficulty and many devices have been tried and are being used to-day. Any improvement in these must be interesting, and we illustrate in the accompanying engraving a new form known as the Gould & Watson trolley wire clip, which is extremely simple and can be most easily applied. As is evident from the cut, this clip is intended to be used without solder, and at the same time requires no screws to bind the clip to the wire. The jaws are made in two pieces, and fit slackly over the wire when being applied, but when the nut is screwed up, it brings these jaws with a vise like grip upon the wire, and at the same time securely fastens the nut to the insulating material, not shown in the cut, but which may be of any of the several forms in use. The upper hole is furnished in either $\frac{3}{8}$ inch or $\frac{7}{16}$ inch sizes, and the jaws are made for either Nos. 0, 2 or 4 wire. The jaws are furnished of either the best composition metal or steel. One important feature of the clip is, that should sagging of a line take place at any time, it is an easy mat-

New Trolley Line Wire Holder.

ter to slacken up all the clips, which can be done by a quarter turn of the nut, when the wire can be pulled up taut and then the clips can be tightened up again. Practical tests have been made of this clip, with most satisfactory results, both on straight line and also upon corners carrying heavy cross strain. The clips are manufactured by the Gould & Watson Company, 35 Hartford street, Boston.

BROWN'S MINERAL ORE DETECTOR.

Electricity has already been applied in numerous ways to mining operations and with such success that a large extension of this work, both in electric lighting and power installations of various kinds, may be looked for in the near future. A recent addition to the application of electricity to mining, and one which seems destined to find considerable use, is a portable device for detecting the presence and nature of a mineral where the latter is exposed in the rock or earth. This apparatus, which is intended for the use of prospectors more particularly, consists of a battery and spark coil, which are enclosed in a box, and the conductors end in two platinum points.

It is evident that if these points be connected to a conducting body and the circuit ruptured, a spark will be formed, the flame and color of which will give some indication of the nature of the body which the electrodes have touched. Thus, by placing the two points against a rock containing metal in a free state, its presence may be detected by merely applying one electrode and passing the other rapidly over the surface.

The machine, which was invented by Mr. F. H. Brown, of Chicago, will, it is said, enable a novice or "tenderfoot" to pick

Brown's Mineral Ore Detector.

up float rocks on the hills and tell instantly whether they contain mineral or not, and even the comparative quantity in a rough way. By means of this instrument, also, it is possible to find a lost "lead" in a shaft or cut by applying it to the walls. Another use to which it may be put is to the sorting of ores, the color of the flame enabling the sorter to separate the different kinds. The apparatus, which weighs about ten pounds, is arranged to be carried on the back and can be used to explode blasts in connection with electric primers.

R. T. WHITE'S RAIL SPECIALTIES.

As our readers are aware, Mr. R. T. White has devoted considerable time and ingenuity to the improvement of rails, chairs, &c., for street railway work, and has secured patents on a number of his devices. He has now issued a circular to the public in which, as the result of what he heard and saw at the Buffalo Convention, he claims that the Lewis & Fowler Girder Rail Co., of Brooklyn, are directly infringing on his patents. He says he will proceed against those who purchase such track material from that company, of whom he remarks: "I have defeated them in all the interference suits between us in the Patent office, and am positive I can defeat them in the United States Courts, as I have patents and they have none."

Mr. J. H. Stahley, well known in electrical work in all parts of the country, has been placed in charge of the new street railway work at Flushing, N. Y.

THE KINTNER LABORATORY.

Mr. C. J. Kintner, the patent expert and electrical engineer, has an experimental laboratory with direct and alternating currents, in any desired proportions, having recently fitted up a room in the basement of 45 Broadway with Westinghouse converters connected to the street mains, and with connections to the direct current incandescent plant of the Aldrich building. He is thus in a most favorable position to make quick and thorough tests of new ideas and inventions.

OKONITE WIRE IN A WESTERN BUILDING.

The Central Electric Co., of Chicago, have just issued a facsimile of a letter received by them from S. G. Cook & Co., of Minneapolis, accompanying a piece of wire attached by red ribbon and seal—altogether quite an official looking document. The letter says: "This piece of Okonite wire was placed in our Lumber Exchange Building in this city 5 years ago and has been used continuously ever since as part of the electric lighting circuit of the building. The wire was originally stapled to the fireproofing and plastered over, and so far as we can see it is as good as ever." At the foot of the letter is a pertinent note from the Central Electric Co. to the effect that they are the Western agents for Okonite.

QUEEN & CO'S. PORTABLE TESTING SETS.

FROM the following flattering testimonials it appears that Queen & Co's. portable testing sets are appreciated quite as much by the public in general as by themselves.

Prof. T. C. Mendenhall, Supt. of the U. S. Coast and Geodetic Survey, says: "The set of resistance coils furnished by you some time since, has been used with great satisfaction. It possesses many advantages in the way of compactness and convenience of arrangement." Sec. H. J. Davies, of the Brooklyn St. R. R. Co., writes: "We are very much pleased with the portable testing set you sold us. We are using it constantly, and it is proving satisfactory." Asst. Engineer R. Fleming, of the Edison Gen. Electric Co., writes: "I would say that the portable testing set I bought of you recently has given every satisfaction, and, for an instrument of its class, surpasses anything I have ever seen for accuracy and reliability. I would heartily recommend it to electricians." Supt. H. A. Wagner, of the Missouri Electric Light & Power Co., says: "We are very much pleased with your new portable testing set, which we have been using about two months, and have no hesitation in saying that it is the best instrument for the price that we have seen. We had it compared with a standard Elliott bridge, and the readings when reduced to B. A. ohms, agreed with the former within one-tenth of one per cent. throughout the range tested." The Schæfer Electric Manufacturing Co. writes: "So far as we have been able to test the set has proved all we could wish for and well adapted to our purposes." Lieut. McLean, of the Newport Naval Torpedo Station, says: "The arrangement of the bridge arms, coils and keys in the portable Testing set, No. 126, is very convenient and satisfactory."

We are informed by Queen & Co. that up to date the orders for these sets have come so fast that it is impossible to turn them out fast enough. They have employed additional force, however, and hope soon to be able to carry a supply equal to the demand.

THE EQUITABLE ELECTRIC RAILWAY CONSTRUCTION CO.

Mr. W. A. Stadelman, who has for some time been connected with the firm of Chadbourne, Hazelton & Co., of Philadelphia, has recently terminated his active interest in that concern, and has reorganized the Equitable Electric Railway Construction Company, of which he was chief engineer. He will devote his entire energies to the new concern.

The new company will be known as the Equitable Engineering and Construction Company, and a new charter has been applied for which will give the company the right to not only equip electric railways but to buy and sell or lease or operate them. The old company will go out of business by liquidation, and the new company will take its place.
